Vaginal leucorrhœa.—As to the first, a slight increase in the normal secretion from the mucous membrane of the vagina gives rise to a discharge that attracts attention by the discomfort it causes. Some women are peculiarly liable to a temporary leucorrhœa of this kind, either from taking cold, from unusual exertion of any kind, or from mental excitement or anxiety. In unmarried girls, vaginal leucorrhœa is common as a result of impaired health from any cause, as excessive study, irregular hours, or any form of social dissipation. Simple, uncomplicated vaginal leucorrhœa is most common in girls, or young married women who have not been pregnant, and its importance depends on whether it is or is not persistent, and whether the amount of loss is large or small. The subjects of a constant leucorrhœa of this kind are pale and anæmic, with a small or capricious appetite, constipated bowels, and sluggish habit. In such cases, the symptom for which we are consulted, though it may be the most annoying or alarming one to the patient, is evidently only a consequence of the relaxed and depraved condition of the system, and it would be inexcusable to make it the target for our remedies. We must attend first to the general health, employing every means in our power to improve it. At the same time, the patient should be instructed to use simple vaginal injections of hot water, which alone exercise a decidedly tonic effect on the parts affected. If the discharge still persists, it may be necessary to direct the use, after the hot water, of some mild astringent. I always insist upon the thorough use, at least once a day, of water as hot as the hand can bear it, for at least ten minutes, the patient lying meanwhile on the back, over a bed-pan or other vessel. The addition of ʒ j. of pure carbolic acid to the gallon of water renders it more efficacious. If the discharge proves obstinate and does not yield to this simple treatment, it may be necessary to use some astringent or other drug. Whatever is used may be conveniently added to the last pint of the injection, so that it shall come in contact with the vagina after it has been thoroughly cleansed by the hot water. The most useful astringent is tannin, ʒ j. to the pint, with the addition of about fl. ʒ iv. of glycerine. The various astringent injections popularly recommended, such as that of white-oak bark, are generally too strong. I do not approve, as a rule, of the use of oily vaginal suppositories. The application of the drugs they contain is uncertain. An excellent injection in many cases of anæmic vaginal leucorrhœa is the fluid extract of eucalyptus globulus, ʒ j. to the pint of water. It is a mild astringent and a decided antiseptic. If these simple remedies, together with careful attention to the general health, do not benefit the patient, and if the leucorrhœa persists, it is our duty to make a physical examination. In the case of unmarried women, this should of course be postponed as long as possible, and looked upon as the last resort; but in the case of married women it is justifiable to make an examination earlier, especially as the probability is greater of finding some condition demanding local treatment. In the virgin we may find a flexion of the uterus sufficient to cause congestion of the cervix, or of the entire uterus. We may find a simple or a gonorrhœal vaginitis, in which case the astringents do harm, and must be discontinued. I have found a gonorrhœal discharge more likely to affect the urethra and bladder early than an ordinary vaginitis, but it is difficult to distinguish between the two. One of the best injections in simple vaginitis is the infusion of tobacco, a pint of it being used after the hot water. But the shortest way of curing any vaginitis is to tampon lightly with carbolized cotton once or twice a day, moistening the cotton-balls with equal parts of glycerine and water. Where local applications are required, we have the choice of many, but the best are nitrate of silver, gr. xx. to ʒ j., the fluid extract of eucalyptus, and the tincture of iodine. If the tamponing is done faithfully, that alone kept up for a week or ten days will often be found sufficient. In cases where the injection is relied on, and the discharge irritates or excoriates, ʒ j. of bicarbonate of soda to the pint of water commonly gives relief. Another excellent injection for simple vaginal leucorrhœa is a solution of common salt, ʒ j. to the pint; and where that does not answer, the same quantity of boracic acid often does well. No rule of treatment can be laid down for vaginal leucorrhœa, even for cases apparently similar; but what I wish to emphasize is the fact that very mild measures will suffice in uncomplicated cases; that such cases may be aggravated and rendered complicated by the early use of powerful astringent or other drugs; that if we begin with simple remedies we shall often end with them; that in all cases, especially in anæmic girls, the general health should never be lost sight of in our anxiety to relieve the patient of a solitary symptom; and that in unmarried women the existence of leucorrhœa without pain or other symptoms very rarely necessitates a physical examination.

[1] Read before the Practitioners' Society of New York, June 2, 1882.

Cervical leucorrhœa.—It often happens that the patient's voluntary description of her symptoms enables us to make a pretty accurate diagnosis. In addition to the leucorrhœa spoken of as vaginal, or in place of it, there is a thick, glairy, intermittent discharge, often resembling white of egg, sometimes stained with blood, and occasionally mixed with pus. This symptom is most commonly found in women who have been pregnant, but may occur in the unmarried. It signifies disease of the cervix. It may be a moderate degree of endocervicitis, or it may be extensive laceration or hypertrophy of the cervical tissue. This can only be decided by examination, which should be resorted to at the outset, in order to ascertain the amount of disease with which we have to deal. We may find ulceration of the cervix, but that is rare. We may find the cervix much congested and enlarged, and the os filled with a plug of tenacious material, which appears to distend it, and which consists chiefly of a hypersecretion from the Nabothian follicles. The cervix is often covered with small cysts, which, on being pricked, exude large drops of clear viscid fluid. In case there has been laceration of the cervix, the edges are everted, and the exposed surfaces, hypertrophied from exposure, are often intensely congested and extremely vascular, so that bleeding follows the slightest touch. It is this condition which is often spoken of and treated as "ulceration."

In the treatment of this form of leucorrhœa the injections recommended for simple vaginal discharges are of little value. Copious injections of hot water do much to reduce the congestion of the cervix, but they do not cure it. The astringent and other drugs are of no use whatever. If the laceration is not extensive, the exposed surfaces may be treated by the direct application of the strong tincture of iodine, of iodoform in powder, of a solution, or by the solid stick of nitrate of silver. Many other caustics are used and recommended for these cases, and during their use the discharge will diminish or even cease entirely, but only to return when the treatment is suspended. Where there is little or no laceration, but a diseased condition of the cervix itself, more powerful caustics, as the strong nitric acid, may sometimes be used with advantage. Where the cervix contains polypoid growths, or where the gland structure is diseased, the cautious use of the sharp curette is sometimes proper. Where the laceration is extensive and of long standing, I have never seen permanently good results from any application, however perseveringly employed. Here it is that surgery must be called to our aid. I have often seen patients who had suffered for years from a profuse cervical leucorrhœa, which had been treated in vain by every application that could be suggested, cured in a few weeks by simply uniting the torn surfaces after they had been carefully freshened and all the diseased tissue removed. In some aggravated cases applications seem to increase the congestion, and render the hard tissue even harder. Where it is desired to make applications, Sims' speculum should be used, and the tenacious secretion entirely removed first. This it is not always easy to do. A little absorbent cotton wrapped on the end of a piece of whalebone often answers well. A small piece of dry sponge held in a pair of forceps facilitates the cleansing of the diseased surface. Another method is to use a long-nozzled syringe, with which to draw the secretion out, or to dislodge it by a stream of hot water. The cervix should then be dried with a little absorbent cotton, the application made, and a flat piece of cotton, with a string attached, pressed against the cervix, and left there for some hours. A method I have sometimes found to answer well, after the congestion has been reduced by hot water, is to apply the solid stick of nitrate of silver over the whole surface, and as soon as it is dry, to paint it over with flexible collodion. One point to be remembered is that unless the exposed surface is perfectly free from secretion, the strongest caustics are neutralized and rendered inert. The prognosis in these cases, treated non-surgically, is bad. They get a little better, then a little worse again; the vagina suffers from the acrid secretion, and the condition of the patient grows slowly and surely worse. Under appropriate surgical treatment, most of such cases as I have described get entirely well. It is not my purpose to speak of the operation itself, further than to say that it should never be attempted without ample preliminary treatment. One other form of cervical leucorrhœa is that which accompanies malignant disease. After the period when epithelioma has been marked by hemorrhage, there is often a long period when there is merely a watery discharge, profuse and offensive, but without a trace of blood. It is observed by the patient to stiffen on the clothing, like starch. I have frequently found advanced malignant disease where the only thing of which the patient complained was "leucorrhœa." The treatment of these cases, when they are beyond the reach of surgery is, of course, only palliative; but it is an immense relief to these unfortunate patients to have the discharge arrested for a time. I have found nothing so efficacious for this purpose as swabbing the ulcerated surfaces with strong nitric acid, being careful to protect the surrounding parts during and after the application. In some obstinate cases of cervical disease brilliant results may be obtained by the use of the sharp curette, but as a general rule this means of cure is not indicated.

Uterine leucorrhœa.—A discharge from the cavity of the uterus is often recognized by its intermittent character. The patient describes it as coming suddenly "with a gush," and then ceasing for a time. It is often purulent, mixed with blood, and of a greenish color. It is particularly apt to irritate the vagina and urethra; it is worse for two or three days after menstruation, and it is often offensive; it is sometimes accompanied by pain. On examination with the speculum, the discharge may be seen pouring out of the os as the sound or probe is withdrawn from the cavity. Sometimes a discharge of pus will alternate with a hemorrhage. This form of leucorrhœa commonly signifies polypoid growths in the cavity of the uterus, destructive changes in a fibroid growth, sarcoma, or other malignant disease. The treatment in detail of these affections it is not my purpose to consider. It includes, in addition to other surgical measures, the use of the curette, and subsequent applications of iodine, strong carbolic acid, and possibly nitric acid. Here, again, medicated vaginal injections are utterly useless. Water alone, slightly carbolized, suffices to prevent the discharge from becoming offensive, and to remove it when it is so.

In conclusion, it must be remembered that we often find all the varieties of leucorrhœa existing at the same time, so that it becomes a matter of some difficulty to judge of the significance of this symptom. It is, indeed, impossible to do so without weighing carefully all the other symptoms; and it is only in this way that we can expect to arrive at rational therapeutic

measures. I wish to lay some stress on what I consider the danger of a routine treatment, which is the same thing as the danger of doing either too much or too little. The indiscriminate use of astringents often does more harm than good. In unmarried women we can often avoid any local treatment by dealing first with the general health and insisting on proper hygienic surroundings. In this class of patients we should resort to physical examination only after other measures have been fully tried, unless there is some evident reason, such as severe dysmenorrhœa, to guide us. On the other hand, in cases where surgical or mechanical aid is imperatively demanded, we should beware of losing precious time by experimental or expectant treatment. We should convert our suspicions into certainty, and give our patients the utmost benefit our knowledge will afford.

REMOVAL OF A LARGE NASO-PHARYNGEAL TUMOR WITH EXTENSIVE ATTACHMENTS TO BASE OF SKULL.

Unexpected Brain Complication—Death.[1]

By GEORGE F. SHRADY, A.M., M.D.,

SURGEON TO THE PRESBYTERIAN AND ST. FRANCIS HOSPITALS, NEW YORK, CONSULTING SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED, NEW YORK.

The following case is interesting from a surgical as well as a pathological point of view, illustrating as it does the possibility of removing by operation a

Fig. 1.

naso-pharyngeal polypus of large size and extensive attachments to the base of the skull, and at the same time demonstrating the inutility of the procedure on account of unexpected complications.

The patient was a lad, aged fourteen, a native of Woodstock, N. Y. Four years ago he began to suffer from symptoms of partial occlusion of the left nostril. A year subsequently he entered St. Francis Hospital, New York, and came under the care of Dr. J. H. Ripley, who discovered the existence of a small gelatinous polypus attached to the upper margin of the left post-nasal meatus, and who removed the growth by means of the finger introduced into the fauces. The noticeable feature of the operation was the great amount of hemorrhage which followed. The boy shortly after returned to his home relieved of all his symptoms.

A few months afterward there were again evidences of occlusion of the left nostril consequent upon the reappearance of the growth. The latter slowly increased in size and was attended with occasional attacks of severe epistaxis until the patient was brought to me, in April, 1882.

At that time his countenance was considerably disfigured by a protrusion of the left cheek, exophthalmus of left side, swollen and distended nostrils, and by the pouting and opened lips of a mouth-breather (Fig. 1). The left cheek was found to contain in its substance a movable tumor, apparently attached to the anterior edge of the masseter muscle of that side.

On opening the mouth the soft palate was seen to be greatly expanded and to be pressed forward almost to a vertical plane, by a growth behind. The summit of the pharynx was explored by the finger, when a tumor, fibrous in character, was found occupying that region, occluding the left nasal opening posteriorly, extending across the nasal septum into the right posterior nares, and attached to the basilar process of the occipital bone and adjoining left side of the body of the sphenoid.

Examination by the rhinoscopic mirror showed the surface of the tumor to be pinkish in color, smooth and velvety in appearance, more or less globular in shape, and of pronounced vascularity.

Fig. 2.

The hearing of the left ear was not markedly impaired, although it was evident that the mouth of the Eustachian tube of that side was closed by pressure of the growth. There were no signs of disturbance of vision nor derangement or impairment of movements of the left eye. No brain symptoms had shown themselves at any time.

The patient complained of a "stuffy" feeling in his nose and throat, and his mother said that he breathed with great difficulty when asleep, snoring so loudly as to disturb the whole household. At times he would have fits of suffocation, apparently due to mechanical obstruction by the tumor. He had a remarkable toleration for digital exploration of the pharynx, of which repeated advantage was taken in subsequent studies of his case.

[1] Read at the meeting of the Practitioners' Society of New York, June 2, 1882.

With a view of making a thorough examination of the patient under ether, he was admitted to St. Francis Hospital. He took the anæsthetic badly, on account of the partial occlusion of his throat. The previous diagnosis was in the main confirmed by Dr. Ripley, who saw the case at that time and who also made a post-nasal exploration. It was quite plain then, to me at least, that the growth was also attached to the internal plate of the left pterygoid process, and possibly still farther backward and to the left. The tumor in the cheek appeared to be unconnected with that in the naso-pharynx. Still there was a suspicion that the case might be otherwise, and that an extension of the main tumor might have taken place through the spheno-palatine foramen into the spheno-maxillary fossa. Also it was suspected that the antrum might be involved.

Either of these possible conditions was capable of explaining the exophthalmus. The extension of the disease into the cavity of the orbit was, however, not thought to be probable, inasmuch as there was no disturbance of motion or sight of the left eye nor complaint of pain in the course of the nerves most likely to be affected by pressure of a growth taking the usual course thither through the pterygo-maxillary and spheno-maxillary fissures.

The case was carefully studied for a considerable period with a view of perfecting the diagnosis, and of determining the best method of operating for the removal of the growth. At first an osteo-plastic operation was thought of, the plan being to lift the cheek by Ferguson's incision, to split the palate from before backward in the median line, saw through the external portion of the superior maxillary bone, on a level with the floor of the antrum, and hinge the fragment, thus partially separated, outward upon the pterygoid process. It was then believed to be possible, after extirpating the tumor, to replace the bony section. In trying experiments upon the cadaver, I found that this would not answer the purpose. Neither would Cheever's operation, also osteoplastic in character, nor would Vallet's, Nélaton's, or Gussenbauer's.

The size of the tumor, its extensive attachments, and the emergencies of hemorrhage during its removal demanded more room than either of these methods would give.

Partial resection of the jaw, as advised by Maisonneuve, was finally determined upon with preliminary laryngotomy and tamponing of the pharynx. The patient was afterward examined by Drs. J. W. Howe, H. B. Sands, Geo. A. Peters, R. F. Weir, L. Elsberg, F. H. Bosworth, J. D. Bryant, and others. The essential points in the diagnosis were confirmed by these gentlemen. all of whom believed an operation for the removal of the growth, in the manner indicated, advisable.

The operation was accordingly performed at St. Francis Hospital, Saturday, May 27, 1882, with the assistance of Drs. Geo. A. Peters and Joseph W. Howe, and in the presence of Drs. H. B. Sands, R. F. Weir, C. K. Briddon, A. G. Gerster, C. McBurney, J. H. Ripley, Walter R. Gillette, J. D. Bryant, D. H. Goodwillie, and O. B. Douglas, also Dr. David Haig, House Surgeon, and the other members of the house staff. The patient having been cautiously etherized, laryngotomy was performed, a gutta-percha tracheal tube of large size inserted, and the pharynx was tamponed with a sponge attached to a stout string. Anæsthesia was kept up by means of a funnel and india-rubber tube attached to the canula.

Ferguson's incision was made from the inner canthus of the left eye, alongside of nose, around left nostril and through the middle of the upper lip. The flap was then rapidly dissected from the bone, when it was discovered that the tumor in the cheek was continuous with the main growth through an opening in the posterior wall of the antrum.

The lower half of the left upper jaw was next removed in the following manner: The exposed external surface of the bone on a level with the floor of the antrum was grooved by a narrow-bladed saw. This manœuvre was somewhat interfered with by the protrusion of the tumor of the cheek. The left central incisor was next extracted, then an incision made into the mucous membrane of the hard palate from before backward, and at a right angle with this the soft palate was cut transversely from its attachment to the palate bone, the under surface of the tumor being protected from injury by the finger placed between it and the palatal curtain.

The hard palate was divided antero-posteriorly by a bayonet forceps, one blade of which was introduced into the nose and the other into the mouth, and a horizontal section of the upper jaw made also through the nose by inserting the other blade of the forceps into the groove previously made by the saw. The bony fragment was then quickly removed. It was necessary to divide the soft palate in order to expose the surface of the tumor.

The growth was attached to the basilar process of the occipital, the adjoining left portion of the body of the sphenoid, and also the adjacent temporal bone. From this point it extended itself in various directions. It filled the superior vaults of the nose and pharynx, closed up entirely the posterior nares of the left side, and partially occupied that of the right side, straddling the post-nasal septum. In a direction to the left it spread itself to a slight degree behind the left pterygoid process into the pterygoid fossa, and was continuous with the tumor in the cheek by a prolongation into the left spheno-maxillary fossa, doubtless through the spheno-palatine foramen. A portion of the posterior surface of the maxilla had been absorbed, and, through the opening this made, a lobe of the tumor had extended into the cavity of the antrum.

The left inferior turbinated bone had been absorbed, the left nasal cavity was greatly expanded, and the septum was strongly deflected to the right of the median line.

This irregularly-shaped tumor was altogether equal in size to an orange, and its extirpation was attended with unexpected difficulty. Its depending portion was hooked forward by the finger, and by means of a raspator the separation of the posterior portion of the tumor from the basilar process was commenced. I had not proceeded far before I became aware that there was a suspicious elasticity of the bone at that point, and, fearing injury to the medulla by direct pressure of the instrument, I was forced to change the level of separation to that of a plane more directly parallel with the surface of attachment. Accordingly the tumor was attacked on its right side by means of curved scissors, and the separation carried toward the left as far as the under surface of the apex of the petrous portion of the temporal bone. This was done as quickly as was consistent with safety to important structures in the neighborhood. The left spinous process of the sphenoid was used as a guide to the finger in protecting from injury the internal carotid and internal jugular at the base of the skull. After a separation of the tumor in the direction indicated, the portion in the cheek was cut off on a

level with the external surface of the antrum, the left side of the growth was then pulled forward and to the right, and with scissors, doubly curved on the flat, all the attachments were severed. Lastly, the scissors was introduced from before backward, through the nostril into the middle meatus of the nose, and the attachments to the antero-inferior portion of the body of the sphenoid cut away. On examination of the deep and irregular chasm thus left, portions of the growth were found to be still remaining, mostly adherent to the neighborhood of the base of the internal pterygoid plate and the pterygoid fossa of the left side. These were snipped off, and, as far as could be ascertained at the time, every particle of the growth had been removed.

During the operation the hemorrhage, which was mostly venous, was very profuse. From the time the first incision was made alongside of the nose until the base of the tumor was fairly reached, the entire field of the operation was a rapidly filling pool of welling blood. It was only by quick sponging, prompt pressure, and rapid clamping that a necessary view of the deeply seated parts could at any time be obtained. Three arteries only required ligature, the angular, internal maxillary, and the sphenopalatine, which latter was greatly enlarged. Other smaller arteries were simply compressed or twisted to save time.

Early in the operation, and immediately after the extirpation of the upper jaw, the patient's pulse became profoundly impressed, and the extremities were elevated and bandaged in order to keep the blood in the trunk and prevent the imminent dangers of combined shock and hemorrhage. Hypodermics of brandy were also administered. The ether was carefully watched, and during the latter period of the operation entirely suspended. Just before removing the last portion of the growth the patient became quite restless, so that one of the gentlemen present suggested that more ether be given. This, however, was not done.

The whole period of the operation was scarcely thirty minutes. At its completion, it became apparent that the patient was in an extremely feeble condition. He soon passed into a state of collapse and died within an hour after the operation. Although the apparatus for transfusion was held in readiness by Prof. Howe, no opportunity for performing the operation was afforded on account of the suddenness of the death.

The result was quite unexpected to me, and I anxiously looked forward to the autopsy for its explanation. It did not seem that the loss of blood, great as it was, was the sole cause of death. I feared that some of the important nerves at the base of the brain, or perhaps the brain itself, had been injured. It did not seem impossible that the cribriform plate of the ethmoid had been fractured by crowding the vomer to one side in extracting the anterior and upper section of the tumor.

The post-mortem examination was made twenty-four hours afterward by Dr. E. C. Wendt; Dr. Ripley, myself, and members of the house staff being present. The lungs contained considerable blood, as did also the stomach. This was partly caused by the accidental and temporary displacement of the sponge tampon during the operation, and partly by soakage through the sponge itself. All the other organs of the body were healthy except the brain. To the under surface of the left middle lobe of the cerebrum there was found attached, by inflammatory adhesions, a fibrous tumor the size of a horse-chestnut (Fig. 3). The under portion of this intra-cranial growth rested into the enlarged foramen lacerum medium of that side, and was evidently continuous with the naso-pharyngeal tumor, the separation from the latter made at the operation being in a plane with the base of the skull. It may be remarked in passing that the extension of the disease in this direction is rare, the usual avenue to the brain being either through the sphenoidal sinuses or cribriform plate of the ethmoid. The floor of the cranial cavity and vicinity was found to have escaped injury save at the foramen lacerum medium, which was enlarged by absorption of its bony margins. The pneumogastric nerve and the larger vessels of the throat were also uninjured. The basilar process of the occipital was very much thinned by absorption, readily yielded to pressure of the finger, but showed no sign of injury upon its intra-cranial surface. The cavity of the orbit was not encroached upon by the growth. The exophthalmus was partly the result of pressure upward from the portion of tumor in the antrum and partly from a crowding of the growth into the sphenomaxillary fossa. The tumor was a fibro-sarcoma.

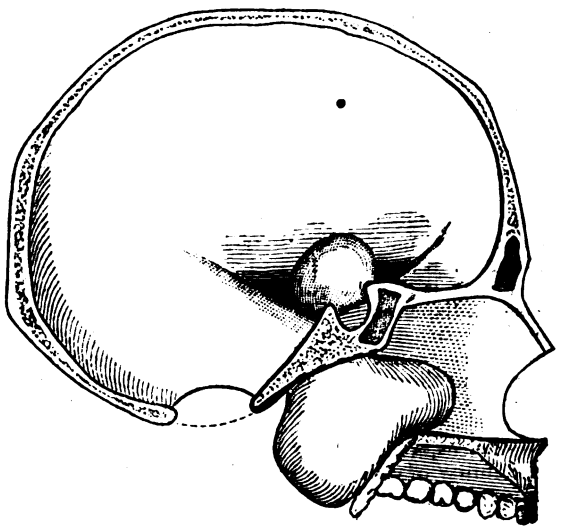

FIG. 3.—Showing attachment of tumor to basilar process and sphenoid, and extension of growth into cranial cavity.

The history of this case and the results of the operation offer several points for study and reflection. Altogether it adds an instructive chapter of experience to the radical treatment of a formidable disease. It proves, in a striking manner, the impossibility of making a diagnosis of the actual limit of naso-pharyngeal polypi of large size. If brain complication had manifested itself by any symptom during life, the operation would, of course, never have been undertaken. None of the skilled surgeons and laryngologists who examined the case suspected such a condition. The extensive attachment of the tumor to the base of the skull, including, on one side at least, every available portion of surface, is a matter worthy of notice. It does not seem improbable that the growth had a common origin from the basilar process of the occipital, the body of the sphenoid, the pterygoid fossa, and the apex of the petrosal pyramid. Certainly, to all these points it was intimately adherent.

It is a question of interest how much the toleration of digital exploration was due to the involvement of

Meckel's ganglion, and of the palatine branches of the superior maxillary nerve, by extension of the disease in the spheno-maxillary fossa.

The kind of operation was decided upon after the most mature deliberation. Every precaution was taken to secure a good result, but in vain. The existence of the partially absorbed basilar process was not ascertained until the time came for attacking the base of the tumor itself. Thus, what would have been a comparatively easy and quick way of extirpating the growth had to be substituted in the emergency for another beset with difficulties.

It was plainly a case in which neither the ordinary loop nor the galvano-cautery wire could have been used. Apparatus (Piffard's) for such purpose was in readiness at the time of the operation, but there was no possible chance, even after extirpation of the jaw, for surrounding the base of the tumor. The particular method of partial removal of the jaw is, I think, the best that can be employed when the tumor is large and its attachment extensive. It affords the freest access to all parts involved in the disease with the least external deformity, and gives ample facilities for after-treatment in case of recurrence.

Laryngotomy was determined upon as a preliminary procedure, on the general ground of increased safety to the patient, but more especially in view of the experience of Dr. Weir, who, during the performance of Nélaton's operation for the removal of a naso-pharyngeal polypus, was compelled to tracheotomize his patient in a trying emergency (vide MEDICAL RECORD, Vol. XXI., p. 608). I am satisfied that it is not only warrantable, but in most cases indispensable. It must be admitted that the entire extirpation of the growth is the only chance of ultimate cure. The ecraseur, the galvano-cautery wire, and the wire snare give no absolute guarantee that the root of the growth is removed. In fact, aside from the difficulty of adjusting the necessary appliances, and, in large growths, the absolute impossibility of doing so, there is the insurmountable objection of working more or less in the dark. As palliative measures for the relief of urgent symptoms when radical means are not available, they certainly, in many cases, serve a good purpose.

Profuse hemorrhage is the rule in the radical operations, and is the chief source of danger. The larger the growth, the more extensive its attachments, and the more numerous its prolongations, the greater the risk. As is well known, the origin of these tumors is in the thick and highly vascular mucous membrane and periosteum covering the basilar process and surrounding parts. Although the substance of the tumor is not very plentifully supplied with blood, the contrary is the case with its investing membrane. Also its situation, manner of growth, and surroundings favor a varicose condition of the veins in and about the summit of the pharynx, notably those of the venous plexuses which go to form the pharyngeal and vertebral veins. Although the larger part of the hemorrhage is venous in character, the various branches of the internal maxillary—the pterygo-palatine, spheno-palatine, and others—supplying the parts and involved in the disease are apt to give trouble. When the mass encroaches upon the spheno-maxillary fossa, the trunk of the internal maxillary itself is liable to be wounded. The only way that suggests itself of reducing the danger to the minimum is to operate as rapidly as possible after the jaw is attacked, exposing and extirpating the tumor with the least possible delay. Much blood may be saved by care in securing all the bleeding vessels in the section of the cheek before taking the next step in the operation. But in certain cases, as in the present, where numerous complications exist, it may be impossible to keep the hemorrhage under safe control. Much in the way of satisfactory result must necessarily depend upon the certainty of diagnosis and the proper selection of the subjects for operation. How such can always be made is still an open question.

247 LEXINGTON AVENUE, NEW YORK.

THE VALUE OF CARBOLIC ACID AS A GERMICIDE AS ESTABLISHED BY EXPERIMENTAL DATA.

BY GEORGE M. STERNBERG, M.D.,
SURGEON, U. S. A.

THAT germicides are destined to occupy an important place in the therapeutics of the future can scarcely be doubted. But that the etiological problems relating to infectious diseases are *now* definitely settled and the germ theory established upon a firm experimental basis, and that the method Déclat, which is based upon this supposition, has inaugurated a therapeutic millennium, is open to legitimate question.

The writer has no quarrel with carbolic acid or with the method Déclat, but having been vigorously assailed by Dr. Déclat in a letter occupying a column and a half of the *Courrier de San Francisco*, July 20, 1882, for certain remarks made in an address before the California Academy of Sciences (in which Dr. Déclat's name was not mentioned and his method of administering carbolic acid not referred to), and being unwilling to discuss a scientific medical question in a daily newspaper, especially in one where Dr. Déclat would have the double advantage of addressing his French compatriots in their own language and of advertising his cure-all without expense, I have thought it proper to publish the experimental data upon which the remarks were founded which have called forth from Dr. Déclat the letter referred to.

My remarks with reference to the use of carbolic acid as a germicide were quite brief and incidental to the subject of my address, which related to unicellular organisms generally and the bacteria in particular. I stated that the value of carbolic acid as a germicide had been pretty definitely fixed at from one to two per cent., and that it seemed impracticable to destroy micro-organisms in the blood of a sick person with this agent, inasmuch as the quantity required to accomplish this would be enormous and far beyond the toxic dose.

Physiologists estimate the blood to constitute one-eighth of the weight of the body, which for a man weighing one hundred and sixty pounds would amount to twenty pounds. One per cent. of this would be one-fifth of a pound, or three and one-fifth ounces.

It is evident that such a calculation can only be considered suggestive, and that a much smaller quantity may have a potent therapeutic effect by restricting the multiplication of germs and thus giving nature the opportunity to effect their destruction or elimination from the body.

It seems proper that my reply to Dr. Déclat should be published in THE MEDICAL RECORD, inasmuch as his method has already received some notice in this journal.

The question whether the carbolic acid "*naissant*"

especially prepared by Dr. Déclat's agents possesses advantages over that which I have used in the experiments recorded below I must leave for the chemists. The acid used by me in my last experiments was put up by Schieffelin & Co., of New York, for the Medical Department of the army. It is contained in pound bottles, in the form of a colorless crystalline mass, and remains solid at the ordinary summer temperature of this place—62°–65°.

There is no doubt that the real value of a therapeutic agent can only be definitely settled by clinical experience, and that theory, experiments upon the lower animals, and laboratory experiments upon micro-organisms are only useful in establishing a basis for clinical experiments. But all physicians know how often these lead to contradictory results or false conclusions, and how necessary it is to withhold our judgment with reference to a certain mode of treatment until we have for consideration extended data, furnished by numerous independent observers. The enthusiasm of the discoverer of a new remedy, the fact that its administration is in accordance with the pet theory of the day, and the potent influence of the *vis medicatrix naturæ* are factors which have not infrequently established for a time the reputation of drugs which have subsequently turned out to be of little or no value. The value of carbolic acid as a germicide, and as a local application in surgical practice, is, I conceive, fully established, and that it may have a somewhat extended and useful place in internal medication seems to me very probable. But that the claims of Dr. Déclat will be fully justified I very much doubt in view of the experimental data recorded below.

The writer commenced experimenting with disinfectants in 1876, and his published results may be found in the "Bulletin of the National Board of Health," vol. i., pp. 219, 227, 287, 363, and vol. iii., pp. 21–23. Referring the reader to these reports for details, and passing by my experiments with carbolic acid as a volatile disinfectant, I call attention especially to the results obtained in Baltimore last year (*vide* "Bulletin National Board of Health," vol. iii., p. 21, and also "Studies from Biological Laboratory, Johns Hopkins University," vol. ii., No. 2, pp. 201–212), as compared with those recently obtained by a different method reported below.

In Baltimore the test employed was destruction of virulence in blood from a septicæmic rabbit, which was proved by repeated experiments to be fatal to other rabbits when introduced beneath their skin in the smallest quantity. A fraction of a drop of this blood, not disinfected, would infallibly kill a healthy rabbit, but when treated with a certain proportion of various agents, commonly recognized as "antiseptics," this blood lost its virulence and could be introduced beneath the skin of a rabbit in much greater quantity—twenty minims or more—without producing any perceptible effect. Twenty minutes was allowed for the action of the disinfectant before injecting the blood into the subcutaneous connective tissue of a healthy rabbit as a test of virulence. The result, so far as carbolic acid was concerned, was that 0.5 per cent. failed to destroy virulence, as proved by the speedy death of the rabbit operated upon, while injections of septic blood treated with 1.25 per cent. and 2.5 per cent. were without effect. Other substances, including iodine and the mineral acids, were effectual in smaller quantities (*e.g.*, iodine, 0.2 per cent.; nitric acid, 0.25 per cent.).

In my recent experiments the same agents have been tested with reference to their power to destroy the vitality of certain micro-organisms, as proved by failure to multiply when introduced into a suitable culture-fluid (sterilized by heat), and placed in a culture-oven for twenty-four hours longer at a temperature of 100° Fahrenheit.

EXPERIMENT I., July 18, 1882.—A sufficient quantity of a standard 4 per cent. solution of carbolic acid (pure) was added to four separate portions of beef-tea containing a micrococcus obtained by cultivation from gonorrhœal pus (eighteen culture) to amount to 2 per cent. in No. 1, 1.25 per cent. in No. 2, 0.8 per cent. in No. 3, and 0.5 per cent. in No. 4. After allowing two hours for the action of the disinfectant, a culture-tube[1] was inoculated from each portion and into the culture-oven.

Result.—The following day Nos. 1, 2, and 3 were found to be transparent and unchanged, while No. 4—0.5 per cent.—had "broken down," and upon microscopical examination proved to contain an abundance of micrococci in pairs—figure of 8—like those used in inoculating the culture-fluid. Nos. 1, 2, and 3 were returned to the culture-oven, and at the end of two and a half days still remained unchanged. They were then inoculated with the same micrococcus from a fresh culture and returned to the oven. In six hours they had completely "broken down."

EXPERIMENT II., July 31st.—In the same way as in the preceding experiment, two tubes were inoculated with beef-tea, containing the same micrococcus, No. 1 exposed to the action of carbolic acid in the proportion of 1 per cent. and No. 2 in the proportion of 0.5 per cent.; time of exposure, two hours. The following day No. 2—0.5 per cent.—had broken down and No. 1 remained unchanged.

EXPERIMENT III.—The above experiment was repeated, using a fluid containing an abundance of *bacterium termo* in place of the micrococcus used in preceding experiments. The experiment was made in duplicate as follows: Time of exposure to disinfectant, two hours. Two tubes inoculated from No. 1—1 per cent. of disinfectant, two tubes from No. 2—0.5 per cent. of disinfectant, and two tubes from No. 3—0.2 per cent. of disinfectant. At the end of twenty-four hours the first two tubes remained unchanged, while the others had all broken down.

The results of these experiments, with two different micro-organisms—*bacterium termo* and a micrococcus from gonorrhœal pus[2]—conform in a remarkable manner with those previously obtained by the test upon a healthy rabbit of septicæmic blood treated and injected as already stated. This correspondence gives strong support to the view maintained in my paper relating to this form of septicæmia,[3] upon experimental evidence of a different kind, which ascribes the virulence of the fluid to the presence of a micrococcus constantly found in it.

If the virulence of the septic blood were independent of the living organisms present in it, the coincidence pointed out would be very remarkable in the case of a single antiseptic agent, and quite beyond the range of probability if found to be true for several.

---

[1] For the writer's method of conducting culture experiments see paper read before the American Association for Advancement of Science, Trans. 1881, also published in Studies from Biological Laboratory, Johns Hopkins University, vol. ii., No. 2, p. 165.

[2] I am engaged in a study of this micrococcus with reference to the question of its possible relation to the virulence of gonorrhœal pus, and will soon be ready to publish my results.

[3] A Fatal Form of Septicæmia, etc. Bulletin Nat. Board of Health April 30, 1881.

I propose to pursue this line of inquiry, and have already found a like correspondence in the results obtained by the two methods in the case of several other antiseptic agents. Thus, in my experiments with septicæmic blood, iodine failed to disinfect in the proportion of 0.1 per cent., but was successful in the proportion of 0.2 per cent. and above. In a recent experiment with this agent the vitality of the micrococcus (from gonorrhœal pus) was not destroyed by 0.1 per cent., but was destroyed by 0.2 per cent. and by 0.5 per cent.

Are we justified in assuming that hypothetical or demonstrated disease-germs would be destroyed by the same agents and in the same amount as are found to be effectual in destroying the micro-organisms used in these laboratory experiments? I think not, and it may be that among these lowly organisms, as among higher plants and vertebrate animals, what is destructive in one case is harmless in another. This certainly is true as regards the thermal death-point of different species, and also as regards the action of germicides upon the same species in different stages of its development. Thus Koch found that contact with a 2 per cent. solution of carbolic acid for three days only hindered the development of anthrax spores without destroying their vitality, while *a one per cent. solution killed the bacilli in a few minutes.* Again the experiments of Arloing, Cornevin, and Thomas[1] upon the virus of symptomatic anthrax show that in a dried condition this virus resists the action of antiseptic agents much better than in a fresh state. The dried virus was, however, destroyed by a 2 per cent. solution of carbolic acid.

In the experiments heretofore detailed, the object in view has been to determine the minimum quantity of carbolic acid which can be depended upon to destroy micro-organisms. But in judging of the therapeutic value of this agent it is evident that the minimum quantity which will prevent their development in a suitable culture-fluid is a more important question and one which must be settled independently, for, *a priori*, it seems very probable that the amount required to completely destroy vitality may be considerably less than is necessary to restrict reproductive activity.

Experiment shows a decided difference in this respect, but this is less than might have been anticipated.

Experiment IV., August 3, 1882.—Sterilized beef-tea containing carbolic acid in the proportion of 0.2 per cent., 0.1 per cent., and 0.5 per cent. was introduced into culture-tubes and these were inoculated with the micrococcus from gonorrhœal pus (twenty-fifth culture) and, separate tubes, with *bacterium termo* in "broken-down" beef-tea.

These tubes were placed in the culture-oven for twenty-four hours, at the expiration of which time it was found that both of the tubes containing 0.2 per cent. of the disinfectant were unchanged, while those containing 0.1 per cent. and 0.5 per cent. had broken down both with the micrococcus and with *bacterium termo.*

Experiment V., August 4th.—The above experiment was repeated with the micrococcus with an identical result, viz.: the organism multiplied abundantly in the solutions containing 0.1 per cent. and 0.5 per cent., but the solution containing 0.2 per cent. remained unchanged.

I find in a recent report to the Committee of Agriculture (Annual Report, Department of Agriculture, 1880) a record of similar experiments by D. E. Salmon, D.V.M., made during an investigation relating to the etiology of swine-plague and of fowl-cholera. A micrococcus was found in the blood of pigs suffering from swine-plague, which, according to the experiments of this observer, multiplied abundantly in urine containing one per cent. of carbolic acid, but not in the same fluid containing two per cent. of this agent. The micrococcus of chicken-cholera was destroyed by a one per cent. solution of carbolic acid, acting for six hours, as shown by loss of virulence in the fluid containing it—proved by inoculation experiments on fowls.

Many other experiments have been made in various parts of the world to determine the power of carbolic acid as a germicide, but the limits of this paper do not permit an extended account of these, and an abstract of results would be unprofitable unless accompanied by a critical study of the methods employed.

If we now make a new calculation from the experimental data given, as to the amount of pure carbolic acid required to prevent the multiplication of micro-organisms in the blood of a man weighing one hundred and sixty pounds, we shall find it to be 0.2 per cent., nearly three-fourths of an ounce (.72), or about four drachms. That is, this amount should be constantly present in the circulating fluid to prevent the multiplication in it of the micro-organisms which have been the subject of our experiments, *if the conditions were favorable* for the growth of these organisms in the living body. But just here the objection will be raised that the living body differs from a culture-flask in our laboratory in that vital processes come into play, which, under ordinary circumstances are sufficient to dispose of *microbes* such as these, even when they are directly introduced into the circulation (this experiment I have several times made upon the dog with *bacterium termo*), and in the case of specific febrile diseases this vital resistance of the living body to the morbific germs (?) of each is in some way reinforced by a non-fatal attack of any one of them. May it not be, then, that much smaller doses of carbolic acid will be useful in reinforcing the vital resistance of the human body? I cannot gainsay this in the absence of experimental evidence upon living animals, but, *a priori*, I should say no, inasmuch as the presence of 0.1 per cent. of carbolic acid in my culture-solutions appears to have *no effect* in restraining the development of the micro-organisms in question. They multiply as rapidly, and the motions of *bacterium termo* are as vigorous in these as in culture-fluids, quite free from any trace of this agent.

Dr. Déclat may properly claim that the power of carbolic acid as a germicide in the case of one or two of these micro-organisms is not evidence as to its power in the case of others—*e.g.*, the hypothetical germs of malarial or of yellow fever. I admit this, but point to the fact that our experimental data include the action of this agent upon several morbific germs, viz.: the micrococcus of septicæmia in the rabbit (author's experiments), the bacillus of anthrax (Koch), the bacterium of symptomatic anthrax (Arloing, Cornevin, and Thomas), and the micrococci of swine-plague and of chicken-cholera (Salmon).

Moreover, the power of carbolic acid as a germicide has been established by experiments upon these microbes, and not, so far as I know, by the individual researches of Dr. Déclat, who, however, seems

[1] Lyons Médicale. Abstract in London Lancet of July 1, 1882.

to infer, from this kind of evidence, that carbolic acid—his preparation—is a cure-all for germ diseases generally. As stated at the outset of this paper, this is a question which must be settled by clinical evidence, and I, for one, will be well pleased if a universal panacea for germ diseases has been found. But for the present I prefer to administer quinine to my malarial fever patients, rather than to resort to hypodermic injections of carbolic acid, as I am advised to do by Dr. Déclat in his letter to the *Courrier de San Francisco*. My reason for this is two-fold. First, I am well satisfied with the results which I have heretofore obtained by the use of quinine; and, second, I am not well satisfied of the truth of the hypothesis upon which Dr. Déclat advocates the hypodermic administration of carbolic acid in this disease. Dr. Déclat intimates in his letter that it is my own fault that I have sought in vain for the yellow-fever germ and for the microbes which have been demonstrated to be the cause of malarial fevers "by Salisbury of Ohio, Tomassi of Rome, and Klebs of Prague." I beg leave to inquire whether Dr. Déclat has himself demonstrated the presence of these organisms in the blood of patients sick with the diseases in question. If not, how can he be satisfied to announce their existence in such positive terms without having first verified the fact by personal observation? I would also respectfully suggest to some of the writers and teachers in this country, who are very ready to give credence to the alleged discoveries of foreign *savants*, that we have malarial fever cases in abundance at home, that good microscopes are easily obtained, and that Dr. Smith or Dr. Jones should be able to see the bacillus of Klebs and Tomassi-Crudelli, if it is really present in the blood and bears a causal relation to this disease. Let us, then, have the *bacillus malariæ* demonstrated to the medical students who are taught that it is the cause of the widely spread malarial diseases which they will soon be called upon to treat, just as they are taught by ocular demonstration the fundamental facts in anatomy, histology, and pathology.

The possibility that the germs of malarial fever locate themselves in the alimentary canal, rather than in the circulating fluid, has, in my opinion, more facts in its favor, and it certainly offers a better chance for the successful application of Dr. Déclat's remedy. Not hypodermically, however, as this would seem to be a roundabout way; and I scarcely credit the story told me by a medical friend in this city to the effect that Dr. Déclat administered carbolic acid to a patient here, by the hypodermic method, for the cure of gonorrhœa.

It seems not at all improbable that we may successfully employ germicides for the destruction of pathogenic organisms in the alimentary canal, and I strongly suspect that the *modus operandi* of some of our most important remedies is to be explained in this way. The beneficial results obtained by sweeping out this long and narrow passage with emetics and cathartics—a method of sanitary policing which had great credit with our predecessors, and is, perhaps, not sufficiently employed at the present day—may also be due to the removal of pathogenic organisms *en masse*, rather than to the fact that we also get rid of "vitiated secretions," which are, perhaps, in many cases vitiated by the action of these living ferments, rather than by the abnormal performance of the cellular elements of the mucous membrane and excretory glands.

But from this point of view we may well inquire whether other efficient germicides, including such standard remedies as the mineral acids, the salts of iron and of mercury, iodine, etc., may not have a place in our therapeutic resources quite as important as that which Dr. Déclat would have us give his favorite remedy.

Finally, I beg leave to quote, without comment, as this paper has already extended to a much greater length than I had anticipated, a recent case of carbolic acid poisoning.

"A case of poisoning by carbolic acid occurred in my practice on May 16th. A housemaid, aged fourteen, after being reprimanded by her mistress, swallowed, intentionally, as nearly as I could ascertain, about six drachms of the undiluted acid. I saw her twenty minutes afterward, when she was breathing stertorously; her face was livid, as if she had taken an overdose of chloral; her pulse was small and irregular; she was quite comatose, and the pupils firmly contracted, but not so small as in opium-poisoning. With the assistance of my friend Dr. Gibson, I washed out the stomach thoroughly with soap and water, and also milk and water; and after persevering for nearly an hour, the lividity became less and consciousness slowly returned, and two days afterward she was able to be sent to her home in the country.

"From the above facts we must infer that carbolic acid is a powerful narcotic, and rapidly absorbed; but, from its volatility, the injurious effects pass off, if it can be quickly removed from the stomach by the stomach-pump. *It did not appear to act as an irritant*, as the girl did not complain of any gastric discomfort afterward."[1] (R. H. Wilbe, Finchley Road, London; from *British Medical Journal* of June 21, 1882, p. 939).

THE EQUILIBRATING VALUE OF NERVOUS CONTROL.

By J. T. SEARCY, A.M., M.D.,

TUSCALOOSA, ALA.

I beg leave to offer the following thoughts, in reference to certain functions of the nervous system, that I regard as fundamental facts in modern medicine.

I think the *equilibrating* value of nervous control in the human body, viewed in the light of modern physiology, is a fact that is not sufficiently appreciated, and not brought forward to its relative rank and importance. It is *the* function in the living organization of the greatest value. If we regard the nervous system in the light of its essentiality in preserving or controlling the healthy actions in the body, and in the light of its potentiality in transmitting disturbing actions, its *equilibration* comes forward as its most important function.

In illustration of such a position, the following line of argument suggests itself.

In all exhibitions of life, wherever we observe it, the essential phenomenon is, always, *action*.

The amount of action there is constantly and continuously in progress in the human body is immense. In the lowest forms of life structure is simple and action is simple. In the body of man there are many kinds of structure and a great variety of actions, and the necessity for a nervous system uniting and controlling them is apparent. Looking at them all in the

[1] We have no reason to suppose that the acid swallowed in this case was Dr. Déclat's special preparation, and it is evident that the pure acid may be given *per orem* in a proper dose without injurious effects.

aggregate, we can form some idea of the *amount of action* there is by observing the amount of machinery in constant action, preparing and furnishing material to support these actions, and also it is shown by the amount of machinery necessary to remove the waste products resulting from such actions. The amount of material consumed and the amount of material thrown off also indicate the amount of constant action.

For convenience, it is easy to divide the actions of the body into *nutritive* and *functional*. The one embracing the processes relating to cell-life; the other the processes relating to the part the cell plays in the economy.

In the human body the complexity of structures and of actions is very great. The complexity of the nervous system exceeds the complexity of other parts of the body. It has functions corresponding to every other function and peculiar functions of its own. The divisions of it into cerebral, spinal, sympathetic, vaso motor, etc., are by no means well defined. They overlap and intermix by their multiplied connections to such an extent that the nervous system is a whole, and is very rightly called a whole. Its tendrils permeate in every direction, penetrating the tissues, arborating into every cellular structure until probably more perfectly than the vascular system, or connective tissue, if isolated, it would represent fully the figure of the body. The complexity of the cerebral portion of the nervous system is so great that physiologists are lost in the labyrinth. Connecting fibrils cross each other in all directions, uniting parts with each other in such a maze of minute complexity that practically every cell seems connected with every other; parts apparently of different functional action are united closely. What can be said of this portion of this system, more completely isolated, can be said of the rest, to a less complex degree.

The entirety of the body is a fact we are very much given to overlooking. So much is our attention directed to parts and portions that we overlook this as a fact, or neglect the importance of constantly considering it. In our text books and in our current literature we neglect, I think, the consideration of this fact: that the body is a whole, and especially the fact that it is made whole, in its living actions particularly, through the intimate and multiplied connections of the nervous system. The extreme multiplicity of these connections would warrant such an assertion or belief, if it were not corroborated by other facts.

Noting, then, as a fact, almost self-evident, the immense amount of action there is constantly going on in the body, nutritive and functional, and coupling this fact with the intimate and multiplied connections of the nervous system, we are prepared to appreciate the other very essential and fundamental fact that the nervous system is a medium of transmitting motion or action, of harmonizing, balancing, equilibrating this general action until the body is a grand and a complete community of action. This is a fact, the value of which, the practical everyday value of which, I don't think is sufficiently appreciated. If we bear it constantly in mind, it will help us to explain many phenomena we witness—much of physiology, many of the disturbed or diseased conditions, and much of our therapeutics.

With this sort of an understanding of what is going on, constantly and continuously, in the living body, we can readily describe *health* as a harmonious condition of action everywhere, all equilibrated. In health the structures are normal, according to function, and the actions natural, in accordance with structure and function. The local actions everywhere are not disturbed or disturbing, and the transmitted actions are harmonious, not disturbing, and easily equilibrated or controlled. Our consciousness of such actions is pleasant and agreeable.

Indeed, *physically considered*, we can define *consciousness* as the resultant, the summating in intellectual brain action, of all the actions brought to it from all parts. When harmonious, agreeable to intellectual action, our consciousness is pleasant. If there comes disturbing action from any source our consciousness is disturbed.

Pain can be defined under this sort of an understanding as disturbing action transmitted from the disturbed part to centres of sensation; or, more properly, pain is a disturbed action of the centres of sensation. Defectiveness of structure and of functional action, disease in the centres themselves may give rise to pain, without the disturbance being transmitted to them.

Under this sort of an understanding we can define *disease*, anywhere, as a disturbance of structure and of action, whether the disturbance go so far as to make structural changes *visible to the eye or not*.

In accordance with the nerve-connections of a part, and the importance of its functional actions, will disturbing action be transmitted from it to nerve-centres and to the rest of the body. The degree and character of the local disease, *i.e.*, the degree and character of the local disturbance of structure and of action, will characterize the transmitted action.

In inflammation in any part, characterized by the local phenomena, much studied and elaborated nowadays, the action that is transmitted is disturbing in many particulars. Disturbance is shown in cerebral action. Intellectual brain action often shows disturbance; co-ordination and control of muscular action shows disturbance; sensory tracts are disturbed and pain results; the nerve-centres that regulate the production and reduction of heat show disturbance and fever results; general cellular action, nutrition, is disturbed. Because of the transmission of disturbing action, there is disturbance of the various vital actions of the body, respiration and circulation, and the like; general equilibrating control is lost, or, rather, disturbed.

In severe local inflammations the transmitted disturbance is so severe as to jeopardize the general equilibration of the various actions, and if it go far enough it may entirely cessate actions in these principal centres and the man die—action everywhere stop.

It is impossible to explain all the general conditions of disturbance in disease through the vascular system. You can admit all that can be shown to result from the distribution of morbific material by the circulation, and then not have gone half way in explanation of the phenomena. Bile, carbonic acid, urea, or any other waste products, or the germs of disease, may make disturbing action wher ever they reach parts; and because so generally distributed may produce a general disturbance, but the transmission through nervous action of the disturbance thus created has to be allowed, even in these general distributions of disturbing agents, before our explanation of the phenomena will be complete.

The various "sympathetic" and "reflex" ac-

tions observed in the body is much easier explained as a transference, by nerve connections, not of the natural harmonious action constant in health, but of disturbing action, and such action produces in connected parts disturbance of nutritive or functional action, or both.

It is astonishing how much of our therapeutics can be explained on such principles—the most satisfactory and successful of all our therapeutics.

Take a man laboring from inflammatory action in any important part. It is not necessary to understand all the cellular processes supervening in the inflammatory action. The structure and the actions, nutritive and functional, of the part are disturbed, and disturbance is transmitted, the action in principal nerve-centres is disturbed, and general disturbance is transmitted. His centres of sensation are disturbed and he has pain; his centres of muscular control, of cerebral action, and of the general vegetative processes are disturbed. He has to lie down, because in that way he gets rid of a great deal of voluntary action that tends to heighten the disturbance. He abates all the muscular and mental action he can. He does all he can to *equilibrate* the general disturbance. "To lie down and keep quiet" is the first rule under any general disturbance, especially when the disturbance is of such a character as to injure control of the processes that regulate temperature. "When a man has fever he ought to lie down," is a maxim. Probably, keeping as quiet as he can is all that will be needed for our patient. If that is not sufficient, we can help him often, or sometimes. We cannot emphasize too much the advantage of cessating all the action the patient can voluntarily.

How do we usually help medicinally such conditions as these?

In our materia medica we have a long list of agents, with which *in health and in disease* we can, to a greater or less extent, paralyze, stop action in nerve-centres. In health, we can abate, or entirely cessate the action constantly going on in these centres by the administration of such drugs, and we do the same in the time of disease or disturbance. Our medicines act in the same way all the time. The very best medicines we have, the ones we most frequently use, the ones we all carry about with us for immediate and confidential use, are of this character. Take opium, the medicine more frequently used than any other in some one of its forms. In health we can produce in nerve-centres, particularly sensory centres, every stage of abated, cessated, or paralyzed action by the administration of different-sized doses. We can completely paralyze the centres with it, stop the natural, constant action, and death ensues—or a cessation of all action in the body. In times of disease, or transmission of disturbing action to these centres, how excellent is the effect of paralyzing these centres, so that the disturbance is abated there, or pain stopped, and the transmission of the disturbing action prevented. What would we take for our opium in times of such disturbance! It is well, though, to bear constantly in mind, how we are accomplishing the good. We can give it in health when it is not needed, for the pleasurable feeling it produces, and by constant administration damage and disease these important centres; and we can in the time of disturbance overdose, completely stop action, and kill our patient.

I select opium as a very good example of what we may call an *equilibrating* medicine, but the whole list of anodynes and anæsthetics exhibits this property as their principal mode of action, and there are others not usually so classed.

The actions in centres of consciousness and sensation seem peculiarly susceptible to the paralyzing effect of anodynes and anæsthetics because of their extreme sensitiveness, their excessive complexity, their high order of development, if you want to put it.

How often in our therapeutics we resort to the use of medicines that have effect in abating action in nerve-centres we have only to have our attention directed to the fact to observe. Take, for instance, among the anodynes, the various forms of the opiates, hyoscyamus, cannabis indica, camphor, assafœtida, stramonium, etc. Among the anæsthetics, alcohol, "the grand prototype of all anæsthetics," chloroform, chloral, ether, amyl, nitrous oxide, etc. And then there are a number of medicines like quinine, the salicylates, the bromides, to some extent the iodides, digitalis, aconite, etc., that evidently abate action, when administered in sufficient doses in nerve-centres not sensory. Most excellently they come in when indicated.

I have probably illustrated enough to show the value of nerve-equilibration. Recognizing in acute diseases, "inflammatory" disturbances, the nervous system as the medium of transmitting disturbing actions, we readily see how such agents as in health have effect to abate action in principal nerve-centres, will, in disease, be excellent to stop or quiet the disturbance in these centres and the transmission of it through them. We can use them like the policeman does his cudgel, to suppress the leaders and quiet the row, or prevent the transmission of excitement.

When we recognize the controlling, balancing, *equilibrating* value of the nervous system so far as all the various functional actions are concerned, and also so far as the constant, continuous, cellular, nutritive processes are concerned in the body, we have a key to many of the phenomena in health, in disturbance or disease, and to many of our efforts in therapeutics. We ought to keep these facts constantly before us.

The equilibrating value of nervous control is a fundamental principle, around which much of the "philosophy of medicine" rotates.

Anatomical Proportions.—A man in his infancy has the breadth of his shoulders equal to the length of the face, and to the length of the arm from the shoulder to the elbow, when the arm is bent. It is the same again from the lower belly to the knee, and from the knee to the foot. But when a man is arrived at the period of his full growth, every one of these dimensions become double in length, except the face, which, with the top of the head, undergoes but very little alteration in length. A well-proportioned and full-grown man, therefore, is ten times the length of his face; the breadth of his shoulders will be two faces; and in like manner all the above lengths will be doubled.—*Students' Journal*, July 15, 1882.

Facial Liniments.—It was Dr. Oliver Wendell Holmes, we are told, to whom, as he was waiting for a prescription, the druggist said: "That is my son, sir, sitting by you; don't you think he looks like me?" "Well, yes," replied the poet; "I think I can see some of your liniments in his face."—*Drug Circular*.

IMPERFECT NUTRITION IN INFANTS.[1]

By E. M. HERMANN, M.D.,

YONKERS, N. Y.

My attention has of late been called to a condition of non-assimilation of food in infants, which I have denominated as above.

This pathological condition may perhaps be already familiar to some, but after carefully searching the works of the most eminent writers on "Diseases of Children," as for instance: Smith, Vogel, Ellis, Meigs and Pepper, Dewees, Underwood, Meadows, Bouchut, Hillier, Keating, and others I find no mention of it.

The only allusion to it I can anywhere find is in West's work. He devotes only a few lines to it, stating that such a disease is sometimes met with, and applying to it the term "the atrophy of infants." We, however, have not made use of this term, because we are convinced that the disease is not so much one of wasting of the tissues, as it is a lack of development produced by imperfect nutrition. This condition is often seen in connection with tuberculosis, rachitis, scrofulosis, etc., as a result of these morbid processes, but as a disease *per se* we are forced to the conclusion that it is of rare occurrence.

The following cases are examples of the disease in question:

Case I.—Homer C——, aged fourteen months. This child first came under my observation two years ago. He was then fourteen months old and weighed nine pounds—at birth he weighed five pounds. The child was thin, the skin was wrinkled and seemed to possess no elasticity, tissues soft and flaccid, child cried and worried almost constantly; vomited some, was restless at night and constipated.

These are about all the symptoms which the case presented; there was no evidence of any cerebral affection—the pupils were normal, and the child appeared bright and intelligent, the lungs were sound, and the kidneys acting normally.

In short, by excluding all diseases, we were forced to the conclusion that it was simply a case of imperfect nutrition. There were only three prominent symptoms, viz.: constipation, restlessness, and non-development.

Upon inquiry it was ascertained that the child had been treated for the constipation by all the physicians to whom the mother had applied.

The condition of the child was explained to the mother, and oleum morrhuæ ordered in ten-drop doses *tris in die*, to be increased five drops at a dose each week until the child was taking ʒ j. t. i. d. Oleum morrhuæ was also ordered by inunction morning and night, and the further use of cathartics was strictly prohibited. This, with an occasional dose of potassium bromide, constituted the treatment throughout. The little patient very soon began to improve, and in two weeks the bowels were perfectly regular, and the child began to gain flesh and has continued to do so ever since. To-day the child is a good specimen of a healthy, robust boy. The treatment was continued for about one year.

Case II.—Carrie K——, aged five months, weight eight pounds. Unfortunately this child was not weighed at birth, and therefore I am unable to state that fact. The parents of the child declare that she has grown slightly in length, but that she has not gained the least in plumpness.

When first seen the case presented about the same symptoms as Case I., viz.: restlessness, some vomiting, constipation, and lack of development. The child was entirely free from any constitutional taint, was bright and intelligent, nor could I discover any evidences of constitutional disease in either father or mother.

The diagnosis was the same as in Case I., and the treatment has been the same.

I regret that I am unable to give the final results in this case, as the child has only been under observation about four weeks. The constipation is already relieved, and the child shows a marked change in appearance, the cheeks are beginning to fill out, and I am confident the results will be as satisfactory as in Case I.

It might also be well to state that this child also had been the recipient of innumerable cathartics at the hands of physicians.

Now, what is the condition which we have presented in these two cases? Simply, feeble children of slow development. If development may be arrested from any cause in the *fœtus in utero*, why not in the infant *ex utero?*

A child grows most rapidly during the first few weeks of its life, and at the end of its first year should weigh about twenty pounds, and gain about four pounds a year for the next few years, and at the end of the first year should be about six or seven inches in height, and gain about two inches each year thereafter. This is the normal standard, according to Vogel.

But here are two children, one, at the end of fourteen months, weighing nine pounds, and the other, at the end of five months, eight pounds. Surely there is a decided lack of development. What is the etiology of this affection?

Undoubtedly, the most frequent cause is deteriorated milk. Improper food and premature weaning we would also suggest. Human milk, according to analysis, contains:

Water	889.08
Solid matters	110.92

These solids are composed of—

Sugar	43.64
Casein and extraction matters	39.24
Butter	26.66
Incombustible salts	1.38

When the milk contains these ingredients in the proper proportion, if it is assimilated by the infant, we have natural growth and successive development; *per contra*, if there is a lack of any of these elements, we have imperfect nutrition as a result.

This food has to exert a two-fold influence in the human organism: first, it has to furnish material for the growth of the body, and second, matter for the maintenance of its temperature. And life cannot long be properly supported except on a diet where the elements of nutrition and the elements of respiration bear a proper proportion to each other. As has been remarked before, if there is an absence of any of the important ingredients of the milk we have imperfect nutrition.

And surely if there is a defective supply of the oleaginous matter which contributes to supply the fat of the body, it becomes at once apparent that we have the condition which we have endeavored to lay before you in this paper.

The result of this defective supply of nourishment is, as we have already seen, that the infant does not increase in size, and the excreting functions of the body are not properly carried on.

[1] Read before the Yonkers Medical Association, January, 1882.

The physiological explanation of this is, that the infant is compelled to force from its own tissues to supply the nitrogenous elements essential to the maintenance of life, unless we fortunately see the case in time to do so artificially by the therapeutic use of oleum morrhuæ as we have suggested.

So much for the etiology, and now as to the pathology.

When we come to examine a body dead from inanition, we find, according to the best authority, a complete absorption of fat, and the removal sometimes of some of the cellular tissues. The liver is congested, the gall-bladder full of bile, and the stomach and small intestines are empty, also pale; Peyer's glands more prominent than natural, and there is remarkable development of the solitary glands of the large intestines, the dark orifice of which render them very evident. In short, there is a general appearance of inflammation of the whole secreting apparatus of the intestinal canal.

Reports of Hospitals.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA.

SERVICE OF WILLIAM GOODELL, M.D.,

PROFESSOR OF CLINICAL GYNECOLOGY.

(Reported by Guy Hinsdale, M.D.)

UTERO-VAGINAL PROLAPSE — CYSTOCELE, RECTOCELE, AND LACERATIONS OF CERVIX AND PERINEUM.

TWELVE years ago, during a hard labor, this woman sustained a laceration of the cervix and of the perineum. After delivery, the physician in attendance performed the ordinary operation for rupture of the perineum, but the wound failed to unite. Ever since that time the uterus has remained heavier than it should be, and the vagina—the hollow column which relies for its sustaining power upon the integrity of its perineal abutment—has been gradually sinking until, in fact, it has become completely everted, just as the finger of a glove may be turned inside out. The womb has descended bodily, and is wholly exposed to view. Not only this, but the bladder and rectum have shared the same fate. The former has been dragged to a great extent outside the body, and the rectum in its descent has carried with it Douglas' pouch and a coil of the intestines.

Let me prove to you that all these conditions are present. You notice that the tumor is pyriform, that it can be circumscribed by the finger, and that the sound passes to a depth of two and a half inches, its tip being felt in the mass outside the body. I now introduce the sound into the bladder, and you observe how readily its lower margin can be defined. Next, I pass my finger into the rectum, and, with my thumb, push up the posterior wall of the inverted vagina. This double touch proves that a pouch of the anterior wall of the rectum is among the constituents of the protruding mass. Douglas' pouch and a few coils of intestine also participate.

The displacement of the bladder renders the woman unable to pass her water in a stream; the detrusor muscles of the abdomen can no longer compress it, and the dribbling of urine and the friction of clothes have produced ulcers on the vagina and cervix. We have, therefore, in the single case before us, a laceration of the cervix and of the perineum; inversion of the vagina, with ulcers; prolapse of the womb; a cystocele and rectocele; and hernia of the intestines.

This is a condition of things which, fortunately, is rare. You might suppose that this unlucky woman had been neglected during childbirth, and was without medical attendance. On the contrary, you will find that many of these cases have been treated in accordance with the most modern obstetrical practice. In the first place, she suffered a laceration of the cervix. Why should that accident happen so often? How shall we account for the fact that, of the women that come to the gynecological dispensary of this hospital, one out of every six has an ununited laceration of the cervix? In these busy days there is an unfortunate tendency to urge on labor. To attain this end it is a very popular thing to rupture the membranes early, to give ergot, and, perhaps, before the os uteri has become dilatable, to resort to the obstetric forceps. Indeed, so common is it to break the bag of waters early in labor, that a member of the British Medical Association made the unchallenged statement "that at one time he thought the membranes were of some use, but he did not now believe it." Such haste and such contempt of Nature's methods ought never to be sanctioned.

But how came the perineum to be torn? Perhaps the child's head was large, or presented in an abnormal position; or it may be that the forceps again were responsible, or that the perineum was not properly guarded. But we must not accuse the attendant of incompetence, because sometimes, in spite of the greatest care, such an accident will happen. If you wish to save the perineum, my advice is not to touch it. In other words, I believe that continuous, firm pressure upon the perineum, with a napkin or without one, with "thumbs up" or "thumbs down," works more evil than good. The perineum becomes hot, bruised, congested, and benumbed; its vitality is impaired, and in the last throes of labor is apt to give way. The support that is needed ought not to be applied to the perineum, but directly to the head itself. When the perineum becomes rigid you may relax it by passing two fingers into the rectum and hooking the sphincter ani; then pulling it forward, with the thumb of the same hand you make the needful restraining pressure upon the head. In this way you not only strengthen the line of greatest perineal tension, and restrain the too rapid advance of the head, but at the same time the circulation of the blood remains free. The nerves are not benumbed by a double pressure, and the perineum remains a living, elastic, and sentient tissue.

As for the forceps, they would work less mischief were they not used so often in the dark, or permitted to retain their hold upon the head until delivery is accomplished. The safest rule to follow is, in most cases, and always with primiparæ, to take off the forceps as soon as the perineum begins to bulge, and to leave the final delivery of the head to the expulsive efforts of the patient.

We shall not, in this case, attempt to do more than one operation at a time, although I have repeatedly done them both together. We shall direct our attention, first, to the cervix. It will be necessary to denude carefully the opposing surfaces of the laceration, and then, by silver stitches, to bring the raw edges of the wound into accurate coaptation.

The after treatment will consist in keeping the patient in bed for two weeks, and in giving opium

to quiet her bowels for six days. It will also be necessary to catheterize her for the first forty-eight hours, and, after the third day, to wash the vagina twice daily with a weak carbolized solution. On the seventh day a laxative will be given, and a day or two later the stitches may be removed.

After the cervix is restored, we can operate upon the cystocele. Our plan will be to denude an oval-shaped surface of the mucous membrane upon the anterior wall of the vagina, and bring the edges together to make a linear cicatrix, which will act like a narrow splint, to stiffen and support this anterior wall. This I shall further support by the restoration of the perineum. In this way, by three different operations, we may hope to cure our patient.

BRITISH LYING-IN HOSPITAL, LONDON.

UNDER THE CARE OF DR. FANCOURT BARNES.

CASE OF PUERPERAL SEPTICÆMIA DEPENDENT ON RETENTION OF PART OF PLACENTA—CARBOLIZED INJECTIONS—RECOVERY.

MARY ANN S——, aged thirty-three, was admitted on March 27, 1882, having been in labor about six hours with her fifth child. The presentation was normal, and the child (female) was born in about twelve hours from the commencement of labor. The placenta was adherent and had to be removed. There was considerable post partum hemorrhage—so much so as to blanch the lips and gums of the patient. The patient was slightly delirious afterward. The pulse was 80, and the temperature rose to 100.5° F.

The next day (28th) the temperature fell to normal; pulse, 84.

March 29th. — Temperature, morning, 99.2°; evening, 104°.

March 30th. — Temperature, morning, 101.5°; evening, 104°. Bowels opened freely by an enema.

March 31st. — Temperature, morning, 101.2°; evening, 104.5°; pulse, 96. Two and a half grains of calomel were given and afterward seven grains of quinine and one-fourth of a grain of extract of opium.

April 1st.—Temperature: morning, 104.8°; at 3 P.M., 104°; at 5 P.M., 105°; and at 9 30 P M., 103.2°. The pulse rose during the day from 120 to 144. A draught containing twenty grains of chloral and the same amount of bromide was given in the evening.

April 2d.—The morning temperature was 104°, rising to 104.8° at 2 P.M At 4 P.M. the uterus was syringed out by Dr. Barnes with carbolic solution (1 in 60), which brought away a few clots without pain. A mixture containing six grains of sulphate of quinine and twenty minims of tincture of opium was ordered to be given every four hours. The temperature rose to 105° at 5 P.M., and reached 105.2° at 8 P.M. Pulse, 136.

April 4th.—Temperature, morning, 99.8°; evening, 105.2°. Pulse, 120 to 140. The uterus was again syringed out with carbolic lotion. The temperature rose to 103° in the afternoon of the 6th, but afterward fell gradually, and on the 7th was normal.

Four grains of quinine with a quarter of a grain of extract of opium were given every four hours.

The temperature continued to vary from 98° to 99° (rising to 100° only once, on the evening of the 9th) till the 11th instant, from which date it remained at normal, and the medicine was discontinued.

The patient improved rapidly from this date, and was discharged on the 22d.

Progress of Medical Science.

CYST OF FIBULA—EXCISION.—J. W. Buchanan operated upon a lad twelve years old, for a large oval tumor on the outer side of right leg, extending from fibular articulation downward for about six inches, and measuring from its inner side to the middle of the leg behind, over its most prominent part, eight inches. On the inner side a slight furrow separated it from the tibia, but behind it could not be distinctly defined. It was immovably fixed, smooth, uniform in outline, hard on palpation, with here and there a spot which gave a semi-elastic sensation, with egg-shell crackle on firm pressure. The skin was freely movable over it. There was no pain nor tenderness to pressure, nor was walking interfered with. He stated that falling from a tree a year before, he had bruised his right leg below the knee. Hot fomentations had caused speedy relief of all painful symptoms, but there had remained a slight thickening of the tissues. A second injury upon the same part had been similarly treated, and had resulted in a similar manner, except that the thickening had been more marked. After a time this swelling gradually increased, then more rapidly, and more lately had remained stationary. As the indications seemed to be that the growth was malignant in nature, amputation was determined upon, and the patient was chloroformed for that purpose. However, upon cutting down upon the tumor, it was found to be a cyst, and Dr. Buchanan simply excised the upper half of the fibula. The patient recovered entirely.—*Glasgow Med. Jour.*, May, 1882.

CASE OF EXPULSION OF A PORTION OF SMALL INTESTINE FOLLOWING REDUCTION OF STRANGULATED HERNIA—RECOVERY.—The above case is reported by Dr. E. Gilly, of Fons-Gard, in the *Courrier Médicale* for June 10, 1882. The patient was a farmer, aged thirty-seven, who, during six years, had been the subject of a right inguinal hernia, which was but little larger than a hen's egg, perfectly reducible, and habitually kept in position by a truss. On May 3d, during a short railway ride, the patient, who latterly had neglected to wear his truss, observed a considerable increase in the size of the inguinal tumor. After quitting the train he walked slowly to his house, a distance of rather more than a mile, supporting the tumor with his hand. On the same day Dr. Gilly was called and found the patient in bed, suffering violent abdominal pains, greatly agitated, and vomiting everything taken into the stomach. The scrotum was of a stony hardness and was distended by a tumor as large as a man's fist, and pyriform in shape. Diagnosis of strangulated hernia. Two attempts at reduction by taxis with the use of moderate force proved unsuccessful. Dorsal decubitus ordered, with head and thighs elevated; application of a bladder filled with cold water; administration of an infusion of nux vomica. May 4th.—No change in hernial tumor. Infusion not well borne. Another unsuccessful attempt at taxis. Bilious vomiting, the vomita having

a fecal odor; almost constant hiccough. Dr. Portal, of Saint Geniès, was called in consultation, and by employing considerable force, grasping the tumor with his large hand, the latter succeeded in effecting complete reduction. Spica bandage ordered. Beef-tea diet. Enema of oil, etc., ordered. At the evening visit Dr. Gilly found the patient very feeble. The enema had been immediately returned, the patient having also a sensation as of an obstacle in the rectum completely blocking its passage. Slight vomiting. May 5th.—Reappearance of hernial tumor; easy reduction. May 6th.—Vomiting had quite ceased. Occasional stools. May 7th.—Patient, disobeying orders, had risen from his bed. Return of vomiting and of hernial tumor. Reduction again. May 9th.—Patient had removed a new truss applied the day before. Vomiting again with great prostration and agitation, and with slight tympanites and some tenderness of abdomen. May 10th.—No further vomiting; slight general improvement and less tympanites. May 11th.—Patient had again risen from bed and had also removed the truss. Vomiting worse than ever. Hernia reduced again, but this time with some difficulty. Ever since May 5th, citrate of magnesia in small and frequently repeated doses had been used to check vomiting and to keep the bowels open. May 12th.—Cessation of vomiting and marked improvement. May 13th.—Convalescence established; no tympanites; stools are formed; hernial tumor well supported by truss. On May 29th, Dr. Portal, while making a round of visits at Gayen, was called to examine a "piece of flesh," which the patient was stated to have passed by the rectum. This was found to be a portion of the small intestine, and Dr. Portal at once brought it for Dr. Gilly's inspection. The piece of gut was twenty-eight centimetres in length, it was ragged at both ends and exhaled an odor of putrefaction. but was found to be quite impervious to water. There was attached to it no fragment of epiploon. From the patient himself Dr. Gilly learned that for eight days preceding the discharge of this fragment of intestine he had suffered from diarrhœa not severe enough to confine him to bed or to the house, yet resisting all domestic treatment. The patient's health at the date of the doctor's report was excellent; bowels regular, appetite good, and all emaciation had disappeared.

Parasitic Nature of Cerebro-Spinal Meningitis and the Infectious Nature of the Accompanying Nephritis.—M. Ernest Gandier has recently published the history of a case of cerebro-spinal meningitis, in which he claims to have demonstrated for the first time the parasitic nature of the disease. The case was that of a woman, aged thirty, seen at the Hôpital Cochin, who was seized suddenly after a suspension of the menstrual flow, with violent headache and pain in the back, accompanied by chill, high fever (temperature, 104°–105.4° F.), and marked typhoid symptoms. Typhoid fever was at first suspected, but the rapid supervention of strabismus. dilatation of pupils, stiffness of neck, and fixed rotation of head to the right. with general hyperæsthesia, delirium, and coma, soon established the diagnosis of meningitis.

Chemical examination of the urine revealed the presence of albumen of two kinds, the *retractile albumen* of Prof. Bouchard (attributed to renal lesions), and the *non-retractile* (considered as an indication of some general infection of the system involving the kidneys). Microscopical examination of the urine and blood undertaken during life and with antiseptic precautions, showed the presence of moving micrococci in great numbers, of various sizes, generally isolated, but in some cases united in pairs.

The death of the patient occurred on the sixth day, from coma. The latter was accompanied by profuse sweatings and retention of urine. At the autopsy, the intestinal follicles were enlarged and prominent, spleen enlarged and softened, liver much enlarged and in a condition of fatty degeneration, lungs congested, heart flabby and "dead-leaf colored," blood black, fluid, and without clots. The kidneys presented the lesions of infectious nephritis as first described by M. Ch. Bouchard in typhoid fever and as observed by the author in diphtheria. Both the cortical and the medullary portions were congested, the former marked by whitish striæ. The microscope showed considerable swelling and granular degeneration of the renal epithelial cells with effusion of granular matter into the lumen of the tubules. The meshes of the cerebral and spinal pia mater showed the usual purulent effusion. This exudation contained numerous micrococci, like those discovered during life in the blood and urine.

M. Gandier ventures to draw from this case the conclusion that the presence of micrococci in the blood and urine tends to prove the parasitic nature of cerebro-spinal meningitis. He attempts to explain in this way both the contagious nature of the malady and its occurrence in epidemic form. At the same time an explanation of the general typhoid symptoms accompanying the meningitic manifestations would be found. The existence of a new variety of infectious nephritis, analogous to that already described by Prof. Bouchard, is also pointed out. The meningitis and the nephritis are to be considered as secondary to a primary parasitic infection of the system.—*Revue Médicale*, June 3, 1882.

Cerebral Irritation in Children.—The *Annales et Bulletin de la Société de Médecine de Gand* for May, 1882, quotes from the *Practicien* an article by Dr. J. Simon bearing the above title. Dr. Simon lays stress upon the fact that this form of cerebral irritation differs very markedly from the affection as seen in adults. He defines it as a slowly progressing neuropathic condition, unaccompanied by any organic lesion, beginning in early infancy, and throughout its course entirely free from any accompanying febrile action. It is not incurable, but, unless subjected, almost from the start, to a treatment both careful and systematic, and, above all, persistent, it will lead inevitably either to sclerosis of the brain or to epilepsy, meningitis, etc.

The child affected with cerebral irritation is one in whom nervous reaction is exaggerated, and in whom over-active cerebral circulation gives rise to a condition of irregularly disseminated congestion. Such a child is commonly the offspring of parents having the nervous diathesis, the subjects, perhaps, of some distinct neurosis, and not infrequently the victims of chronic alcoholism. Syphilis in the parents is another predisposing cause. As immediate exciting causes, we have exposure of the child to the excitements of society life, especially as it exists in large cities, and also the use of tea, coffee, or wine.

Beginning even in the infant at the breast, cerebral irritation may persist up to the fifth or sixth year of life. At this age it either disappears or undergoes a modification of its character, as it now shows it-

self under the form of epilepsy, sclerosis, meningitis, etc. The symptoms of cerebral irritation in the child do not lead the parents to suspect either existing or threatened disease. By them the child is merely regarded as wilful, capricious, nervous, excitable, restless, etc. He is subject to night terrors, to sleeplessness, is easily agitated by day, and shows fickleness in his moods, while a general lack of harmony is observable in his actions. The cutaneous sensibility is disordered. To a careless observer many of the symptoms would seem to point to the approaching onset of some acute inflammatory disorder, such as pneumonia, scarlatina, or typhoid fever, but there is never any rise of temperature, neither is there any delirium. Again, there are no persisting epileptiform phenomena, no paralytic attacks, no motor disturbances, such as succeed the congestive attacks of cerebritis or cerebral sclerosis. This condition is, as before stated, a frequent sequela to the purely irritative morbid condition mentioned, and, unlike the latter, is accompanied by organic lesions.

The prognosis of cerebral irritation in children is necessarily serious. Nevertheless, not fatal, as serious consequences may be averted by rigorous and persistent treatment. For the success of such treatment the physician must have entire control of the case. While constantly on his guard against the ever threatening termination of the condition in cerebral sclerosis, the physician must be prepared for the occurrence of eclamptic seizures. They are, indeed, very easily provoked, and, if frequently repeated, predispose in their turn to cerebral congestions. A complete cure, however, is not to be despaired of, even though, as the result of such attacks, the patient be brought, as it were, upon the very verge of sclerosis. Symptoms due to attacks of cerebral congestion will sometimes be more marked upon one side of the body than upon the other. This may be true of a sense of formication, or, perhaps, we may find a slight degree of weakness in a single limb, or it may be in the upper and lower limbs of the same side. All such phenomena being in pure cerebral irritation of children extremely transitory in their nature.

In most cases, cerebral irritation quite disappears after a certain age. Nevertheless, occasionally it appears to lie dormant and ready to break out in severer cerebral symptoms on the advent of some intercurrent malady.

Treatment should be both hygienic and by drugs. As a main factor of the hygienic treatment, the child must be carefully guarded against excitement of all kinds. Among drugs, Dr. Simon has found bromide of potassium by far the most efficacious. He gives it in steadily increasing doses until a slight degree of prostration is produced. To a child of two years he administers as much as a gramme per diem at the start, dividing it into three doses, and invariably directing that it be taken before meals. This quantity he increases to a gramme and a half, and then to two grammes per diem, and continues giving the latter amount for four or five days. The dose is then progressively diminished. In no case, however, should the drug be completely suspended for any length of time. Treatment must be kept up until every nervous symptom has disappeared.

Besides potassium bromide, Dr. Simon employs mild derivatives, preferring the application of dry cups along the upper portion of the spinal column, and at points on a level with the mastoid processes, rather than the use of vesicants. Tepid baths he also recommends, as well as certain medicated baths, *i.e.*, *bains de tilleul, bains de valériane*. The use of electricity or of the douche he strongly condemns, and he considers sea-air objectionable. Constipation is, of course, to be avoided, as tending to induce cerebral congestion, and the digestive organs must receive careful attention.

GOITRE, CRETINISM, AND IDIOCY.—Dr. Hermann contributes a memoir on this subject (Friedreich's *Blät. für Gerichtl. Med.*, 1882, p. 128), and arrives at the following conclusions: 1. Although poor living, badly ventilated dwellings, improper clothing, etc., may influence the development of these diseases, they cannot actually produce them. 2. There is no connection between the number of marriages between blood-relations, and the number of instances of cretinism. Marriages between blood-relations appear rather to diminish than to increase the tendency already present of producing cretinism. On the other hand, idiocy may be, and appears to be, produced by such marriages; *e.g.*, Howe records seventeen cases of marriages between blood-relations, producing 95 children, of whom 45 were idiots, 12 scrofulous, 1 deaf, and 1 dwarfed. 3. Cretinism is never uniformly manifested in one locality, but is developed at varying times in certain streets, or houses, and that it becomes active at the time when the human organism is not yet fully developed. 4. The hereditary character of the malady is in certain cases undoubted. 5. In the case of cretinism in the children of healthy parents, there must be a direct specific alteration of the germs by the deleterious matter, without any change occurring in the parents themselves. They are, so to speak, the vehicle for the peccant material. On the other hand, it appears that, when the disease has once appeared in a family, a specific tendency thereto can be traced in the descendants. Even if this tendency have been latent for a time, it often reappears in consequence of some either normal physiological cause, or some newly developed pathological irritation.

ERGOT IN PERTUSSIS.—Dr. John Dewar, in the *Practitioner*, May, 1882, draws attention to the great value of the liquid extract of ergot in whooping-cough, in which disease he believes it to be the best and safest of all remedies. In the *Edinburgh Med. Jour.*, 1863, Dr. Griefenkel reported a case of a lad, six years old, who was cured of whooping-cough in eight days by the use of ergot.

AMYL NITRITE FOR AGUE.—Dr. Saunders, of Indore, India, reports in the *Indian Medical Gazette*, a number of cases of ague successfully treated with amyl nitrite. He asserts that in every instance the disease yielded quickly and permanently to the amyl treatment. He mixes the drug with an equal volume of oil of coriander, to make it less volatile and to cover its odor, and administers it as follows: Four drops of the mixture are poured on a small piece of lint, which is given into the hands of the patient for him to inhale freely; he soon becomes flushed and both his pulse and respiration are much accelerated, and when he feels warm all over, the inhalation is discontinued, as the symptoms continue to increase for some time afterward; a profuse perspiration now sets in, which speedily ends the attack, though in some cases the cold stage merely passes off without any hot or sweating stage.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 16, 1882.

A DRUG-TAKING NATION.

In a series of articles in the *Medical Press and Circular*, Mr. Frederick Newcome gives an account of the Chinese materia medica, and makes a number of striking statements regarding the drug-taking capacity of the descendants of the Sun.

The Chinese are, he says, pre-eminently a medicine-making and medicine-taking people. At Hankow alone, one of China's nineteen open ports, over twenty million pounds of drugs pass annually through the foreign customs, besides a nearly equal amount of other substances used in drug manufacture. At most of the other ports medicines in the form of dried bulbs, roots, leaves, bark, and stalk, stand fifth or thereabouts on the list of imports and exports. At the port of Ningpo the trade in drugs of all kinds represents from one-third to one-half of the total commerce of this place. To all this must be added the immense quantity interchanged overland and conveyed in native-owned junks. There is hardly a herb in the Flowery Kingdom to which some medicinal property is not attributed.

The raising of medicinal plants, and manufacture of medicines therefrom, has thus become a separate and extensive industry, so much so as to make China the eighth wonder of the world in this respect. Moreover, this industry is yearly increasing.

Curiously enough, the Chinaman, although addicted to drugs, is, so to speak, a Thompsonian, and uses vegetable remedies almost exclusively. Mineral compounds are only employed externally, as a rule, and even mercury in syphilis is neglected, the opinion being that it will cause impotence or barrenness.

Another peculiarity of the Chinese materia medica is that, although so extensive, it apparently is quite different from ours. The Chinese do not even use, to any extent, such drugs as rhubarb, aloes, castor-oil, or ordinary camphor, although they raise and export them in large quantities. Concerning rhubarb, the Chinaman, while not employing it much himself, is profoundly convinced that it is an essential to European civilization, a bulwark indeed of the Christian social fabric. During the war of 1839–1840, the policy was seriously discussed of cutting off the exports of rhubarb, it being believed that the Europeans would then soon die of constipation.

Mr. Newcome enumerates somewhat over a dozen drugs which are particularly popular with the Chinese, and mentions many others widely used but whose properties are little known to Europeans.

Ginseng, naturally, heads the list. Despite European and American criticism it still holds its place in the affections of the celestial. Furthermore, the price of some varieties is enormously high, as much as five dollars an ounce being paid for the wild Manchurian variety. Millions of pounds sterling are spent yearly in its growth and purchase.

Mr. Newcome thinks that foreigners have not given it a fair trial; that the specimens raised in America or brought here and to Europe have been poor. This view takes some plausibility from the fact that there is a great difference in the quality of the plant in China itself. The popularity of the drug is certainly immense, and it may almost be said to form part of the daily diet of every well-to-do inhabitant.

Tangkuei is the name of a drug made from the roots of the *Aralia Edulis*, a shrub quite common in China. The annual consumption of it amounts to several million pounds a year. The annual exports at Hankow in 1880 were valued at $250,000. It is used in debility and in uterine disorders, but it seems to be nothing more than a cheap tonic.

Paichu is the forked roots of a species of distaff thistle. It is estimated that two million pounds of it are raised annually. It has, like most of the drugs described by Mr. Newcome, reputed tonic and stimulant effects.

Yüangshên, of which over a thousand tons are raised every year, is given to women after confinement as a stimulant to the mammary gland. It is also a tonic, but is used, in addition, in fevers, and in heart, lung, and kidney diseases. It is a kind of cheap substitute for the great panacea, ginseng.

Maitung is the tuber of a liliaceous plant, *Ophiopogon Japanicus*, and has reputed properties as a tonic and refrigerant. It is given as a remedy for vomiting, blood-spitting, dry cough, and lung diseases generally. In large doses it is narcotic.

Peium is the decoction of an herb, *Liliacea revularia*, which is highly esteemed as a safe cure for fevers, dysentery, internal hemorrhages, gravel, and bladder diseases. It is also used as a liniment.

Shengti, the roots of *Repinannia Chinensis*, is used by the physicians of Canton as a blood purifier and alterative.

Yuanho is also a blood-purifier and alterative, but in addition has astringent and sedative properties. It is thought to be of especial value in female disorders.

Yujon is a drug in much repute for worms, fevers, and especially as a stimulant to the sexual organs.

The above are examples of some of the more popular Chinese drugs. It would hardly be worth while to prolong the list thus given. The actual knowledge of their medicinal value, nevertheless, is slight. Almost every one seems to be either a tonic or a panacea.

There is plainly a fruitful field for medical study in China if the field can only be reached. The opportunity is particularly good for those who believe in empirical therapeutics. But the nihilist may also, if he chooses, draw from Mr. Newcome's statements some pleasing reflections, and for the latter's comfort, the fact may be mentioned that the Chinese, in common with the inhabitants of India, do not take to European medicines very enthusiastically, although they admit the superiority of our surgery. Are our drugs poor, or are theirs better, or are both equally bad?

At any rate, the Chinaman seems to be a drug-taking animal. We opine that he is driven to this habit by the fact, quite well attested, that he is under-clothed, under-fed, over-crowded, and altogether a sickly creature. And man seeks the apothecary, not because drugs are so potent, but because he feels so miserable.

THE HYPNOTIC VALUE OF CANNABIN TANNICUM.

Trousseau, in his "Treatise on Therapeutics," predicted such a future for hashish. Now, Dr. Fronmüller, of Fürth, asserts, in *Memorabilien*, July 21, 1882, that such a future is assured. Through the help of the chemist, Merck of Darmstadt, he has obtained a preparation of hemp, the tannate of cannabin, which he finds reliable, effective, and easy to administer. His description of the drug and of his clinical experiments with it are of interest.

The tannate of cannabin is a yellowish brown powder, insoluble in water or ether, slightly soluble in alcohol, and easily dissolved in water that has been made slightly alkaline. It has a taste like tannin, and a not unpleasant smell. In the distillation of hemp, two volatile oils are developed, cannabin oil and its hydrate. These are rapidly acting, irritant poisons. They are said to be removed in the preparation of the tannate.

In describing the dosage and practical use of the cannabin, Dr. Fronmüller states that he has used hemp itself considerably for thirty years, and that there has been a steady increase in the strength of the preparations furnished him.

Thus, thirty years ago, he began with a dose of eight grains, ten years later he had to reduce it to four, and latterly to two grains. The dose of the present preparation, the tannate, ranges between gr. ii. and gr. x., the most frequent dose being gr. v.

The drug was used fifty-seven times in hospital and six times in private practice. The patients consisted of twenty-one men and forty-two women, varying in age for the most part between twenty and forty years. Forty of them were suffering from phthisis, the remainder had different diseases, generally of a chronic nature.

The common symptom in all cases was insomnia, and it was for its hypnotic effect that the cannabin was given. Good results were obtained in thirty-seven cases out of the sixty-three, and moderately good results in fifteen cases. It was called a good result when quiet and uninterrupted sleep came on within an hour after taking the medicine, the patient awakening with no toxic after-effects. In twelve cases no result was produced. Many of the patients had been taking opium.

From the sixty-three trials thus reported, Dr. Fronmüller concludes that *cannabin tannicum* is a very useful hypnotic, powerful without being dangerous, and one which does not disturb the secretions or leave unpleasant toxic after-effects, if given in proper dose.

It is very probable that some of our American fluid extracts, now in the market, will secure about the same results as those obtained by Merck's preparation.

THE MORTALITY AFTER AMPUTATIONS IN CITY AND COTTAGE HOSPITALS.

In connection with the subject of cottage hospitals, which we discussed a short time ago, we call attention to certain facts reported in the *Medical Press and Circular* by Mr. Henry C. Burnett. This gentleman has undertaken to settle the long-mooted question whether the mortality after amputations in cottage hospitals is not less than that in large metropolitan hospitals. Some fifteen years ago Sir James Simpson wrote upon this subject and tried to prove that there was an excessive mortality in the large metropolitan hospitals, due to a condition which he described as "hospitalism." Simpson's views and statistics have been very vigorously criticised. Mr. Burnett's statistics, however, tend to sustain them. This gentleman sent circulars to one hundred and sixty cottage hospitals and obtained available replies from sixty-one. The cases of amputation thus collected numbered three hundred and twenty-six, and the mortality among them amounted to a little over seventeen per cent. On the other hand, the mortality from amputations in four large London hospitals, containing over one thousand eight hundred beds, was estimated by Erichsen to have been 37.8 per cent. The mortality in Parisian hospitals,

as given by Malgagne and Hussen, Holmes and Bristowe, amounts to sixty per cent. The mortality at Zurich between 1860 and 1867 was given by Bilt as forty-six per cent.

The lowest mortality rate after amputation in any of the hospitals referred to by Sir James Simpson was 34.4 per cent., while the highest rate was 47.3 per cent. Of the deaths which occurred in the cottage hospitals nearly one-half were from shock while five were from pyæmia.

Mr. Burnett's conclusion is that amputations done in cottage hospitals in the country are on the whole more likely to be followed by favorable results than those performed in the city. And he states that the country population is beginning to find this out, and to prefer the local hospital to the discomforts of a journey to the city, provided a choice can be made.

Our writer has collected his facts with great care and fulness, so that they deserve careful attention from those who would disagree with him. The most obvious criticism to be made, however, is that he has been dealing with the statistics of ten, twenty, and thirty years ago. Within a decade there have been changes in the surgical management of city hospitals and of wounds, little less than epochal. Comparative statistics are of slight value, therefore, if they go back more than five or ten years. It is a belief entertained very widely by metropolitan surgeons that a ward in a city hospital can be made as safe for most operations as if it were in the country. The history, for example, of what the late Dr. James R. Wood accomplished at Bellevue Hospital justifies such a view.

Taking the past fifty years, Mr. Burnett proves his point, but whether the mortality after amputations is now greater in large than small hospitals is quite another question, which remains open.

Schuylkill Water.—The Sanitary Committee of the Board of Health recently presented to the main body a report on the impurities in the Schuylkill River, which occasioned some alarm a short time ago. Examinations and analyses trace the trouble to an unusual chemical condition of the river water. The water was of a singular blue color, with an appearance of soap-suds, and the surface was covered with dead fish. This condition was caused by a superabundance of sulphuric acid from the coal mines of Schuylkill County. This is poured into the river at all times, but is usually neutralized by lime-water from the Maiden and Tulpehocken Creeks near Reading, the union of the streams forming sulphate of lime, which is precipitated upon the bottom. The precipitated sulphate of lime carried down with it to the bend of the stream the organic matter floating in the water, and as the fish sought this for food the sulphate stuck to their gills, producing mechanically death by suffocation.

Persian Insect Powder is made from pyrethrum flowers, and is said to be almost uniformly adulterated.

Reviews and Notices of Books.

La Sabbat des Sorciers. Par Bourneville et E. Teinturier. Bibliothèque Diabolique, pp. 45, illust. 25. Paris: Aux Bureaux du Progrès Médicale. 1882.

This is a curious work upon witchcraft. It describes the old ideas regarding this delusion. Many quaint and some questionable illustrations are inserted, all taken apparently from old works and executed in Middle Age style.

Transactions of the Medical Society of the State of Pennsylvania at its Thirty second Annual Session, held at Lancaster, May, 1881. Vol. XIII., Part 2. 8vo, pp. 893.

The State Society of Pennsylvania generally does very good work. The meeting of last year, the details of which are published in the volume before us, is no exception to the rule. The addresses are short, and, in the main, have much practical merit. The number of papers contributed is quite large. Those having a particular value are as follows: "Local Treatment of Inflammation of Cervix Uteri in Pregnancy," by Jacob Price, M.D., Westchester; "Extirpation of Ovaries for Insanity," by William Goodell, M.D., Philadelphia; "Diseases of the Ear in Locomotive Engineers," by Laurence Turnbull, M.D., Philadelphia; "Fractures in Close Proximity to Knee-joint, and Deformities from Fracture near the Elbow-joint," by Oscar H. Allis, M.D., Philadelphia.

Manual of Diseases of the Skin; with an Analysis of Eight Thousand Consecutive Cases and a Formulary. By L. Duncan Bulkley, A.M., M.D. New York: G. P. Putnam's Sons. 1882.

The little book before us embraces a concise account of the principal cutaneous affections met with in this country. The descriptions are well written and accurate. The principles of treatment advocated by the author are sound, and the work, as a whole, is superior to the foreign contributions of the same class that have of late appeared in the market. It is well worth its purchase-money.

A Curious Mode of Committing Suicide.—An inquest was held in the end of May upon a woman who had been a patient in the Hospital for Women, in Cork. She had been under treatment for endocervicitis for a month, and was about to be discharged, but it appeared she did not wish to go home; and at 6.15 one morning, she was found dead with part of a stocking protruding from her mouth. She had been seen at 5 P.M., by another patient, to rise and close the shutter, and return to bed, after which she had heard her moaning—not an unusual circumstance in a hospital. Dr. Cummins deposed that the woman died of suffocation, and he produced a very long stocking which he said he had taken out with the greatest difficulty, as it was very firmly fixed in the throat. The case is interesting medico-legally, proving what some have doubted, that persons may commit suicide by stuffing things into their throats, and doing so without making any disturbance likely to attract attention.—*Cor. of N. E. Med. Monthly.*

Reports of Societies.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, June 2, 1882.

DR. GEORGE F. SHRADY, PRESIDENT, PRO TEM., IN THE CHAIR.

THE paper of the evening was by DR. JAMES B. HUNTER, and was entitled

UTERINE AND VAGINAL DISCHARGES.

[The paper is reported in full on page 309.]

The subject being open for discussion,

Dr. James B. Hunter, in response to a question by Dr. Ball, regarding

CURETTING THE CERVIX,

said that he had often found granulations extending from the uterine cavity into the neck. He had curetted them with advantage.

DR. S. BRAYTON BALL said that he had thought that Dr. Thomas recommended such treatment in obstinate leucorrhœa. He had tried it several times with only palliative effect.

DR. GIBNEY referred to some cases of

LEUCORRHŒA IN CHILDREN.

He had been accustomed to meet several cases every year of sero-purulent vaginal discharges in children of two to six years of age. He had found them invariably in children of a strumous diathesis. In a few cases the patients had seat-worms.

A recent case was that of a delicate girl, five years old, suffering with acute synovitis of the knee-joint. He found after a week or so that she had a discharge from the vagina and had been using some astringent wash. Dr. Gibney put her upon calcium sulphide, gr. $\frac{1}{10}$ q. 3 h. At the end of a week there was no improvement. He then ordered warm and slightly carbolized injections. At last accounts she was not better. He had prescribed iron and cod-liver oil also. A little later the mother brought a second and then a third child suffering in the same way. He could find no cause.

DR. F. P. KINNICUTT had seen a number of cases of leucorrhœa in children, particularly in the Children's Department of the New York Hospital. They had in several instances been of a very obstinate character. The leucorrhœa was associated not infrequently with a strumous diathesis, but occasionally careful investigation had only revealed the presence of a large amount of uric acid in the urine. He suggested that the leucorrhœa might be due to the extension of a urethral inflammation, excited by this salt, to the vaginal mucous membrane. That a urethritis might be produced in this way there was no doubt. Moreover, a vaginal catarrh was of not infrequent occurrence in gouty women. In the gouty diathesis it is well known that the mucous membranes throughout the body are prone to take on an inflammatory condition. In other words, there was present in the diathesis both an increased susceptibility of the mucous membranes and an irritant (uric acid) capable of acting locally. In the cases referred to by the speaker there was marked irritation of the external parts. Examination of the urine showed a very marked uric acid condition, occasionally almost amounting to "gravel." Dr. Kinnicutt cited several cases in illustration, in which the leucorrhœa was pronounced, but of short duration. In his experience the leucorrhœal discharge, associated with the strumous diathesis, frequently persisted for weeks and even months. He had felt some doubt as to the propriety of local treatment in such cases, if it could be avoided.

DR. GIBNEY said that in his cases there was no uric acid in the urine.

DR. SAMUEL SEXTON had noticed that when patients suffering with aural affections experienced an exacerbation of co-existing uterine disease the aural trouble was very often temporarily worse. There was, he believed, an important reflex connection in such cases which very often complicated treatment.

DR. JAMES B. HUNTER, in reply to a question regarding

THE TREATMENT

of these discharges in children, said that he had generally found constitutional treatment and bathing of the external genitals sufficient. As a last resort he would certainly recommend injections.

DR. BEVERLY ROBINSON was inclined to lay less weight upon the diathesis in the cases under discussion. Local treatment was generally much more effectual.

The speaker referred to the fact that vaginal injections were more often used in Europe, and especially in France, as a mere matter of cleanliness, and he thought there was less leucorrhœa there than among American women in consequence. In the treatment of a vaginitis he suggested the probable advantages of cold rather than warm injections. In regard to the effect of the uric acid diathesis in producing leucorrhœa, he felt rather skeptical. It might be a coincidence. Irritations result also where there are large amounts of phosphates in the urine.

DR. HUNTER said he did not feel at all sure that leucorrhœa was more frequent in American than in French women. He had not used cold water injections because he believed them injurious, and had, indeed, seen bad effects from them. He said that in chronic cases he knew of no differential point. In acute cases the thick, creamy character of the discharge in specific vaginitis often enables one to distinguish it.

DR. C. L. DANA referred to the possibility of curing leucorrhœa, even when quite chronic, by constitutional measures. He thought that in young, unmarried women especially, local examination and applications made by the physician should be deferred to the very last resort. This was not always done by any means.

DR. HUNTER, in response to an inquiry, said

HORSEBACK EXERCISE

in persons suffering from leucorrhœa, even slight, was not a good thing as a rule. He had had occasion often to forbid its use, and with the best results. Dr. Sims had said, aphoristically, that no woman ought to ride horseback.

DR. DANA thought it made a great difference whether the woman was a good rider or not. Women who ride well and rise in the stirrups, according to the mode now in fashion, are not jolted.

The discussion being closed,

DR. GEORGE F. SHRADY related the history of an

OPERATION FOR REMOVAL OF A LARGE NASAL PHARYNGEAL POLYPUS,

illustrating the same by photographs, and by a skull, to the base of which a model of the tumor was attached.

[The case is reported in full on page 311.]

The subject being open for discussion,

Dr. Robert F. Weir said that he could add little to what Dr. Shrady had said. He thought with him that the great danger in such cases was from hemorrhage. Yet this could in most cases be guarded against. In future he should divide the operation into two steps. He would expose the tumor, ligate vessels, and stop the hemorrhage. He would then, after waiting a few days, finish the operation.

In these cases the hemorrhage is mostly venous, and it can be lessened by occasionally elevating the head and letting the blood escape from the mouth, as is done in cases where semi-narcosis is produced, or the patient should be placed in a semi-erect posture.

Dr. Shrady stated that it was impossible to have divided his operation into two distinct stages. Having started, there was no way but to finish as quickly as possible. He remarked that his patient's head was raised as high as seemed possible without seriously interfering with the rapid progress of the operation. He believed, however, that the position alluded to, when it could be employed, was a serviceable one, in moderating venous hemorrhages of the head and neck.

Dr. Sexton, in commenting on Dr. Shrady's case, alluded to the effect of such tumors on the organ of hearing; it was difficult to understand why deafness had not been induced by the growth in this instance. He related a case reported by Dr. Charles H. Burnett of a patient with a malignant growth (round-celled sarcoma) in the naso-pharynx where aural symptoms had appeared early. He thought an examination in these cases would nearly always show that some deafness existed. Judging from the photograph presented, Dr. Shrady's patient must have been compelled to habitually breathe through the mouth, owing to the interference with the physiological functions of the pharyngeal muscles and the mechanical closure of the naso-pharyngeal passages, which must have greatly interfered with intra-tympanic air-renewal. In such cases the membrana tympani would very likely be found greatly retracted, and the tympanic cavity more or less filled with retained mucous secretions.

At the close of the discussion the Society elected the following officers for the ensuing year: *President*—Dr. James B. Hunter; *Secretary*—Dr. Charles L. Dana.

Cystitis Treated by Urethrotomy—Fatal Case of Litholopaxy.—In Vienna I have seen nothing of especial interest recently in the clinical way, except two unpublished cases of Prof. Dittel's. In a case of very old and very obstinate cystitis, which had resisted all the usual therapeutic measures, Dittel made external urethrotomy in the membranous portion, introduced a catheter *á demeure*, and washed out with boracic acid solution. Within two months the patient went home with healthy urethra and bladder.

In a litholopaxy, last week, Dittel introduced the No. 30 catheter for washing out the bladder. Five days later there was thrombosis of the dorsal vein of the penis, soon followed by chills, and by gangrene of the glans. Patient (man of sixty-four years) is expected to die in a few days of septicæmia. This is, I believe, the first "*malheur*" that Prof. Dittel has experienced in nearly a hundred lithotrities.—*W. T. Belfield in Chicago Medical Journal and Examiner.*

Correspondence.

THE TREATMENT OF PILES BY DILATATION AND HOT WATER.

To the Editor of The Medical Record.

Sir: I have just read Dr. J. L. Powell's paper, in the last number of The Record, on the treatment of hæmorrhoids by dilatation and hot water irrigation, which, while I entirely approve of his method and admire his reasoning upon it, forestalls a paper I have been preparing on the same subject. I perceive if one would be first to give a new idea, he has no time to wait for numerous illustrations, for nature, like a politician, has a sly way of whispering the same secret to half a dozen in the same day in as many parts of the world.

To come at once to the point, I advised on March 5th, a patient, Mrs. W. H——, who was decidedly anæmic from hemorrhage from the rectum, occurring daily in large quantity, whenever the bowels were moved, and who was averse to rectal examination, to distend the rectum with as much hot water as it would contain, immediately after each natural evacuation from the bowels. She succeeded in retaining eight ounces daily, and at the end of ten days there was no further appearance of hemorrhage, but by advice continued the use of the hot water two weeks longer, and reported herself completely cured of what had been at times a frightful complaint. On March 31st, her husband consulted me regarding internal hæmorrhoids accompanied with bleeding. Iodoform suppositories were ordered at bed-time, a laxative enema in the morning, followed after movement from the bowels by the injection of eight ounces of water, as hot as could be borne. This was continued for a fortnight with entire relief to the troublesome symptoms.

April 2d, I ordered laxative enema, followed after movement with hot water injection, in the case of a carpenter, Mr. W——, who was subject to constipation with slight prolapsus ani accompanied with bleeding whenever the bowels moved. Eight ounces of hot water were injected and retained, and at the end of a month he was greatly improved, the hemorrhage having ceased, but he neglected further treatment, and I am not able to state his present condition.

June 5th, I directed the same treatment for Miss B——, who was weak from loss of blood occurring in the same manner as in Case No. 2. She soon began to improve and the hemorrhages entirely ceased at the end of eight days, but the prescription was persisted in a few days longer, and no further bleeding has occurred.

July 17th, I prescribed the same treatment for Mr. A——, who met with daily loss of blood when the bowels were moved. His, like the others narrated, was a chronic case, but yielded like the others, and I am told there has been no bleeding since the 1st prox.

There was no irrigation employed in any of these cases, as in that detailed by Dr. Powell, nor was any of them so bad as his, but the principle is much the same. A half pint of hot water was retained by each of these patients when the rectum was unloaded of fecal accumulation, and began to act at once on the mucous surface, constringe the hemorrhoidal veins, and exert that far-reaching influence

on the pelvic circulation Dr. Emmet speaks of. This it continued to do for some minutes before cooling to the natural temperature of the body, and it can be said of it in all the cases given that it answered the purpose intended; but for continued irrigation in graver diseases Dr. Powell's method presents greater advantage, though I cannot see that dilatation is necessary but in few cases, as an accompaniment.

In Dr. Kelsey's new work on "Diseases of the Rectum and Anus," just issued by Wood & Co., I see no mention of any such method of treatment, but I would strongly advise it before resorting to radical operations.

Very truly yours,
GEO. T. WELSH, M.D.

KEYPORT, N. J., August 14, 1882.

CHLOROFORM NARCOSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In their eagerness to furnish recent news to the secular press, some of the correspondents of the more extensively circulated newspapers seem not to think, nor to care much, whether the items they supply are likely to affect individuals injuriously or otherwise; and the utter recklessness displayed by some of them in giving rumors or unauthenticated intelligence to the public of a private character has given occasion to uncalled-for and unnecessary pangs of disquietude, if not unhappiness, to such persons as misfortune or accident expose to the rapacity of the newsmonger. This utter disregard of the consequences that might result from the publication of imperfectly understood accidents was strikingly illustrated in the case of a lady who is said to have died from chloroform narcosis in Charleston, a short while ago; and the injury arising therefrom might, and probably would, have proven injurious to the professional business of the gentleman in whose hands the accident occurred had not the South Carolina State Medical Society come promptly to the rescue of an honorable and deserving member thereof. I refer to the action taken by that enlightened body in the case of Professor R. A. Kinloch, M.D., of Charleston, under whose professional care the death of the lady alluded to occurred. Dr. Kinloch's attainments and professional reputation are too well known to require any vindication at my hands, and after a perusal of his clear and manly account of the unfortunate occurrence, as published in the MEDICAL RECORD of the 5th instant, I hazard nothing in saying that it would be difficult to find any physician, *deserving the name*, who would not cheerfully exonerate him from *all* blame in the premises. I have administered chloroform, in civil and military practice, in hundreds of cases, without the occurrence of a single death, and yet such an accident might take place in the very next case in which it is used. In this matter, Dr. Kinloch's professional brethren are almost as much interested as he is personally, and any word said in his behalf should be regarded as defending the whole profession, as all are liable to experience misfortune from the use of anæsthetics. I fully endorse the course pursued by Dr. Kinloch, and the justly distinguished Dr. J. Marion Sims, of New York, in reporting the accident from the agents employed by them, and believe that all deaths taking place under the use of such agents should be promptly made known to the profession through a medical journal, and by the physician under whose professional care the accident occurred, and in no instance should such cases be reported in a secular paper *first*, however well-informed and careful their editors or conductors might be. The reasons for this statement must be obvious to any person of ordinary intelligence and observation.

I am, very respectfully yours
HARVEY L. BYRD, M.D.

127 ARLINGTON AVENUE, BALTIMORE, September 2, 1882.

TRUMPED-UP LUNACY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your editorial of September 2d, under "Trumped-up Lunacy," interests me, as I was one of the physicians who examined Mr. Silkman.

His statement of my examination is incorrect. I spent one hour and forty minutes with the examination of him, and then formed my uninterested and unbiassed opinion of his mental condition. He was then under arrest. I had presented to me written statements, "sworn to," that he had repeatedly threatened the lives of his friends and children. He had sleepless nights; had an unnatural expression, was overworked, his mind was unsettled, and had attacks of desperation, he said caused by a physical ailment that gave him distress, pain, and interfered with his nutrition. Talked rapidly and incoherently, said he "would rather see his children in the grave than to have them provided for by his friends—that he then could communicate with them in the spirit world, as he had done with other deceased friends." He said he was an investigator and not a spiritualist.

I did not know that he was a member of the Land League until after he was in the asylum. Then, some people doubting his insanity, I wrote to the asylum, and Dr. Jocelin, Assistant Superintendent, replied, "that beyond doubt he was insane." He was transferred to Poughkeepsie, instead of Middletown, and Dr. Kellogg, the Superintendent of the Hudson River State Lunatic Asylum, testified that he did not then think he was insane, but he was on the *border line* of insanity. And repeated evidence came that he had threatened to blow up his children's house, and warned people not to go there; carried an outside window-blind to New York City and pasted verses on it and placed it near his brother-in-law's office to annoy him. Took the keys from his children's house and buried them in the yard to prevent the carpenters from completing the repairs.

I am sure there has been a change in the man from the past—refined and highly educated; to do this and other strange freaks is something more than madness. He has improved physically and, I hope, mentally in the asylum he so much abuses.

A. C. BENEDICT, M.D.

YONKERS, N. Y., September 5, 1882.

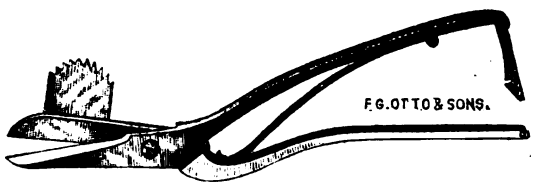
AN ERROR IN DIAGNOSIS.—A man treated for eight months in a hospital for chronic dysentery went home without being relieved. Believing that he had piles, he applied to a physician, who found no evidences of hemorrhoids, but, being interested in the pathology of dysentery, proceeded to explore the rectum, in which he discovered a number of fibrous bands and the original cause of the tenesmus and colitis—a piece of beef-bone impacted above the sphincter. Its removal gave immediate relief, and there was no further trouble.—*Practitioner.*

New Instruments.

PLASTER BANDAGE SHEARS-SAW.

By W. P. WATSON, A.M., M.D.,
JERSEY CITY, N. J.

This illustration conveys a good idea of an instrument, the use of which greatly facilitates the removal of plaster-of-Paris bandages. It consists of Henry's shears slightly modified, *i.e.*, made much lighter, less curved, and blades of equal length, with a convex saw-blade attached to the upper blade. As most of the sawing is done on the pull, the teeth



are pointed backward. In using this instrument in removing plaster bandages, I usually make two parallel incisions with the saw about one-third of an inch apart, on any convenient aspect of the dressing through the plaster to the muslin from end to end of the plaster. The strip of plaster between these incisions is easily removed by using the lower blade of the shears as an elevator, after which the muslin is readily cut through with the shears. The instrument is made by F. G. Otto & Sons, 64 Chatham Street, New York.

A NASAL ELECTRODE.

By F. H. BOSWORTH, M. D.,
NEW YORK.

In an article of mine on nasal catarrh in The Medical Record of June 10th, reference was made to a nasal electrode, for use in cases of catarrh attended with recurrent attacks of temporary stenosis of the nares, due to turgescence of the erectile tissue in the deep layer of the membrane covering the turbinated bones. This turgescence, I believe, to be due in part, at least, to lack of tone in the muscular coat of the venous sinuses. The accompanying cut

illustrates an electrode which I have found of value in these cases. It consists of a silver plate, A, inserted in a thin plate of ivory, B. C is an insulated flexible stem, terminating in a broad piece, into which the conducting cord, D, is inserted, thus doing away with the use of a handle. The electrode is inserted into the nostril with the metal side upon the turbinated bone, after which the circuit is closed by the patient grasping the sponge of the other electrode, or by applying the sponge to the temporal region. The current used should be the mildest possible, and should be continued about three minutes. The application may be repeated in four or five days. My experience has been entirely with the Faradic current, and has been a very favorable one, though the galvanic current may be equally valuable, and probably less painful.

The instrument was made for me by The Electro-Medical Manufacturing Co., 38 Union Square.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from August 27, 1882, *to September* 2, 1882.

Comegys, E. T., Capt. and Asst. Surgeon. Assigned to duty at Fort Supply, Ind. Ter. S. O. 174, Dept. of the Missouri, August 30, 1882.

Hubbard, Van Buren, Major and Surgeon. Orders to Fort Wingate, N. Mex., revoked. To report to Commanding Officer, District of New Mexico, for duty at Fort Stanton, N. Mex. S. O. 174, Headquarters Dept. of the Missouri, August 30, 1882.

Wakeman, William J., Asst. Surgeon. Assigned to duty at Fort Douglas, Utah. S. O. 91, Dept. of the Platte, September 1, 1882.

Some Sort of Systemic Poison.—Dr. W. S. Higgins, of Penfield, Illinois, writes: "In the first number of this year Dr. Ward has come very near accounting for so much malaria in altitude that excludes the theory of marsh poison, by attributing it to 'some sort of systemic poison.' I have long been convinced that the *economy generated poison*, when its functions were obstructed by cold damp surroundings sufficient to prevent free exosmosis of effete matter. The retention of that which should be deposited on the surface, sets up a terrible commotion—why not say a sort of *rotting* process begins. When decomposition of animal matter is sufficient to generate bacteria, 'systemic poison,' can we not readily comprehend the situation? To the thoughtful and inquiring mind a hint is sufficient."

The late Dr. James B. Reynolds, New York. —*Whereas* the Medical Board of the New York Foundling Asylum has learned with deep regret and sorrow of the death of Dr. James B. Reynolds, in the midst of his usefulness and in the prime of his manhood.

Resolved, That the board holds in the greatest esteem the remembrance of the active interest our late associate always took in promoting the welfare and prosperity of the New York Foundling Asylum, at one time its only medical officer; how well he discharged the laborious and onerous duties devolving upon him then, the good sisters can well attest.

Resolved, That as a citizen he was upright in all his transactions; as a friend he was supereminent in combining a suavity of manner with a noble and disinterested elevation of mind; as a husband and relative he discharged all the moral and social duties of life with a conscientious regard to affection and love; but as a professional brother and friend his sorrowing colleagues will long have to deplore the melancholy event which deprived them of the aid and counsel of so good and true a man.

Resolved, That we tender our warmest sympathy to the family of our late associate in their bereavement, and that a copy of these resolutions be sent to the family; also, that a copy be entered for preservation, as a minute, in the records of the Medical Board, and copies be forwarded to the medical journals of the city for publication.

J. Lewis Smith,
Joseph O'Dwyer,
Geo. F. Carey,
} *Committee.*

New York, August 31, 1882.

The Seamen's Retreat Hospital at Stapleton, S. I., long and ably conducted by Dr. C. Henry King, has been closed. All merchant seamen will now be cared for at the Marine Hospital, Bedloe's Island, and in the city hospitals. Dr. King has been appointed physician to Snug Harbor.

A Peculiar Medico-Legal Case occurred a few weeks ago in the Glasgow Royal Infirmary. A poor little boy, playing in a court, happened to sit down on a flagstone above a printer's shop. In the flagstone was an aperture, and some one in the shop passed a red-hot iron through this some inches into the boy's rectum. The injury resulted in death two days after. Two apprentices have been apprehended and committed for trial in connection with the affair.—*Cor. of N. E. Med. Monthly.*

Photograph of Small-pox.—In the Tenth Annual Report of the Board of Health of the City of Boston is a fine photographic representation of the typical umbilicated pustules of small-pox, taken on the eleventh day of the eruption.

Hot Applications for Heart-Failure.—A writer in the *Lancet* (Dr. Gill) advises, for heart-failure, the application to the chest of cloths dipped in hot water.

Syphilis by Skin-Grafts.—Another case in which syphilis was conveyed by skin-graft is reported by M. Féréol, in Paris.

The Circumanal Glands.—While operating for piles lately at the Soho Square Hospital, Mr. Reeves took the opportunity of demonstrating to the visitors present an affection of the circumanal glands, which is sometimes mistaken for fistula. The glands become the seat of inflammation, and get overdistended. A probe introduced through the small orifice shows that the cavity burrows for about half an inch in various directions. The best treatment is to slit them up and then to touch the exposed surfaces with nitrate of silver. Curiously, this small source of irritation is not described in any of the books on Surgery.—*Cor. N. E. Med. Monthly.*

Vaccination in Illinois.—Two millions of persons have been vaccinated in the State of Illinois during the last fifteen months. For this reason small-pox has made small progress of late in the State, the disease in the majority of cases having been confined to those first attacked.

Concerning Chewing-Gum. — A correspondent from Boston writes: "Noticing an extract from your columns in regard to the collection and use of chewing- (spruce) gum in Maine, I should like to state that a prominent manufacturer of petroleum products in this city told me some years ago that they sent most of their second class (*i.e.*, not dirty or impure, but softer) paraffine, to make chewing-gum for the Maine market. As he expressed it, they had a lecturer down there who had got every man, woman, and child in the State to using it. They were about to send him out West, and expected a demand for that region."

Carbolic Acid Treatment of Piles.—Dr. E. B. Fenn, agency physician for Sac and Fox Indians, Indian Territory, writes: "I notice in The Medical Record of July 20, 1882, an extract from the monthly report of the Southern Illinois Penitentiary, by Dr. H. Z. Gill, in which it was said a dozen cases of piles had been successfully treated by the hypodermic injection of carbolic acid, with enough glycerine to hold crystals in solution. The following treatment has been successful with me in every case: Take carbolic acid, ninety-five per cent. sol., fluid extract ergot, aa. equal parts. Inject from five to ten drops into each tumor, repeating the operation in a week or ten days if necessary. I have treated a number of severe cases of long standing in this manner, and believe it to be far better than amputating or ligating, because it is less painful, and unaccompanied with any danger whatever to the patient and is equally efficient."

American Academy of Medicine.—The next annual meeting of the Academy will be held at Philadelphia on Thursday, October 26, 1882, the council, under the authority vested in it by the by-laws, having deemed it expedient to postpone it until that date. It is very desirable, in the interest of the Academy, that the membership should be materially increased, so that its influence may be more widely disseminated and the objects of its institution more thoroughly accomplished. At the last annual meeting of the Academy the constitution was amended, so that those who have simply received the degree of A.B. *or* A.M. are now eligible to fellowship, and not, as heretofore, those only who had received the degree of A.B. *and* A.M.

Taking his own Medicine.—Dr. Smith, of Chelsea, Vt., lately prescribed for a patient, who soon after returned ailing more than ever, and suggested that the medicine was poison. Dr. Smith remarked that he had "just as lief take a pint;" so, putting the bottle to his lips, he drank half its contents. Then the doctor's head began to whirl, and he rushed to the drug-store for an emetic, which saved his life. It seems that belladonna had been put in by mistake. The patient was not seriously injured. Happily, there is not yet a vacancy for the waiting medical man. Moral—Medicine is for the sick.

Indications for the Use of the Bath. — "I think a bath daily would be beneficial in your case," said a physician to a patient. "Well, I don't know, doctor," he feebly replied. "I took a bath once, a year or two ago; I felt better for awhile, but it wasn't long before I was just as bad as ever, and I have been growing worse ever since." This is almost equal to the French medical writer, who objected to bathing, because it removed the natural secretions of the skin.

THE CHEYNE-STOKES RESPIRATION.—The phrase, Cheyne-Stokes respiration, means, of course, the kind of breathing described by Drs. Cheyne and Stokes. The first reference to the peculiarity was made by Dr. Cheyne so long ago as 1816. Dr. Stokes recalled this fact to the attention of the medical profession in his classical work on diseases of the heart and aorta, thirty years afterward. He also contributed some additional facts, and hence his name is rightly honored by association with Cheyne's in this suggestive phrase, Cheyne-Stokes breathing. The condition signified by this phrase is a peculiar irregularity of breathing, associated with certain morbid conditions. Not all kinds of irregular breathing can be so designated. Indeed, the term is already misused, and there is a growing disposition to include under it all kinds of breathing associated with irregularity and sighing. As described by Cheyne, and afterward enlarged upon by Stokes, the kind of respiration to which this phrase is properly applicable consists in the following phenomena: A pause in the breathing—a complete suspension in the respiratory acts for a period of time, during which breathing might occur several times in the normal manner; then the resumption of respiration very feebly and slowly, and a gradual and progressive increase in the number and depth of the respirations, until the maximum is reached; and then again a gradual and progressive diminution, in the same order, in the number and depth of the respirations, until a pause occurs. Thus the movements of respiration oscillate, from an extreme in which all the muscles are laboriously engaged, to a minimum in which the respiratory organs seem hardly to act at all, and then a period of repose or of apnœa of longer or shorter duration; to be followed again by the gradual rise to the maximum. During this time of cessation of breathing the arterial tension falls, the pulse quickens, the pupil contracts, there occurs a lateral conjugate deviation of the eyes, the face becomes pale, and the mind—the intellect and the general sensibility—are for the moment obtunded. On the other hand, during the period of maximum activity in the respiration, the arterial tension rises, the pulse slows, the pupil dilates, and more or less cyanosis of the face and extremities appears.

The morbid states with which Cheyne-Stokes breathing is associated consist of certain chronic affections of the heart and arterial system. Stokes laid much stress on it as a sign of fatty degeneration of the heart. It has been observed in cases of aortic insufficiency, especially when caused by the calcareous deposits of senility. The first case described by Dr. Cheyne was one in which atheroma of the vessels led to attacks of cerebral hemorrhage. Chronic arteritis, arteritis deformans, and cardiac lesions arising under the same conditions, are the chief factors. The irregularity of breathing which belongs to tubercular meningitis has been said to have the Cheyne-Stokes type, but there is merely distant resemblance—by no means identity. The irregular respiration occurring in the course of the nervous symptoms of chronic albuminuria approaches more nearly in characteristics to the Cheyne-Stokes breathing; but here again there is resemblance, but not identity.

Cheyne-Stokes breathing is of evil omen, as a rule. This view of its prognostic value is a necessary corollary from its pathogeny. Due to changes in the arterial tunics, which interfere with the normal supply of blood to the medulla, the respiratory centre functionates in a spasmodic manner. The special rhythm of the respiration, which it is the office of the respiratory centre to maintain, is, under these circumstances, perverted. The irregular evolution of the rhythmic force signifies the onset of fatal symptoms, for the damage done to the walls of the vessels must continue in an increasing degree to interfere with the circulation in the medulla. The numerous examples of irregular respiration, bearing a more or less close resemblance to the genuine Cheyne-Stokes breathing, have a prognostic importance determined by the associated and causative lesions.—*Philadelphia Medical News.*

THE GERMAN UNIVERSITIES.—This year's summer session has again witnessed an increase in the attendance at the German universities. The influx of foreigners also continues to augment. All in all there were 23,830 students regularly matriculated. This figure represents an increase of 8,711, as compared with the attendance of ten years ago. Of this number there belonged to Berlin, 3,900; Leipzig, 3,111; Munich, 2,017; Breslau, 1,532; Tübingen, 1,400; Halle, 1,377; Würzburg, 1,091; Göttingen, 1,083; Bonn, 1,061; Heidelberg, 922; Königsberg, 863; Strasburg, 823; Marburg, 766; Freiburg, 721; Greifswald, 659; Erlangen, 575; Jena, 570; Giessen, 435; Kiel, 381; Münster, 326; and Rostock, 236.

SIX MEDICAL JOURNALS are now regularly published in Japan. Surely the Japanese are becoming very much civilized.

THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.—We have received the announcement of the New York Post-Graduate School. It is now thoroughly organized with a corps of ten Professors, eight Associate Professors, and nine Instructors. The names of the Professors and their departments are as follows: James L. Little, M.D., Professor of Clinical and Operative Surgery; William A. Hammond, M.D., Professor of Diseases of the Mind and Nervous System and of Medical Electricity; D. B. St. John Roosa, M.D., Professor of Diseases of the Eye and Ear; Clinton Wagner, M.D., Professor of Diseases of the Throat; Henry G. Piffard, M.D., Professor of Diseases of the Skin; Frederic R. Sturgis, M.D., Professor of Diseases of the Genito-Urinary Organs and of Venereal Diseases; Montrose A. Pallen, M.D., Professor of Diseases of Women and of Operative Midwifery; Thomas E. Satterthwaite, M.D., Professor of Histological and Pathological Anatomy; Mary Putnam Jacobi, M.D., Professor of Diseases of Children; Edward C. Spitzka, M.D., Professor of Medical Jurisprudence and State Medicine. The list of Associate Professors includes the well-known names of Dr. W. J. Morton, Dr. W. H. Porter, Dr. S. M. Roberts, and others. The Faculty announces that it will endeavor to make available the vast mass of clinical material which this city affords. There will be didactic and clinical lectures, and also laboratory work. The college building is that of the College of Pharmacy, conveniently located on East Twenty-Third Street. There will be three courses of seven weeks each during the winter. The price of tickets for each series of lectures will be $20. The lectures begin November 6, 1882.

THE YELLOW FEVER EPIDEMIC.—The epidemic continues in about the same degree of severity at Brownsville, Texas. From fifty to sixty cases a day are reported. Fortunately, the death-rate is very

low. At Matamoras there are but few cases. The disease has increased at Pensacola, Florida, and is now epidemic there. From eight to ten new cases are reported every day. The inhabitants have been obliged to appeal to the country for aid.

Death of Medical Inspector B. F. Gibbs.—Medical Inspector Benjamin F. Gibbs, of the United States Navy, died last week, at Trieste. He was born in New Jersey. He entered the navy November 12, 1858, as Assistant Surgeon. In 1877 he received his commission as Medical Inspector, the rank he held when he died. His death promotes Surgeon Edward S. Bogert and Passed Assistant Surgeon John C. Wise.

Drug Store Profits.—An out-of-town druggist entered one of Boston's apothecary stores and handed a clerk a simple recipe. "One dollar and fifty cents," said the latter as he handed the medicine over. "Isn't that pretty steep?" asked the customer, adding, "I'm in the business myself, and know somewhat about the cost of these ingredients." "Oh! that alters the case," was the response; "seventeen cents, please."

Iodine Injections in Lymphoma.—Dr. Karl Körbl (*Wien. Med. Woch.*) records twenty-three cases of lymphoma treated by subcutaneous injections. He tried Fowler's solution, carbolic acid, iodoform, etc., for this purpose. Latterly he has used tinc. iodi, and injects into the most prominent part of the swelling a sufficient amount to cause distinct tension. This is followed by much swelling and pain, but by the third day these are nearly gone and massage is then practised. The injecting is to be repeated as may be required.

Faith an Essential Element of Success in Practice.—Dr. Fothergill, in referring to this subject, utters some very sensible remarks. There is no doubt that many physicians make the most lamentable failures on account of their want of faith in therapeutic measures. The effect of the mind on the body is well known, and when the patient sees a lack of confidence in the physician, he is depressed thereby, and the condition is made worse, instead of better. One of the most successful practitioners in one of our Western cities attributes his success in great measure to the faith he himself has in the effectiveness of drugs properly administered, and the confidence that his faith inspires in his patients. Dr. Fothergill says: "If the medical man speak to the patient with doubtful accents and hesitating utterances, he does not inspire confidence; he really sows distrust. This is the explanation of the successful treatment of a case by one man where another has failed, the remedial measures being much the same. The one carries the patient with him to the restoration of health; the other intensifies a morbid state and tends to make it permanent.

"This is a matter too little thought about. Just as a weak-willed medical man fails to do certain patients good; and lack of decision of character unfits a medical man for dealing with emergencies, where the judgment must be prompt and the action energetic; so the therapeutic nihilist, who doubts the efficacy of drugs and leaves the patient to nature, disheartens many patients, and leaves them chronic valetudinarians; while in the hands of an enthusiast the cases would soon move onward to a satisfactory termination. There are some men who are 'doubting Thomases;' there are others who decry what they do not understand, and deprecate remedies with whose potency they are unacquainted, who do infinite, immeasurable harm to their patients. An eclipse of faith in medicines has now existed some time; but the darkness is beginning to move away, and a return of faith, stronger, firmer, more capable of giving a *raison d'etre* for its existence than in the past is dawning—the daybreak of happier times for those who are stricken down with illness, or crippled in their working power by incapacity in their digestive viscera. This therapeutic nihilism is a passing wave of opinion, a temporary mental state, the end of which is at hand; and the sooner it is over the better for all. The patient's prospects will be all the brighter, the medical man all the happier for feeling that the patient has got some 'value received' in return for his outlay. A healthier condition of thought on matters medical will generally obtain; for quacks, charlatans, and irregular practitioners of all kinds are to a great extent fostered by the recent want of faith in the medical profession. When a man is sick, what he wishes is to get well; the means to him is a matter of comparative indifference."

Removal of Plaster-of-Paris Bandages.—Dr. F. H. Murdock, of Bradford, Pa., says: "A very convenient way to move a plaster-of-Paris bandage is as follows: Take a strong solution of nitric acid, and by means of a camel's-hair pencil paint a strip across the bandage at the most desirable point for division. The acid will so soften the plaster that it may be readily divided by means of an ordinary jack-knife."—*Nashville Journal of Medicine and Surgery.*

College of Physicians in Ireland.—Two important appointments in the gift of the Fellows were recently filled, viz.: the King's Professorship of the Practice of Medicine, and the Professorship of Midwifery in the School of Physic of the University of Dublin. Dr. J. Magee Finny, a graduate of medicine of Trinity, was elected King's Professor of Medicine. For the chair of Midwifery there were six candidates—Dr. J. Rutherford Kirkpatrick being successful.

For Toothache a saturated solution of chloral hydrate in glycerine is recommended.

Venesection.—Dr. Fordyce Barker advocates greater frequency of this now nearly obsolete measure. He is convinced that in certain cases it is essential to bleed the patient, and that life may be saved thereby.

Hofrath Franz Ritter von Skoda, in memory of his deceased brother, Professor Dr. Joseph Skoda, has just presented to the Burgomaster of Vienna the munificent sum of 20,000 Austrian florins as a contribution to the Charitable Fund.

A Heavy Brain.—Dr. Halderman, of Columbus, is responsible for the following (*Cincinnati Lancet and Clinic*, July 22, 1882): "The subject was a mulatto man, named Washington Napper, aged forty-five, who died recently in St. Francis Hospital, this city, of blood-poisoning, induced by abscess of the thigh. He was a native of West Tennessee, and was a slave till 1862, when he deserted his master and afterward came North with the Forty-Sixth Ohio Infantry to this place, which he made his home until the time of his death. His brain was found to weigh sixty-one ounces. He was about six feet in height, and of rather ungainly build; had long, ape-

like extremities, massive head, and coarse physiognomy, thick lips, protuberant lower jaw, high cheek-bones, but lofty and expanded frontals. He was never regarded as of much intellectual brightness, but is spoken of as having been of rather reserved and thoughtful disposition; and, later in life, to have become of quite a moral and religious turn of mind. He was illiterate, but managed, by industry as a common laborer, and by close economy, to accumulate some little property, which, on his death-bed, he bequeathed to his church and to the Sisters of the Poor, in return for their care of him during his fatal illness. It will be observed that but two brains, whose weight are credited by scientists, are on record heavier than this, namely, those of Cuvier and Abercrombie: the former, as is well known, weighing 64.33 ounces, and the latter, 63 ounces. So that if, as is held by some, intellectual greatness lies in the quantity of brain substance alone, who knows but with this man passed away another whose—

> 'Hands the rod of empire might have swayed,
> Or waked to ecstasy the living lyre?'"

Muriate of Pilocarpin in Diphtheria.—Dr. Franklin Townsend, of Albany, N. Y., writes: "I almost feel it incumbent upon me to report, through the medium of your excellent columns, seventeen cases of diphtheria, occurring during the months of April and May last, in my practice among the children of the Babies' Nursery of Albany. The treatment adopted, and persevered in throughout the whole number of cases, was that as recommended by Guttmann only a few years ago, and which has now become so well known by the profession. I refer to the use of the muriate of pilocarpin.

"Five of the seventeen cases that came to my notice were exceedingly malignant and severe, the nasal mucous membrane, as well as the post-pharyngeal wall and soft palate, being deeply involved by the diphtheritic exudation. The remaining twelve cases were also more or less severe, but the diphtheritic deposit here simply implicated the pharynx and soft palate. Out of the whole number infected, only *one* died; this being one of the five cases, where the nasal mucous membrane was involved by the morbid process.

"That the little ones were suffering from diphtheria there can be no doubt, I think, as several prominent medical gentlemen saw many of the cases with me in consultation, and were able to confirm the diagnosis. From this experience, small as it undoubtedly is, but made comparatively large, when coupled with that as already published by others, I fain would take the liberty of urging upon the profession the propriety of testing further the utility of the muriate of pilocarpin in this much-dreaded disease before its condemnation becomes a matter of course."

Bearded Infant.—The *Tiempo*, of Valencia, notes the birth of an infant with a well-developed beard and a full set of teeth.

Deformity of the Middle Ear.—Dr. Samuel Sexton describes a malformation of the sound-transmitting mechanism of the middle ear in the *American Journal of Otology* for October, 1881. These anomalies, which seem to have been studied with much care, serve to explain the origin of some of the more obscure and intractable cases of deafness so common in early life. The defect consists in a perverted development of the membrana tympani and the consecutive displacement of the ossicles, especially of the malleus and incus. The membrane's anomalistic position is emphasized by the unusual position of the manubrium, which is found to be deflected upward and to lie somewhat parallel to the posterior fold of the membrana flaccida. Owing to these misplacements the membranous structure lying above the malleus handle is thrown into two or three folds which radiate, fan-like, from the short process of the malleus. Behind these folds the long process of the incus is frequently seen.

Viewed as a whole, the entire upper segment seems to be thrust outwardly by the malposition of the malleus, whose prominence is increased by the displacement. The unusual prominence of the short process especially gives the membrane the appearance of being raised above its normal plane and produces the folds alluded to. Lesser folds are formed in the same way—by the stretching of the membrana tympani over the malleus—which for the most part extend anteriorly.

The retracted inferior segment is also frequently relaxed, and the malleus handle, besides its deflection in the direction described above, is more or less foreshortened. The frequent coexistence of chronic catarrhal inflammation of the middle ear in these cases nearly always gives the membrane a characteristic appearance.

Dr. Sexton, in seeking for an explanation of this very common deformity in the ears of young people, first gave his attention to the natural conditions which influence the development of these parts: it is well known, he says, that the membrana tympani requires the presence of air on both its external and internal surfaces for its development as well as for the performance of its functions. The tympanum, comprising the superior terminus of the air-passages, may be considered to be as dependent for its development on a normal air-supply as the pulmonary structures themselves, and when, therefore, from any cause during the developing period of childhood, the usual intra-tympanic air-renewal fails, an anomalous development of the conductive mechanism ensues. And it is not difficult to see how this takes place, since at birth the membrana tympani lies in an almost horizontal plane and is immovably attached to the annulus tympanicus which, it should be borne in mind, develops *pari passu* with it. Now, while the circumference of the tympanic membrane gradually assumes its more perpendicular aspect, the unresisted atmospheric pressure upon its external surface depresses it toward the inner wall of the tympanic cavity.

While development is proceeding under these unfavorable conditions, traction is in the meantime kept up by the membrane until the malleus handle is diverted from its articulation with the unyielding os temporis to a greater or less degree. In the ensuing deformity the incudo-temporal and malleo-incudal articulations are also liable to be more or less affected.

As regards the causes which prevent intra-tympanic air-supply, the author mentions among others the structural changes which interfere with the physiological movements of the pharyngeal muscles, or offer a mechanical obstruction to the entrance of air into the guttural mouths of the Eustachian tubes. Such causes include chronic nasal catarrh and its consequences, and enlargement of the tonsils. Chronic catarrhal inflammations of the middle ear, and of the Eustachian tube also exert a certain influence in these cases. Indeed, any interference with normal respiration which induces

habitual mouth-breathing prevents intra-tympanic air-renewal, since this is accomplished by the gentle tympanic inflation which takes place during the expiratory act; its withdrawal being brought about by the succeeding act of inhalation.

The author believes that this perverted development during the transition period of early life is of very common occurrence, for he has found the characteristic changes above referred to in the tympanic membrane of children at a very early age, even before it was practicable to estimate with accuracy the degree of impairment of hearing. The deformity very often incapacitates children very much as regards their early acquisition of language; and where the tympanum of the newly born has never been aërated, the ear is entirely deprived of the service of its sound-transmitting mechanism, and deaf-mutism results.

Fortunately, however, deafness is not invariably complete in these cases, and improvement may naturally be looked for in certain instances where the causes disappear with advancing age or by means of treatment. The characteristic disfigurement remains, however, in most cases, a permanent feature, and moreover it is usually found in both ears.

It is in some of these cases that forcible inflation of the tympanum distends the much-relaxed lower segment of the membrana tympani, drawing the malleus handle outward and downward, and thus putting the transmitting mechanism in a more favorable relation for the transmission of sound, that such marvellous, but temporary, improvement in hearing is accomplished.

Centenarians.—There are three hundred and fifty-nine persons in Prussia who are over one hundred years old. Of these one hundred and twenty-eight are men, two hundred and thirty-one women. Only twelve men and nine women had been unmarried.

Some Facts Concerning Leprosy.—We are in receipt of the Board of Health Report, published at Honolulu, for the biennial period ending March 31, 1882. It contains an interesting account of an official visit made by Dr. Emerson to the leper settlement at Kalawai Molokai. In his report the writer briefly considers some of the theories and views in regard to the nature and sanitary management of leprosy. The assertion that leprosy is but a fourth stage of syphilis, he holds to be unsubstantiated by any medical authority whatever. Historically the former antedates the latter by centuries. Neglected and untreated syphilis is common enough, but it never runs into leprosy. Syphilis produces only syphilis, leprosy only leprosy. Again the latter appears in groups, affecting families and people living together; it does not occur sporadically. In order to satisfy the condition of the "fourth stage" argument, it must be clearly proven that every leper was first syphilitic, and that none but those having syphilis in the advanced or third stage have shown leprosy, the so-called "fourth stage." There are, however, many cases of uncomplicated leprosy among the Hawaians who have been and are free from syphilis. Owing to a want of distinction on the part of the natives between a simple venereal sore and a true chancre, a Hawaian will be likely to say he has had syphilis (kaokao, or pala), when he has merely had a non-syphilitic venereal ulcer. On the theory of "hereditary immunity" of Erasmus Wilson, the Hawaians who have had a century of syphilis, ought by this time to have purchased some amelioration in the disease. As leprosy, however, is vastly more severe and stubborn than any stage of syphilis, the "fourth stage" doctrine seems illogical. The writer then indicates some of the points of differential diagnosis between leprosy and syphilis. Too much emphasis, he continues, cannot be put on the fact that leprosy is a contagious disease, or at least capable of communication from the leper to the well person. The germs lie latent for many years; but at length they produce a crop, and they finally kill. "Our whole theory of leprosy rests incontestably on a sad fact," write Danielson and Boeck, "it is that within the bounds where it commits its ravages, it can be made harmless to the rest of the people only by isolation." Experiment with any other theory than this is dangerous. The victims among the white people are few because, firstly, the latter are more careful than Hawaians in their choice of companions, and secondly, because the whole number of whites in the country is comparatively small.

Registration of Midwives.—A bill is to be brought into the English Parliament by the General Medical Council, providing for the registration of midwives. There are over ten thousand women in England practising as midwives.

Unhealthy Seaside Resorts.—The consternation excited at Seabright, recently, by the appearance of typhoid fever at one of the hotels, has had a parallel at Brighton, England. The *Lancet* announced one week that the place was unhealthy, the drainage bad, and that visitors were in constant danger of blood-poisoning. Much alarm was excited; many persons left, and the hotel trade was so much injured that a suit has been brought by the town authorities against the *Lancet* for damages. Investigation hardly confirms the statements of the *Lancet*, although they undoubtedly had some foundation.

Dr. Chiéne has been appointed Professor of Surgery in Edinburgh University, in place of the late Prof. Spence. The appointment is received with considerable criticism. It is thought in some quarters that the best man was not selected.

Arsenic and Iodine in Intermittents.—Dr. G. N. Jennings (*American Medical Weekly*, July 22, 1882), says that he has had the best success in intermittents with equal parts of tincture of iodine and Fowler's solution, given in ten-drop doses after meals.

Very Much Behind.—Although it is now a year since the International Medical Congress was held, some of the German and French journals have not yet finished filling their columns with the proceedings.

A New Function for the Cerebro-spinal Fluid.—Dr. Bechterew, of St. Petersburg, has made experiments upon dogs, in which he removed the cerebro-spinal fluid from the third ventricle. He is of opinion that this fluid, circulating in the third ventricle and aqueduct of Sylvius, has a function in preserving the equilibrium. It acts similarly, he thinks, to the fluid in the semicircular canals.

Bromism in a Nursing Child.—Lowry reports a case (*Gaz. des Hôp.*) of a woman who, while nursing an infant, was taking gr. xxx. potassium bromide a day. The infant speedily emaciated, became anæsthetic, and showed signs of potash in the urine. On removing the child from the breast it speedily recovered.

Original Lectures.

LECTURE ON HÆMATURIA.

By ALEX. W. STEIN, M.D.,

SURGEON TO CHARITY HOSPITAL, ETC., NEW YORK.

Hæmaturia, or the passage of blood with the urine, is a symptom common to a variety of diseases affecting the urinary apparatus, and it is often a matter of considerable difficulty to determine the source and cause of such a loss of blood. I cannot lay down any fixed rules that shall invariably serve you in making a diagnosis, but I believe that a careful notation of the history and symptoms, together with the chemical and microscopical examination of the urine, with certain manipulations to be mentioned, will, in the majority of cases, enable you to come to a satisfactory conclusion relative to the nature of the case. Hemorrhage from the urinary apparatus may assume one of three forms, viz.: 1, hæmoglobinuria, or the escape simply of the coloring material of the blood with the urine; 2, parenchymatous hemorrhage, or capillary oozing of blood; 3, free hemorrhage from rupture of large vessels. In examining a case of suspected hæmaturia the questions which will naturally present themselves to you are: 1st. Is it a case of hæmaturia? 2d. From what point of the urinary apparatus does the blood come? and 3d. What is the cause of the hemorrhage? In deciding the first question you must know that a peculiar coloration of the urine, not unlike that indicating the presence of blood, may be produced from various causes. The internal administration of rhubarb, santonine, senna, logwood, and various other substances will, under certain circumstances, impart a color to the urine easily mistaken for blood. In order to impress this fact upon your mind, let me give you a simple illustration. Here is a sample of urine passed by a patient in Ward 9, this morning, to whom was administered last night one ounce of the syrup of rhubarb. It has now a clear amber color, and litmus indicates its acid reaction, but if I add a little aqua ammonia, so as to render the urine distinctly alkaline, the whole strikes a purplish red color. If once more I change the reaction by a few drops of acid, the urine again assumes a natural amber tint. You thus learn that to alkaline urine rhubarb (and other substances) lends a coloration which might at first sight be easily mistaken for blood, and as this mistake has been repeatedly made, I guard you against it by reminding you that associated with bladder disease, in which you might naturally expect hæmaturia, you very commonly have an ammoniacal condition of the urine, and it is important to question the patient whether he has taken for food or medicine anything which is likely to produce this change of color, and it is always well to resort to the acid test, which will at once indicate whether the coloration is due to some vegetable coloring material or to blood. If it is the latter, no change will be effected, but the addition of the acid in coagulating the albumen, which is always present in some quantity with blood, will confirm your diagnosis. Generally, however, bloody urine is characteristic enough, if it is not so to the unaided sight the microscope will set aside all doubt, for it is only in hæmoglobinuria that the blood-corpuscles are absent. and then we have to resort to the special tests for hæmoglobin. The spectroscope, you know, is unerring in detecting the smallest quantity present. Bloody urine varies in color from a bright red to a reddish-brown, dirty or smoky hue, all depending upon the quantity of blood present, and the length of time it has remained in contact with the urine. In hæmoglobinuria the urine is always of a smoky or brownish color, and so it may be also in parenchymatous or capillary hemorrhage. This is due to the deoxydizing influence which the urinary constituents exert upon the red oxyhæmoglobin, converting it into a brown methæmoglobin. This conversion can only take place when the escape of blood is very gradual, or the corpuscles have remained for some time mixed with the urine. Parenchymatous hæmaturia may, however, be distinguished from hæmoglobinuria by the presence of red corpuscles. These can always be found in large numbers under the microscope, although the destructive influence of the urine upon them is manifest not only in the change of color, but also in the change of shape, size, and general appearance. In order to appreciate how much blood or rather how little blood is sufficient to bring about the changes of color mentioned, let us take an ounce of urine and add one or two drops of blood, you observe that almost immediately the fluid takes on a dingy, smoky hue; if we add eight drops. it already becomes a deep cherry-red, while the addition of from twenty to twenty-five drops renders it indistinguishable in color from the pure blood contained in this bottle. So you see very little blood shows for a good deal. Allowing these glasses to stand for a short time, you will note the metamorphic influence of the urine on the corpuscles, especially on this last specimen, in changing color from a blood-red to a dark brown.

The next question, often a perplexing one to answer, is, from what point of the urinary apparatus does the blood come? This will involve the following considerations: 1, time of appearance of blood in its relation to micturition; 2, color of the urine and quantity of blood it contains; 3, appearance of coagula; 4, results obtained from certain instrumental manipulations.

In regard to the first, (*a*) blood may flow during the intervals of micturition; (*b*) it may appear at the beginning and again at the end of micturition (very rarely); (*c*) it may appear only at the end of micturition; (*d*) it may appear at the beginning and remain uniformly mixed with the urine to the end. When blood flows from the urethra during the intervals of micturition it does so from some portion of the canal anterior to the compressor urethræ. The source of the hemorrhage is made out from the fact that the blood flows continuously or can be made to flow from some portion of the canal by pressure, or else the blood coagulates in the urethra and remains there until washed out in thread-like or worm-like coagula with the first gushes of urine. The diagnosis of hemorrhage from the anterior urethræ rarely presents any difficulties, and inasmuch as the blood is not passed with the urine, excepting as it is washed out from the urethra, it does not properly belong to the subject under consideration. The question of greater interest is the recognition of the hemorrhage, as it may come from behind the compressor urethræ and between it and the vesical sphincter; second, from the vesical neck; third, from the interior of the bladder; and fourth, from the kidneys. Blood issuing from the prostatic sinus rarely escapes at the meatus during the intervals of micturition, it may coagulate, or some portion of

blood may enter the bladder, though this, too, is exceptional; the urine may contain blood at the beginning and again at the end of micturition, or more commonly a few coagula appear with the first urine, and bright blood with the last. Characteristic of hemorrhage from the vesical neck is the markedly bloody appearance of the urine that comes with the last expulsive act of the bladder, this may be differentiated from prostatic hemorrhage in that in the latter case catheterism will give issue to clear urine.

The differential diagnosis between vesical and renal hemorrhage is sometimes especially difficult. In all obscure cases our conclusions will rest chiefly on the evidence, symptomatic and physical, to be obtained of disease of the bladder or of the kidneys, respectively, and on the evidence furnished by the urine after careful examination, as to its reaction, specific gravity, color, appearance, and shape of coagula, presence of renal casts, pus, or other products of disease.

When the hemorrhage proceeds from the kidney, the urine is usually of a smoky or of a brownish hue, and of an acid reaction, while urine of florid red color, with alkaline reaction, is more indicative of vesical hemorrhage. The first condition of urine indicates a hæmoglobinuria, or at most a parenchymatous hemorrhage, the forms of hemorrhage most frequently met with as coming from the kidneys; the blood oozing from the vessels at once mixes with the excretion, and the urinary constituents have ample time to effect a reduction of the red oxyhæmoglobin into a brownish methæmaglobin, and as the quantity of effused blood is small, its alkalinity is insufficient to effect the normal reaction of the urine. The blood-red urine is significant of rupture of larger vessels, a condition more commonly met with in vesical hemorrhage. Here the blood, being poured out in large quantities, its presence occasions a stimulus to expulsion before the urine has had time to effect its metamorphic influence upon the corpuscular elements of the blood, and the urine retains its blood-red color.

Nevertheless, you cannot rely on the color of the urine alone as a diagnostic sign; it is only a presumptive evidence of the seat of trouble, for the smoky urine may result from a scanty parenchymatous hemorrhage from the bladder, while the bright red urine may represent a free hemorrhage from the kidneys.

In the parenchymatous variety, the blood diffuses itself so thoroughly with the urine that no coagula are formed, but in free hemorrhage the examination of the clots, as to color, consistence, shape, etc., furnish most important data for diagnosis. If the hemorrhage has been recent, the coagula will be soft, and of a dark red color, but if the time of its occurrence is more remote, and the coagula have consequently remained longer in contact with the urine, they will have a firmer or fibrinous consistence, and will appear fleshy or colorless. A soft, reddish, shapeless, coagulum affords little information as to the source of the bleeding; the hemorrhage may be vesical, but it may also be renal, for the blood may flow in a fluid state into the bladder, and coagulate after it gets there, but often the coagulum assumes a definite and characteristic shape, taking the impression of the cavity in which it is formed, and then it becomes an element of the greatest value in diagnosis. If, for example, you find long, cylindrical, or worm-like coagula, and you are at the same time certain that such coagula have not been formed in the urethra, you may be equally certain that the point of hemorrhage is above the bladder, from the pelvis of the kidney, or from the substance of the organ itself, and that the blood in descending has coagulated in the ureter, and represents the cast of that tube. Such clots, too, in their transit toward the bladder, are apt to occasion symptoms not unlike those due to the passage of a renal calculus. If, added to these signs, the microscope reveals blood-casts of the uriniferous tubules, the evidence of renal hemorrhage is complete. In examining a mass of clot always put it in water, let it float and unravel; by so doing, you will get a better idea of the shape and character of the original cast. If the hemorrhage has been intermittent, the clot will appear stratified, layer after layer peeling off in the water. Bladder clots are irregularly shaped, flattened masses, bevelled off and fimbriated at their edges. Prostatic clots often assume the ovoid configuration of the cast in which they are moulded, while those formed in the urethra, anterior to the prostate, are long and round.

In making a diagnosis as to the source of the hemorrhage, you must look, I repeat, to the subjective as well as to the objective signs, and consider the circumstances which are well known to produce bleeding at the different localities of the urinary tract. But if you are still in doubt as between vesical and renal hemorrhage, take a full-sized flexible catheter, introduce it gently and just far enough to draw off the urine. then wash out the bladder with a few ounces of water, and repeat this several times; if the water so injected comes away each time tinged with blood, you conclude that the hemorrhage has its origin in the bladder; if, on the contrary, after the first washing, it comes away clear, the inference is that it does not come from the bladder. Again, having washed out the bladder, you allow the catheter to remain for a few minutes, the urine trickling from the ureters will escape at once by the instrument, and if the urine so collected appears bloody, you have a pretty positive assurance that the source of the hemorrhage is beyond the cavity of the bladder.

In looking for the source of the bleeding, you will, in the majority of cases, discover the cause. Renal hæmaturia results from traumatism in all conditions of hyperæmia, as during the exanthematic fevers, in acute nephritis, or as produced by overdoses of cantharides, turpentine, and other drugs. In purpura and scurvy, and from parasites, tumors, calculi, etc. Among the more common causes of vesical hæmaturia may be mentioned injuries of any kind, vascular and malignant growths, presence of heavy, rough calculi, passive congestion, determined by too rapidly evacuating a greatly distended bladder, inflammation, ulcerative, tuberculous, diphtheritic and croupous. These affections express themselves generally in well known and unmistakable symptoms. Hæmaturia is sometimes vicarious to the menstrual flow. A varicose condition of the veins at the neck of the bladder is occasionally the source of free hemorrhage. This condition, although not very common, presents itself in persons subject to hæmorrhoidal affections, one condition supplementing the other, the dependent position, abundance and close relationship of the vesical plexus of veins at the neck of the bladder with those of the rectum account for this. Hemorrhage from this source is apt to occur at intervals of from a year or more to one or two months or oftener; it comes on suddenly without any apparent cause.

There is an absence of all symptoms or physical signs of disease of the bladder, or of any portion of the urinary tract. The patient feels well, unless the hemorrhage is free or too frequent, when he may become decidedly anæmic and exhausted.

Langier (*Gaz. des Hôp.*, No. 81, 1854) mentions a case in which the bleeding was so profuse as to cause death. At the autopsy large varices were found at the neck of the bladder, upon one of which was a large ulcer. In other respects the bladder was perfectly sound. A similar case occurred in our Workhouse Hospital, Blackwell's Island, not very long since. Dr. Marie Vogtlin (*Wien. Med. Woch.*, 1879) reports an interesting case of a large varex projecting from the posterior wall of the bladder at the point of junction with the urethra, the exact point with which the cervix of an excessively retroverted uterus had been in contact, interfering with the circulation and causing distention and final bursting of the vesical veins. A large Hodge (ring) pessary was applied, after which no further trouble ensued. Endemic hæmaturia, so-called, is a remarkable form of hæmaturia occurring chiefly in Egypt, at the Isle of France, Mauritius, Brazil, and at the Cape of Good Hope. It is due to the presence of a minute parasite known as the Distomum hematobium, or the Bilharzia hematobium, a name given to it in honor of Bilharz, who discovered it in Egypt in 1851. The parasite is supposed to enter the body with the food and drink. In Egypt it is said to inhabit the waters of the Nile, and it is believed that only those who drink this impure water or eat salads, etc., which have been sprinkled with it are affected with this form of hæmaturia. The parasite entering the intestinal canal makes its way into the veins and by predilection into the more or less dilated veins of the rectum. From thence it passes into the veins of the bladder (sometimes the pelvis of the kidney and ureters are also affected) where the female deposits her eggs. The eggs, which are produced in large quantity, soon obstruct the smaller vessels, these latter rupture at various places and the eggs with some blood escape into the surrounding tissues. The parasite, its ova and embryo, can always be found in the urinary deposit. Finally, I must make mention of a peculiar affection known as "paroxysmal hæmoglobinuria," characterized by the sudden advent of hæmoglobin in the urine of individuals in apparent health. This mysterious affection is ushered in by shivering, resembling the chill of ague. The extremities and ears are cold and bluish, and the temperature at this time is subnormal, a dull aching is often complained of in the region of the loins, sometimes headache, nausea, and vomiting. Following this, very soon comes a period of reaction in which the temperature rises, and now the urine suddenly appears discolored, varying from a smoky to brownish or reddish brown color. Under the microscope, much granular matter is found, consisting of the detritus of blood-corpuscles, epithelial and hyaline casts, with oxalates and urates. If red corpuscles are found they are very few and altered in appearance. Chemical tests reveal the presence of hæmoglobin and the characteristic bands of this substance are shown by the spectroscope. Albumen is always present. After this urine has been voided, the other symptoms cease and the patient experiences relief. The dark color of the urine disappears at times with the first micturition, sometimes it continues discolored for weeks, but usually this is less apparent with each act of micturition, and the next day the urine has regained its natural appearance. The attacks come on at intervals, varying from a few hours to several years, with no regularity or periodicity like that of ague. In the intervals between the attacks the general health is good and the urine appears quite natural, all abnormal ingredients disappearing with the other symptoms, occasionally a trace of albumen remains for a longer time. The cause of this malady is obscure. Malaria, gout, rheumatism, scrofula, syphilis, hepatic derangements, traumatism, and many other causes have been repeatedly suggested and as many times rejected. One thing only we know, that exposure to cold is almost invariably the exciting cause. It is noteworthy that no attacks occur during the night, while the individual is warm in bed. It occurs in infancy as in old age, and in both sexes, though more frequently in the male. Of the pathology of this affection nothing positive is known. It has never proved fatal, and consequently no opportunity has offered to examine the parts concerned. That the kidneys are not the seat of any organic change would be indicated by the fact that after the attack is over, the renal function is perfectly restored, this, notwithstanding the attacks may have been frequent. By many it is regarded simply as a paroxysmal neurosis of the vaso-motor nerves, the mechanism being an increased vascular tension in the renal glomeruli, disintegration of the red corpuscles, and the escape of hæmoglobin through the intact walls of the capillaries. The theory of arterial tension is sustained by the fact that associated with hæmoglobinuria, there is albuminuria. The question, what causes the disintegration of the corpuscles, where does this take place, remains unanswered; by some it is supposed to occur in the kidney, others believe it takes place in the blood, possibly by contact with the bile acids, the liver being with the kidneys under the influence of the vaso-motor neuroses. In support of the view that the changes occur in the blood, we have the statements of Hayem and also Mesmit, that they have found hæmoglobin in the serum of the blood during the attacks. More substantial evidence, however, is needed on this point.

In regard to the gravity of hæmaturia, *per se*, independent of the causes that produce it, I may say that slight hemorrhages, repeated, after a time exhaust the patient and produce a condition of cachexia which gradually leads to death, while free and rapidly fatal hemorrhages have ensued from lesions in themselves quite insignificant. Again, the accumulation of clots in the bladder are often a source of intense suffering to the patient, provoking violent spasms of the viscus, with retention of urine and great distention of the bladder. This condition demands the most prompt and judicious interference, both for the relief of the patient and for the prevention of serious, if not fatal sequelæ, such as suppression of urine, uræmia, etc.

The treatment of hæmaturia will depend upon the seat and cause of the hemorrhage, and it will be radical or palliative, according as the cause is removable or not. If the cause is not well ascertained, or if ascertained, cannot be removed, the following is the outline of treatment to be adopted: 1. Absolute rest must be enjoined. If the hemorrhage is due to the presence of a calculus the horizontal posture, with elevated pelvis, will of itself be sufficient to cause the hemorrhage to cease, but the recumbent posture is in all cases of the first importance, unless possibly in malignant disease of the kidney, when, as the late Bence Jones used

to insist, the bleeding would be greatest when the patient was warm in bed. 2. Subdue vesical spasm and pain, tranquillize the nervous system, and reduce the force of the circulation. For this purpose opium and veratrum viride are the great remedies, but they should be given in doses sufficient to produce the effect desired. The miserably small doses of opium, often given in these cases, is worse than useless. 3. Derivate from the seat of congestion. In congestion of the prostate or vesical neck, especially in varices of the bladder, the least tendency to constipation must be overcome. If the hemorrhage is due to renal congestion, cupping over the loins, diaphoretics and hydragogue cathartics will relieve and afford physiological rest to the kidneys. 4. Seek for and remove all pressure or mechanical impediment to the return pelvic circulation. 5. Constringe blood-vessels. Ergot, gallic acid, sulphuric acid, iron, matico, turpentine, alum, lead, and the host of other astringents that have been recommended for this purpose, will lead you to infer that you cannot pin your faith on the value of any one drug. Sometimes one, sometimes another, will seem most efficacious, again all will disappoint you in turn, although given—as they must always be—in large and frequently repeated doses. 6. Local treatment, always more satisfactory, consists in the application of iced water or ice bags to the loins in renal hemorrhage, or to the hypogastrium and perineum in vesical hemorrhage. Pieces of ice may also be pushed up the rectum or vagina. In vesical hemorrhage, the temptation to inject the bladder should not be yielded to until the above means prove to be inadequate, then a flexible catheter, open at its extremity, should be introduced as far as the vesical orifice, and cold water or an astringent solution, such as tannin, iron perchlo., alum, or argent. nit. may be injected with good effect. But great care and gentleness is necessary in these manipulations to accomplish the maximum of good with the minimum of harm. Finally comes the important question, what shall be done with the clots that sometimes accumulate in large quantities in the bladder? If they do not interfere with the functions of the bladder or otherwise occasion distress, leave them undisturbed. The coagula—exercising pressure and acting as a foreign body inducing contraction of the bladder walls—constitute nature's very reliable means of arresting hemorrhage. In the majority of cases it is not only unnecessary, but useless and even harmful to interfere. Unnecessary, because there is no danger of the coagula not finding their way out of the bladder by nature's unaided efforts. Useless, because if the clots are removed before the hemorrhage ceases, they are pretty sure to be reproduced and harmful because any mechanical interference, however gentle, is apt to induce a renewal of or an increase in the flow of blood. On the other hand, however, the coagula may occasion so much pain, vesical spasm, difficulty in micturition, retention of urine, and inordinate distention of the bladder, that immediate relief is absolutely demanded, not only to prevent functional impairment of the bladder or kidneys, but even to preserve life. Under these circumstances the clots may be removed either by repeated injections of small quantities of water, alternating perhaps with some astringent solution which will act favorably both on the bleeding surface and on the clots, facilitating their escape, or the bladder may be evacuated by aspiration. The catheter employed should be of large calibre and with as large an eye as possible. Let me again enjoin upon you great care and gentleness in these manipulations, and to guard against two things, namely, that you do not augment the distention of the bladder by throwing in more fluid than comes away after each injection, and per contra, that you do not empty the bladder too precipitately, for by so doing you not only favor the occurrence of passive hemorrhage, but endanger the subsequent functional integrity of the bladder. It is a safe rule, that the longer the bladder has been over-distended, the longer should be the time occupied in removing the hydrostatic pressure to which it has been accustomed. Hence it is a good plan at first to inject nearly as much fluid as has been drawn off, so that the bloody urine and clots are simply replaced by the injected fluid and afterward allowing the bladder to empty itself by degrees, occupying, perhaps, many hours in so doing. If the bladder cannot be relieved by injection and aspiration, it may be necessary, as a *dernier ressort*, to open the urethra in front of the prostate and reach the clots in that way.

Original Communications.

SCURVY.

By FREDERICK SCHWATKA, M.D.,

LIEUTENANT, U. S. ARMY.

Upon my first visit, during the winter of 1878–79, to the American whaleships wintering in the ice at Marble Island Harbor, North Hudson's Bay, in order to procure dogs from the Esquimaux for my proposed sledge journey to King William's Land during the summer of 1879, I came in contact with a great deal of scurvy—that bane of the Arctic sailor. Prevailing as it did among the ships, and in the large number of crews, with heterogeneous nationalities and temperaments, and seeing the various methods employed to combat the evil, I gained an insight into the scourge which I could not have had in such a comprehensive manner under any other circumstances. This, combined with my after experience, although of a negative nature—as my party never suffered from the complaint—and the researches of others, offered me a rare opportunity to narrow the disease within more definite limits than now exists, especially in regard to its causation, which has had such a wide field accorded to it in the past by Arctic and other writers.

There is in the animal and vegetable kingdoms a definite but unknown vital property or principle which exists in the living state, and which disappears more or less rapidly after the so-called death of the organism. Death, in a legal or religious sense, is sufficiently established when the visible manifestations of life have ceased and the organism is beyond resuscitation, but any one familiar with even the rudiments of physiology knows that death is a process, a series of steps which no one has yet had the boldness to tell us which is the last, and which is the harder to determine, the lower the form of life. This death is very rapid in the animal, but slower in the vegetable kingdom, and all of the efforts made by man in desiccating, preserving, curing, or otherwise preparing the foods derived from these two kingdoms, seems inadequate to completely retain this mysterious property, so absolutely essential

to maintain a healthy state in the omnivorous human. The retention of this principle, whatever it may be, is more easily accomplished with fruits, grains, and vegetables, owing to their slower death, as already noted, than with animal food, and it is therefore to them that we must look for our main supply of those articles of diet which are prepared at home for an Arctic expedition; yet the fact must never be lost sight of that they are, after all, only approximately *fresh* food, and not to be wholly depended upon.

The greater variety of animal life in the frigid zones over the vegetable—the latter having hardly an edible representative in the whole Arctic flora—makes it, after all, the main dependence on which the polar voyager must rely to secure exemption from that disease which must enter into all his calculations. Every exertion should therefore be made to make the procurement of game as certain as possible, by being well provided with the very best of arms and ammunition, and hunting and fishing implements, and above all, with good native hunters, who, from habit and acclimatization, are superior to any others in these bleak frozen localities.

The prime essential causation of scurvy is the *want* of *fresh* meats, fruits, and vegetables, to which, in the Arctic regions, are superadded the powerful auxiliaries of damp quarters, exposure, the depressing effect of the long-continued polar night, and, in badly conducted expeditions, poor ventilation, uncleanliness, illy cooked food, and lack of sufficient exercise for both body and mind; but none of these auxiliaries, or their combinations, are sufficient within themselves to determine this disease until the vital forces have been lowered by protracted abstinence from *fresh* foods. An ounce of prevention is *not* worth a pound of cure, and in order that a fresh diet should be a perfect prophylactic it is necessary that it should enter somewhere near the proportion it does in home consumption. It must always be borne in mind that fresh food is not a *medicine* to counteract certain pathological conditions; it is an essential vital nourishment, given to combat a systemic debility, whose visible manifestations are called scurvy. The régime, therefore, to be successful, can never be homœopathic. It is the fact that this parsimony of proper food has often been combined with the other depressing influences noticed above, and has led many to give undue value to the latter in the etiology of the complaint, and to produce such a wide and discordant range of opinions on its causation even by those who have met it face to face.

Sir John Ross thought that it was produced by the want of fresh bread, yet my party was without fresh bread for two years, and nearly a year without bread of any kind, which was certainly fair enough test to exclude it from any of the essential causes; still the use of fresh bread as an auxiliary prophylactic can not be too strongly dwelt upon, and no expedition is complete within the powers of man to make it so whose culinary department cannot furnish fresh bread to the exclusion of all other, especially during those long, weary nights when the disease is most likely to make its invasion. The flour employed upon an Arctic expedition should be recently ground from the very latest crop of wheat or other cereals employed, and be preserved in hermetically sealed tin cases. Sir John believed that his second expedition showed that vegetable nourishment alone was not competent to make headway against it, whereas he only proved that prepared vegetables were so; and when we reflect that from 1829 to 1833 vegetables and fruits were illy prepared compared with the present methods, which are still not invincible, his scurvy can easily be accounted for, especially when we find that an addition of fresh fish or recently killed seals to the ordinary diet of the ship's stores was an effective preservative to the health of the crews.

One of the greatest obstacles to be encountered in the employment of fresh animal food in the polar zones is the antipathy with which such a diet of fish-eating animals is received by the consumers. The flesh of the reindeer is at once acceptable, and that of the musk-ox reasonably so, but the walrus, polar bear, and different varieties of seals have peculiar flavors, which, with some people, it is almost impossible to overcome. The most tenacious epicures are to be found in the forecastle. The educated officer, whose mess table in the past may have been a perfectly animated market report, can, with an honorable incentive ahead of him, more readily relinquish his varied bill of fare than can the foremast hand with his "hard-tack," "salt junk," and bitter coffee to which he is so firmly wedded. There was no necessity for the scurvy on board of Parry's ships when wintering at Igloolik, as that place is notoriously abundant with seal, walrus, polar bear, and fish at all times, and with reindeer and musk-oxen in the summer; and I am not only inclined to second the idea of American whaling masters, that those persons who will take this disease before they will eat bear, seal, or walrus are not only the least useful men of the ship's crews, but to go a step farther, and to say that for an Arctic exploring expedition, where the stomach is called upon to bear its share of the uncomfortable changes and hardships, they are simply worthless. A cook who has had some experience in converting these objectionable meats into more or less palatable dishes should form a part of the help in the culinary department.

Sir Edward Parry believed that the principal cause was in the clammy moisture of the ship's quarters, and especially, when the crew were compelled to sleep in damp bedding, yet I found no dampness whatever in most of the whaleships suffering with the disease, and the innumerable cases where large parties of men have been long subjected to this inconvenience without incurring it, makes it a mooted question whether such value can be attributed to it as has been done by such eminent authority as Sir Edward Parry. The dampness in Arctic ships is undoubtedly a powerful ally to the principal cause, and may, no doubt, readily determine the disease when the latter has, so to speak, established the scorbutic diathesis in the system, or seriously compromise its cure. If the winter-quarters of the vessel be near the abodes or within reach of the visits of Esquimaux, these adepts in snow architecture can easily "house" the ship so perfectly that dampness may be reduced to an insignificant minimum. Where it is not expected they will be encountered, persons familiar with their methods should form part of the crew, as Arctic whalemen, etc. During Sir Edward Parry's wintering at Melville Island he found freshly gathered sorrel an effective remedy, despite the dampness of his ships; but this plant, unfortunately, is not to be found in all Arctic localities, and most expeditions to these parts, being compelled to prosecute their labors on shipboard during the short summer months, have but little chance to gather the few simple herbs that are then in the prime of their short existence.

Captain McClure's expedition, which spent its third winter in Bay of Mercy, Banks' Land, and which, despite the fact that all hands were fed on fresh (?) meat three times a week, suffered somewhat from the malady, is often cited as an instance (and I believe is the only Arctic instance) to illustrate the fact that such a diet is not in itself adequate to stay the progress of the complaint. But if we take all the game secured by that expedition and mathematically divide or distribute it among the large crew during their three years' Arctic sojourn, the amount becomes so very small that one is forced to admire Sir Robert McClure more for his admirable good sense, tact, and judgment in conducting his crew so safely through under such discouraging circumstances, than for the conclusions he reached in dealing with the few cases he encountered. It should also be remembered that the reindeer, his main supply of fresh food, migrates southward from Banks' Land as early as the latter part of September, and cross Dease's Strait to the North American mainland as soon as that channel freezes over in early October, and remain absent until May or June. His winter's supply of reindeer meat could, therefore, hardly be called fresh, for even if preserved by freezing, it will lose much of its value. Payer, of the Austro-Hungarian expedition, an equally careful observer, has said, "We spent the latter half of August in seal-hunting, for it was only by the use of fresh meat that we were able to contend with, if not prevent, cases of scurvy." I shall again refer to the meat diet question under another head.

There is also a prevailing idea that the constitution of a white man steadily deteriorates in this enervating climate, and each recurring winter finds him less able to combat the scurvy and other Arctic debilitating diseases, until it is a mere matter of time when the strongest and healthiest of them must succumb. This is true just so far as drafts of vitality are made upon the healthy organism to support it, instead of doing so by proper fresh food, and this evil, like any other, can become accumulative until it will undermine, in a definite period of time, even the hardiest constitutions. I do not hesitate to state that, with an ample supply of fresh palatable food, the Arctic regions are the healthiest of all zones to these white men who are of sufficient health, strength, and endurance to be enlisted for a polar expedition, and this for an indefinite period of time. This statement is conclusively proven by many typical cases.

Among the earlier navigators, provided with only the coarsest salt provisions and no method of transporting fresh food, it was found impossible to go into polar winter quarters without the direst results, and expeditions were only fitted for a summer's cruise. The many unfortunate terminations to these winter experiments were then universally attributed to the salt provisions with which they were provided, a theory which is yet zealously maintained by some. Salted provisions are deleterious in direct ratio to the amount of fresh food they displace and for which they are unfortunately often substituted, it being nearly always animal food which is thus prepared. Other than this, salted provisions have no influence in the clinical history of the disease. I believe, indeed, that the salted mess pork of the whale-ships is equal, if not superior, to the prepared pemmican of Arctic explorers as an Arctic diet, especially if the latter be lacking in fat. Both are worthless if not freely supplemented with the meats obtained in the Polar regions, and the latter is anything but an effective antiscorbutic. The Russian army at the siege of Azof suffered from scurvy, and yet they had no salt provisions, in fact, they suffered no less severely from a want of this very essential condiment, even attributing the former to a lack of the latter. It sounds strangely incongruous with this theory that eminent practitioners of both continents have often recommended saline medication, especially the salts of potassa, to counteract a deficiency of these constituents from their normal proportions in health, a well-known pathological character in this disease. Dr. Flint, one of the best American authorities says, "that the antiscorbutic virtue of certain vegetables and fruits depends, to a greater or less extent, on the presence of the salts of potassa is altogether probable. Evidence of this is afforded by the fact that the isolated potash salts are useful in preventing the disease." The closely allied chemical and medicinal properties of potassium and sodium and their derived salts makes it highly improbable that the former can have such virtues and the latter such vices in the same pathological conditions. But we have already noticed that Sir John Ross has said (and he is amply corroborated) that a vegetable diet (*i.e.*, Ross's prepared vegetables) is not sufficient to hold the disease in check, and it is not probable that the process of preparation has robbed them of their chemical salts. The true virtues of vegetables are to be found in the freshness of their condition, and the efficacy of saline medication is well shown in the simple laws of assimilation. As the system is lowered the stomach and assimilative powers first reject the most indigestible or the inorganic elements of nutrition. The consequent lack of necessary salts produces the desire for saline foods, as salted provisions, etc., a well-established character of this complaint; but unassimilated, they fail in their object and pass through unchanged with the excreta, until the proper tone of the digestive organs has been raised by a plentiful supply of recently gathered food. The benefits to be derived from the proper use of the often-abused salt provisions under the latter circumstances are obvious.

From all these conflicting theories the only harmonious outlet is my previous statement, that it is in some unknown *vital* principle that the antiscorbutic properties of all vegetables reside, a statement which is further supported by the fact that raw and unripe potatoes, cabbage, fruits, and green corn, apples, etc., *i.e.*, when they are at their very maximum of vitality, are known to be more efficacious either as prophylactic or curative agents than at any other time, although at this time they are far less digestible than when ripe.

And this is no less true in the animal class of food. It is often recommended to drink the warm blood of a freshly slaughtered animal, a popular remedy among Arctic whalemen; and no doubt the flesh of it, if partaken of at the same time—a mode I have known to be used myself in one case with surprising effect—would be equally efficacious. Raw meat is assuredly superior to that which has been cooked, and in which it is not unreasonable to infer much of its peculiar vitality has been lost. Of the same kind of animals, the younger and more vigorous are the best, and of different species, those of a more active nature, indicative of greater vitality, are to be preferred. Some Arctic whaling masters believe, and not without reason, that seal and walrus are preferable to reindeer, although the latter is more acceptable to the palate; but the reason of this is be-

cause the former animals are nearly always killed right at the winter harbor of the ships by hired native hunters, while the reindeer furnished them are generally saddles of those slain in the autumn, during or before their southward migrations, and kept quite a period before being used. Such meats are generally sufficient to prevent the scurvy if amply provided, but if the disease has appeared they are slower in their curative powers than that freshly slain. These facts make McClure's situation, already noticed, more intelligible. The assumption advanced by some, that a too restricted diet of fresh meat has developed the scurvy, receives such a negation from the Esquimaux—who are not only essentially carnivorous, but eat their meat mostly in a raw state, and often warm from the freshly slaughtered animal—as to completely settle such a point, and only shows how carelessly causes can be diagnosed by some observers. Fresh, pure air as a causation of consumption is not more absurd. There was more reason displayed in Sir Gilbert Blaine's ideas, that the disease is contagious, which are now only brought forth to be properly ridiculed, inasmuch as it has one property of contagion, slim as it is, and that is the fact of almost simultaneous appearance in a community. Should the Esquimaux, however, be considered so low in the Darwinian scale as to make dietetic analogies unsafe, I might add, that my party of four white men lived on nothing but fresh meat, often raw, for a period of nine months, and were surrounded by all the known auxiliary scorbutic causes besides, and could have only escaped it, in my opinion, by this very diet. I should not have spent even these few words upon this part of the subject, had not this statement, presumably copied from elsewhere, been found under the pen of such authority as Dr. Flint, of New York City. That scorbutic dysentery, a channel that scurvy is prone to follow in warm climates, may be aggravated by the too rapid ingestion of very fresh meat, superadding the *enteric lesions* generally due to such a diet in tropical lands, to a greater extent than the value obtained as an antiscorbutic, is obvious, and this fact would at once indicate the proper treatment under such circumstances. Such was the case in Lord Anson's famous voyage, when, with a crew suffering from scorbutic dysentery, on the West Coast of Mexico, a palliative treatment by very fresh meat, suddenly assumed, only aggravated the enteric malady with unfavorable results.

Scurvy slowly depresses the whole vital powers of man, until at last the ultimate *strain* has been reached in the weakest organ, when it seems to concentrate its powers at this point or points, and owing to the diversity of constitutions, climate, and other causes, this gives a variety to its clinical history which covers almost all the known *ailments* of mankind. It is plainly beyond the scope of this article to designate the various forms it may assume due to these causes. It is often allied with other diseases, which may have been determined by the scorbutic ailment or not, oftener, no doubt, than is generally supposed, but since this is more likely to deceive the practitioner in the torrid or temperate zones than one equally skilful in the Arctic, who is more on the lookout for its invasion, it does not concern us here. A few centuries ago scurvy raged endemically during the winter in cold climates, until civilization furnished better means of preserving vegetables and fresh meats. Then a winter's supply of meat was killed in the autumn and variously prepared, and vegetables at that season were unknown. Now animals are slaughtered to meet the immediate demand, and a plentiful supply of vegetables are carefully housed, or even raised in hot-beds, or imported fresh from neighboring climes, and, as a consequence, scurvy has disappeared in civilized and populated districts, unless war, pestilence, or other great causes unsettle the regular course of events.

The only real antiscorbutic remedies which I am disposed to acknowledge are *fresh* foods, and by fresh food I mean *anything* recently deprived of life, or having the powers of preservation of the living principle to an eminent degree, and when I say anything I mean every living organism not actually poisonous, even including such as leaves, *weeds*, *insects*, and reptiles. The first voyagers to Canada prevented and cured the disease by eating the fresh foliage of the spruce pine (*Abies Canadensis*). Captain Cook fared likewise in partaking of the fresh leaves of an evergreen tree in New Zealand; the sorrel of Parry has already been alluded to; and the scurvy-grass of the Arctic, a rough, tasteless, cruciferous plant of that region is famous for the good it has done. Lord Anson gave a most practical illustration to this theory when he directed a small boat to land on the Island of Juan Fernandez, and procure anything whatever so that it was green. A boat load of weeds was the result, but they did their desired work so well that their efficiency as antiscorbutics is beyond cavil.

Any process which will destroy vitality itself, as boiling, burning, violent chemical action, etc., will, if used in the process of preserving food, do much to destroy its efficiency as an antiscorbutic, therefore we find the most efficient fruits and vegetables to be those simply dried by atmospheric exposure. Dr. J. H. Wilson, of the U. S. Navy, in "Naval Hygiene," says: "It seems to us that various fruits and vegetables, and even flesh, lose less of the peculiar properties which belong to each of them as fresh food by simple desiccation than by any other process of preservation yet imagined, not even excepting the use of air-tight cans." Those juices obtained by simple expression, as lime, lemon, and orange juice, carefully bottled from the fresh fruits; of meats, those dried in the sun and preserved in their own tallow, as the pemmican of the prairie Indian, which bears no more relation to the pemmican prepared for Arctic voyagers by contract, than their scalping does to a shampoo—all of these are known to be better than fruits or vegetables prepared by boiling, or better than chemically prepared tartaric, malic, citric, acetic, or other vegetable acids derived therefrom, or meats that have been boiled and canned, or salted and smoked, although, so far as chemistry can determine, their essential ingredients remain unchanged.

Freezing completely "kills" the antiscorbutic property of lime, lemon, and other fresh juices, and they lose much of their value by age. Fruits and vegetables whose strong vitality is not destroyed by the preservative properties of weak acids are very good, in fact, in direct ratio to the amount of freshness thus preserved, as green cucumbers, onions, etc., in vinegar prepared from fresh fruits. Cranberries, despite their high price, must enter more largely into Arctic foods hereafter from their splendid property of long preservation in the weakest of all known acids, pure water. Their strong vitality, thus indicated, would show them to be good if properly dried, if that step ever comes to pass.

Those articles of food which consist of the seeds of plants are valuable, as beans, peas, wheat, corn, etc., taken whole, as the preliminary soaking which is almost always necessary, if properly conducted, produces a germination, a true vegetable growth, which almost classifies them as freshly grown. This property of sprouting is partially lost with age, although wheat taken from the mummies of Egypt, and older than decipherable history, will germinate if placed under favorable circumstances.

Vinegar, so variously lauded and condemned, is valuable if prepared from fresh fruits, as cider vinegar, etc., but prepared from malt or liquors, or worse than all, prepared chemically, it is more or less worthless.

Molasses has also various qualities dependent upon the amount of vitality of the cane that is destroyed in its preparation, as will be readily inferred from the following extract from Surgeon Wilson, U. S. N.: "The best is a syrup made by merely evaporating the juice of the cane to a proper consistence; the next best is the first drainage from the crystallization of brown sugar; the worst in this respect is sugar-house syrup, however excellent it may be in other respects."

As scurvy is assumed by us to be the product of a want of food containing its necessary alimentary stimulus of vitality, the most natural conclusion would be that this disease would be sooner developed in those who had already made excessive drains upon their vital powers, as by long-continued debaucheries, injurious medication, excessive venery, chronic maladies, and other debilitating causes, a conclusion which we find thoroughly supported by unfortunate facts. The expression *vitality*, which has been so often used, while, according to some, not scientifically exact, is yet sufficiently descriptive to the intelligent reader to convey the impression desired.

Condensing this whole article into a nutshell, scurvy has but one prime essential causation, and but one specific cure, the want on one hand and ample supply on the other of fresh vitalizing nourishment, and any considerable deviation from these simple facts will lead one into an intricacy of clinical histories, pathological characteristics, irrelevant diagnostics, and, worse than all, empirical therapeutics, that can only be encompassed by the medical libraries of the world.

THE AMERICAN STUDENT IN LONDON.—Is it a slander? *The Medical News*, an infant weekly of London, publishes the following: "I have frequently been a listener during the time that discussions have taken place at a certain large hospital in London on the subject of American students of medicine. At the particular hospital in question, the 'Yank' is a recognized institution even now, but formerly it was a difficult matter for any Britisher to get within hearing distance of the principal members of the staff during their visits to the wards. Jonathan's representatives entirely shoved aside all who endeavored to see or hear, and having carefully surrounded the beds and the demonstrator to the exclusion of regular students of the hospital, the lecturer would proceed, to the edification and, let us hope, instruction, of the untutored Westerns. Experiences of this kind have tended rather to exaggerate our notions of the offensive character of the American."

CASE OF CYSTIC TUMOR OF LIVER CAUSED BY IMPACTED GALL-STONE IN COMMON BILE-DUCT.

REPORTED BY ALFRED NORTH, M.D.,

WATERBURY, CONN.

J. H. D——, aged forty-five, merchant, first came under observation in July, 1881. For the seven years previous has enjoyed fair general health, this condition being only interrupted by seven or eight "bilious attacks," as he termed them.

The symptoms at these times were pain and tenderness over the right lobe of the liver, slight rise in temperature, some acceleration of the pulse, with vomiting and jaundice. These attacks were treated and relieved by hypodermics of morphia and dry cupping, followed by diaphoretics. Their frequency was seemingly increased by exposure to cold and over-exertion, and diminished by the prolonged use of small doses of hydrarg. bichloride.

In 1878, fearing an incurable disease of the liver, the exact nature of which could not be determined, he, by advice, consulted Dr. James R. Leaming, who, unable to find sufficient evidence of any organic disease, was compelled to regard it as a functional disorder of the liver. In accordance with his advice, the use of the hydrarg. bichloride, in gr. $\frac{1}{12}$ doses, was continued with some apparent benefit for the space of two years.

On July 8, 1881, occurred another attack, which proved to be his last illness. For some ten days previous nausea was present, with general malaise, previous paroxysms having occurred with few or no premonitory symptoms. The disease proper ushered in by a slight chill, followed by vomiting and pain, this latter being not as usual in the right, but in the left hypochondrium, chest, and shoulder. The treatment mentioned as adopted on other seemingly similar occasions was repeated now, but without affording the usual relief.

July 12th.—Has had a bad night, with little sleep, notwithstanding an injection of morphia at a late hour. The pain is still very intense and spasmodic in character, aggravated by motion, and relieved only by very hot fomentation. Vomiting occurs with little effort, and with great temporary relief to the gastric oppression. Jaundice general, and well marked; stools clay-colored; urine contains no albumen; temperature, 100°; pulse, 104.

July 25th.—Condition not materially changed since last note, except that there is great loss of flesh and strength, patient being unable to turn in bed without assistance; jaundice more extreme; vomiting not quite so frequent; has at times some appetite and retains food forty-eight hours or more; still requires morphia, both for the pain, which is still liable to great exacerbations on change of posture and for the relief of the sense of complete exhaustion which oppresses him. Urine, passed to the amount of a pint and a half daily—deeply bile-stained, containing numerous hyaline and granular casts, but no albumen; abdomen at times quite tympanitic, at others nearly normal; bowels only act in response to enemas or cathartics.

Case again examined by Dr. Leaming, who, after a thorough exploration at two visits, now considers it to be cancer of the liver, complicated with subacute enteritis. Physical examination of chest and abdomen reveal no lesion of any other organ.

September 5th.—For past four weeks little change has been experienced, but that for the better. Du-

ring one week the jaundice almost entirely cleared up, but soon reappeared. General emaciation has slowly progressed, although the nausea and vomiting have for some time been nearly absent, and food has been taken with appetite and relish. Bowels have been easily regulated by the free use of fruit. Is able to sit up a little in bed, and begins to be confident of recovery. Skin still has the waxy, jaundiced look, suggestive of cancer of the liver. A fulness has been noticed over the stomach for the past few days which has now increased so as to cause a perceptible bulging of the four left lower ribs. Percussion over it gives dulness, and palpation shows fluctuation—painless on pressure, but a sense of prostration and faintness caused by much manipulation. There is evidently a cystic tumor present, probably of the liver, which, considering his present improved condition, it is thought best to simply watch without active interference.

September 8th.—Was called to see patient in the night. The pain had suddenly returned with greater severity than at any previous time. Pulse 120, and very feeble. Countenance haggard and anxious. Tumor has rapidly grown during last three days, and is now especially prominent in epigastrium.

5 P.M.—Patient has rapidly failed during the day. Pulse, 130, weak and irregular. To remove the pressure of the tumor it was now decided to aspirate. It is accordingly done at a point three inches below the sternum, and five pints of coffee-colored fluid are drawn off, the operation giving great relief to the patient.

September 10th.—Patient was much better yesterday in all respects, but passed a wakeful, restless night. Mind has been wandering, and pulse very feeble. Has passed scarce any urine since operation, and a catheter introduced finds the bladder empty. Patient rapidly failed during the afternoon, and died at 7 P.M.

Autopsy, twelve hours after death.—Rigor mortis well marked, body much emaciated and highly jaundiced.

Abdominal cavity: Contents stained a deep bronze by the bile, especially the omentum and peritoneum. Intestines in many places adherent to each other and to the omentum, but with this exception and their color, normal. Contained small amount of fæces rather more highly colored than normal in upper part. Stomach slightly distended with gas, contained twelve ounces milk. No evidence of disease. Spleen, on section rather too pale, otherwise normal. Kidneys: left, normal to all gross appearances; right, congested, small cysts, size large pin-head and several in number. No apparent parenchymatous changes. Bladder contained one ounce turbid urine, normal. Liver, about normal in size, but pushed to the right side, the left lobe reaching barely to the median line, by a large cyst. This cyst was situated immediately below the diaphragm, to which it was adherent, adhesions also to the posterior aspect of stomach and upper extremity of spleen. These were easily separated, but there existed with it and the left lobe of the liver so strong an attachment that it could not be separated except by tearing the sac. The cyst was simple unilocular, size about that of a man's head, and walls about twice the thickness of the normal stomach. Contained about a pint of fluid like that withdrawn before death. Its inner surfaces resembled a granular mucous membrane, being rough and studded with numerous small fleshy points or granulations.

The point of origin of the tumor was determined with difficulty. It was unpedunculated, but the strong and intimate connection with the liver, the nature of its walls and its contents, gave that organ as its origin.

Fluid removed was of specific gravity of 1015, contained albumen in large amounts, bile in considerable quantity, together with bile salts and biliary coloring matter. Examined closely for echinococci with negative result.

The liver itself was in a state of moderate fatty degeneration.

The gall-bladder contained little bile, but a calculus an inch in length and half an inch in diameter, which was freely movable.

Impacted in the ductus communis choledochus, about an inch from its outlet, was another calculus about the size of a common marble. This could be moved easily backward, but was effectually prevented from advancing by the smaller lumen of the duct beyond.

Heart normal.

Lungs normal except a slight pleuritic adhesion at left apex.

Remarks.—This case seems to me to present several points of interest. The immediate cause of death appeared to be the exhaustion succeeding the operation, together with the suppression of urine. The remote cause, the impaction of the calculus, causing retention of the bile, interference with the liver function and consequent inanition, as well as giving rise to the cyst already described.

Cysts of the liver seem of rare occurrence and are not readily recognized, resembling in these particulars cysts of the pancreas, with which they are readily confounded. Barlach and Atlee have each reported one case; in both there was a communication with the common duct, and in Barlach's also a communication with the stomach, bile and food being found in the cyst.

The history of our present case would go to confirm the statement of Nothnagel, that in jaundice of much intensity and duration, no matter what the cause, casts appear in the urine, sometimes without albumen.

Previous to his last illness the patient's urine had been repeatedly examined and neither albumen nor casts found. The post-mortem showed no evidence of organic renal disease, yet subsequent examinations by Drs. Welch, Heitzman, and Buck, of New York, all showed abundance of casts, with little or no albumen. Dr. Welch has subsequently confirmed Nothnagel's statement, though he reports never to have before seen casts in such large numbers in any case of jaundice without Bright's disease.

I know of no cause for the sudden suppression of urine after the tapping; previously, during the course of his illness, there had been a good average daily amount excreted. It is probable that the calculus had been lodged in the duct for a long time without at all times completely obstructing it, as for the past four years there had been frequent attacks of jaundice without the severe pain which characterized former attacks, and which would be likely to follow the fresh introduction of a calculus into the duct.

THE SULTAN OF TURKEY has given a site in Jerusalem for the purpose of erecting a hospice and ophthalmic dispensary under the auspices of the English branch of the Order of St. John.

A DERMOID ENCYSTED TUMOR OF THE EYELID.

By HENRY G. CORNWELL, M.D.,

CLINICAL LECTURER ON OPHTHALMOLOGY AND OTOLOGY, STARLING MEDICAL COLLEGE, ETC., COLUMBUS, OHIO.

Dermoid encysted tumors of the eyelids are very rarely observed. The following case came under my observation during the present year.

T. M——, aged three years; parents English, residing in Columbus, was brought to me at the Eye and Ear Dispensary of Starling Medical College, June 23, 1882, by the family physician, Dr. C. F. Turney. The tumor exhibited itself as a slight swelling at birth, which gradually enlarged with the growth of the child. On examination at the dispensary it was observed to be about the size of a hazel-nut, and of firm doughy consistency so that an indentation made with the finger remained as though the tumor was formed of stiff putty. An incision over its convexity gave exit to a thick material, which came out on pressure in the form of a long cylindrical mass creamy-white in color, having fine longitudinal dark stripes, which on careful examination proved to be long hairs. The sac-wall was excised, and the wound closed with a couple of stitches, a small opening being left for drainage. Dr. Bleile examined the contents of the sac, and found it to be made up of epithelial cells, whole and disintegrated, fat, and a large quantity of hair.

The orbit and its environments seem to be a favorite situation for the development of encysted tumors. They are of varying character and origin, and on this account are interesting subjects of study.

There are two rare varieties of cysts of the integument of the lids, viz.: (1) The retention of sebaceous cysts, due to the obstruction of the orifice of one of the ducts of a sebaceous gland, and (2) dermoid cysts. The first variety is observed most frequently on the upper lid, near its outer angle, just below the point where the brow cysts are oftenest observed. They attain sometimes the size of a chestnut. On account of the fewer sebaceous glands in the lower lid, it is the seat of such formations in extremely rare cases. Occasionally there is observed very small cysts, having thin fluid contents of the retention variety at the margin of the lid. They may be sebaceous, the contents of the sac having undergone serous metamorphosis, or more probably they are formed from an obstruction of one of the sweat-glands in this locality, which, according to Moll and Stieda, here give up their coil-like form and become wide canals opening into the excretory duct of the hair follicle. The second and rarer variety, the dermoid, is observed most frequently at the upper and outer angle of the orbit, where the integument of the lid joins that of the brow. These congenital cysts of the eye are observed in the order of their frequency (1) over the brow at the external angle of the orbit, (2) on the lid, (3) in the orbit.[1]

In some instances these tumors contain almost clear fluid fat.[2] It is pretty generally believed that they are formed by an invagination or involution of a portion of the external blastodermic membrane during fetal development.

181 East State Street, Columbus, O.

Reports of Hospitals.

NORTHEASTERN HOSPITAL FOR CHILDREN, LONDON, ENG.

Service of Mr. RICKMAN J. GODLEE, M.S.

Case I.—*Acute suppuration of right elbow-joint—Cure.*—Esther W——, aged eighteen months, attended first as an out-patient in February last.

The mother stated that she had two other children living and healthy; no deaths; suffered from cough; had had three miscarriages; no phthisis in family; father healthy.

The present child was healthy from birth up to the end of November last, when she had varicella, and was ill eight weeks. A few sores remained on the head, but she continued in fair health, though weak, till January 29th, when the mother noticed a slight swelling in front of the right elbow, and the child cried whenever she was moved or touched. She brought the child to the hospital the same evening, when splints were applied by the house-surgeon and the mother told to attend again the next day.

When first seen in the out-patient department, the elbow presented a diffuse œdematous and tender swelling in front and behind. There was an obscure sense of fluctuation on the outer side of the olecranon. No history of injury could be elicited. The child had had a slight cough two weeks; no diarrhœa; was fed on milk and broth. As an application, equal parts of ext. belladonnæ and glycerine were ordered without any marked effect. Poulticed. Œdema less by following day and the elbow seemed better. On the day after, however, fluctuation became very evident, and the child was admitted (February 4, 1882). Temperature taken and found to be 99.6°. An anæsthetic was administered and the abscess opened (under the spray) by two incisions, on the inner and outer sides of olecranon respectively. About half an ounce of pus escaped. The opening on the inner side led to a large cavity at the back of the humerus; bone bare but not rough. That on the outer side formed a free communication with the interior of the joint. Cartilages of joint completely bare but not felt to be crowded. No bare bone felt. Two drainage-tubes were inserted and the wound dressed antiseptically. The elbow was fixed by bandaging the limb to the side of the body, the lint being drawn well up to the opposite shoulder; no splint applied. Temperature in evening 97.6°.

February 5th.—Dressed. Temperature, morning, 98°; evening, 97.4°. Urine black (from carbolic acid).

February 7th.—Dressed. Temperature, 97°. Child sweating profusely.

January 10th.—Dressed again. Temperature continues sub-normal; very little discharge; very little swelling about joint. Ordered mist. ol. morrhuæ and vin. ferri ℥ss ʒj. Takes food well; bread, milk, and beef-tea.

February 13th.—Dressed. Temperature, 97.2° and 98°. One inch of drainage-tube in sinus on outer side of olecranon; two inches in that on inner side. No splint applied, but elbow kept at a right angle and bandaged to chest, a flannel bandage being employed and cotton wool placed in axilla and over front of chest.

February 14th.—Both wounds look healthy; drainage-tube left out of outer opening.

February 18th.—Dressed. Wounds healthy and no doubt still aseptic, though the discharge is not altogether free from smell. Tube in inner opening shortened.

February 21st.—Outer opening healed.

February 28th.—Tube removed from inner opening.

March 3d.—Temperature has been subnormal till this evening when it rose to 99.2°.

March 4th.—Temperature again subnormal. Boracic lint dressing substituted for antiseptic gauze. Passive motion every morning.

March 6th.—Temperature rose to 99.6° in evening. This and the evening of March 3d were the only occasions during the patient's stay in the hospital on which the temperature rose above 98.6° and during the greater part of the time the temperature was subnormal.

March 10th.—Wound (inner) quite healed.

March 18th.—Discharged to-day. Extension fairly good; complete extension not permitted, pronation and supernation perfect.

[*Remarks by Mr. Godlee.*—"The appearance of the case at first was very much that of one of acute periostitis; but the fact that on opening the abscess no bare bone was felt, whereas the joint was certainly open, and that no sequestrum separated, make it clear that it was really a case of acute suppuration of the joint. The position in which the limb was kept (the same that is recommended by Dr. Thomas, of Liverpool) gave very satisfactory results both in acute and chronic disease of the elbow. If the child be out of bed, the arm is kept, of course, inside the clothes. It is doubtful if any splint has been devised which keeps the limb at such perfect rest."]

Case II.—*Scalded throat—Tracheotomy—Measles—Death.*—Edward B——, aged three months, was scalded about 5 P.M. on January 28, 1882, through sucking the spout of a kettle. He was brought to the hospital and admitted about 10 P.M. On inspection the fauces were seen to be red and clogged with mucus. Laryngeal stridor marked, slight falling in of lower ribs during inspiration. The breathing gradually became worse and the sinking in of the ribs very marked. At 2 A.M. (29th) tracheotomy was performed by the house-surgeon and a bivalve tube inserted. Breathing relieved, but became bad again on introducing inner tube, so this was left out pro. tem.

January 29th.—Air enters freely, but worse on introducing inner tube, so it is not left in. Much discharge of mucus at first and blood, but not now. Child flushed, sleeps heavily; pulse full and strong; temperature, morning, 101.2°; evening, 102.8°; pulse, morning, 176, evening 168; respiration, morning, 56; evening, 60. Takes milk well.

January 30th.—Sick twice during night. Restless during night and slept little. Motions loose; cough very frequent; only mucus, no blood. Able to swallow well and took a pint of milk yesterday without difficulty. This morning at 4 A.M. the breathing began to get much worse and is now (10 A.M.) very quick, but regular; no stridor. Pulse regular, 144; Temperature keeps at 102.8°; respiration, 64. Slight retraction of epigastrium. Restless, occasionally rolling from side to side. Alæ nasi do not dilate in inspiration. Abundant râles over chest; no fine crepitation. At 11.45 the tube replaced by another, larger, and with an inner tube. Profuse discharge of muco-pus through opening and tube. Inner tube can now easily be borne.

January 31st.—Sick once last evening, not since. Has taken one and one-half pint of milk since last night and slept well. Poultices to chest last night; cough very frequent; abundant discharge of very fetid muco-pus through tube; a streak of blood. Tube removed every half hour all day yesterday.

Pulse good, 132; occasionally intermits; expression anxious, but aspect less blue. Respiration, 50, regular. Temperature, 101° throughout the day. On removing the tube this morning child was quite unable to breathe through larynx, which became apparently immediately choked with mucus. Poultices continued to chest; lips very blue; profuse perspiration and urgent dyspnœa. On auscultation râles and rhonchi over both sides of chest. All over left back breathing somewhat tubular in character, especially at the apex, where there is abundant fine crepitation. Brandy (3 ss. every four hours) ordered. Carbolic acid in steamed kettle. Stronger toward evening.

February 1st.—Slept well and is better this morning; breathing quiet; no lividity; bowels not open; cough the same; still abundant discharge of mucus through tube. Pulse, 144; respiration, 52; temperature, morning, 102°; evening, 101°. Takes plenty of nourishment. To discontinue brandy.

Tube removed at 11.30, when child soon became livid and blue with great dyspnœa and cold sweating. A bivalve canula introduced. Prostrate and rather collapsed.

Discharge abundant and fetid.

February 2d.—Slept well. Breathing quiet and regular. Bowels acted twice in night. Temperature, morning, 101.2°; evening, 102°; pulse, 148°. Takes about a pint and a half of milk during the night. Coughs a good deal after hand spray of carbolic acid, which is used through tube every four hours. Tongue cleaning at tip and edges, but covered elsewhere with thick white fur. Chest: Loud mucous râles and rhonchi abundant over both sides of chest. At left back dulness with tubular breathing over a small area just below angle of scapula. To stop brandy.

February 3d.—India-rubber tube introduced. Less discharge and this less fetid, but still streaked at times with blood. Slept well and looks better this morning. Takes milk well. Temperature, morning, 100.2°; evening, 101°.

February 4th.—Tube removed every two hours to-day. Does not seem so well. Temperature, 100°.

February 6th.—Appears to have less strength to cough up mucus. Very little through tube—at times streaked with blood. Morning temperature, 98.8°; evening, 100.4°.

February 8th.—Still profuse discharge through tube. India-rubber tube changed each morning. Takes nourishment well. Temperature, 98.8° and 100.2°.

February 10th.—Respiration rapid. Profuse discharge through tube, which gets clogged. Carbolic steam continued. Very little œdema of neck. Two or three pustules about face.

February 11th.—Sleeps well. Discharge more thick and this morning again offensive. Alæ nasi dilating.

February 13th.—Tongue thickly coated with large white fur. Takes nourishment well. This morning breathing quiet—appears a little improved. Poultices continued.

February 16th.—Improved. Cough very troublesome. India-rubber tube again inserted yesterday. Discharge through tube the same. Takes milk and beef-tea well. Ordered mist. ammon. et ipecac., ʒ j., every six hours. Temperature, normal.

February 20th.—On removing inner rubber tube and placing sponge over opening, not the slightest amount of air enters the larynx, and the child immediately struggles and face becomes blue. Discharge considerably less, not fetid. Tongue coated with moist fur in centre. Temperature, subnormal; pulse, 126°. Left base behind still dull, with tubular breathing. No dulness elsewhere, but râles and rhonchi all over chest.

February 21st.—To have some bread. Evening temperature fell to 97.6°.

February 23d.—Comfortable all night, but coughed more than usual. This morning breathing more short. Dull and heavy, and not inclined to sit up. Discharge more profuse from tube. Temperature, 103.6°, falling to 100.2° in evening.

February 27th.—Much better last three days. Sits up in bed. Respiration quiet. Still a good deal of discharge comes through tube. India-rubber tube changed every two hours.

February 28th.—Full diet.

March 11th (11 P.M.).—Breathing has become more rapid since morning. Did not take dinner during afternoon. During the afternoon there was much embarrassment as if trachea was blocked below tube. At present there is great dyspnœa and some rattling in tube, but the signs of obstruction are not so marked. Pulse fair, 132°. Perspiring freely. Discharge rather copious and thick. This afternoon poultice ordered and vin. ipecac., ɱ v., added to mist. ammon. c. ipecac. To have a drachm of brandy every four hours. No blood in discharge. Lungs: Air not entering freely. Rhonchi and sibilli very marked. Resonance somewhat generally diminished. Tube frequently cleaned out with feather. Temperature has been subnormal till to-day, when it rose in evening to 100°.

March 12th.—Restless in night. Dyspnœa very marked. Discharge more fluid—very abundant. Temperature, 99.8°, and evening, 101.8°.

March 13th.—Two spasmodic attacks of dyspnœa during night. Discharge through tube very abundant. Does not take nourishment except milk. Abundant râles over both lungs. No dulness. Air seems to enter freely but some sucking in of lower ribs.

March 21st.—Temperature has been gradually falling (with evening exacerbations) since 16th, and is now normal. Pulse, 132°.

April 1st.—Glycerine and perchloride of iron have been applied to larynx every morning since March 22d. Temperature subnormal.

April 19th.—Nitrate of silver applied to trachea through opening. Great distress when tube removed. Temperature still subnormal, but rose to 99° this evening.

April 20th.—Steam discontinued.

May 12th.—Transferred to Isolation Ward, as symptoms of measles have appeared. Temperature rose to 103.4°, and (with morning intermissions) reached 104.4° yesterday evening; pulse, 144. Eruption well marked.

May 16th.—Lately symptoms of increasing broncho-pneumonia in both lungs. Great dyspnœa. Evening temperature, 103°; pulse, 168; respiration, 60.

May 17th.—Temperature, 102.4°; pulse, 184; respiration, 72. Died to day. No post-mortem allowed.

[*Remarks by Mr. Godles.*—"Up till the last few days this case was merely an illustration of the numerous difficulties that are associated with these somewhat common cases of scald amongst the poorer classes. The child had made a satisfactory recovery from the immediate effects of the injury and then from a pretty severe attack of pneumonia; but at the end of four months there was scarcely any improvement in the character of the respirations when the tube was taken out. It cannot be doubted that considerable destruction of tissue and subsequent cicatrization in the larynx had taken place, and what the result would have been if the child had not died of the intermittent attack of measles can only be guessed. Probably attempts would have been necessary to pass bougies through the larynx, unless the child had been allowed to continue using the tube indefinitely."]

CASE III.—*Noma vulvæ—Death.*—Isabel D——, aged ten months, was admitted on May 10, 1882.

The ulceration began about fourteen days previously. A small patch first appeared between the labium and thigh, and spread. No blood or 'bits of flesh' came away. On admission, a deep ulceration was found between the thigh and left labium. Its surface was irregular, grayish yellow, sloughy, not very offensive. It extended about four inches along the fold ascending to the groin, and was surrounded by a thickened red border. Left labium dark and swollen. Right labium swollen and of a deep purplish color. The child had a pale anxious expression. There were patches of eczema on the face. Death occurred at 5.30 A.M. on the 3d. Post-mortem, seven hours after death. Body well nourished, but muscles flabby. No œdema of extremities. Left labium and groin a mass of unhealthy ulceration, the former infiltrated throughout its whole thickness, and the ulceration extending into the tissues of the groin. Right labium swollen, not ulcerated. Two considerable hemorrhagic infarcts of anterior border of upper and lower lobes of left lung; lungs otherwise healthy. Left ventricle of heart slightly contracted; right ventricle empty, not contracted. Liver and spleen normal. Kidneys somewhat contracted. Brain normal.

[*Remarks by Mr. Godles.*—"Cases of noma in this situation are not uncommon among the poor in the east end of London; often they are milder in character and under the administration of tonics and the application of iodoform end favorably. Two cases of a similar character about the external ear have been recently treated at this hospital, one of which, in a very marasmic child, ended fatally, the other recovered."]

VAGINAL HEMORRHAGE IN A NEW-BORN CHILD.—Dr. Josef Pollak, in Devecser, reports the following case in the *Wien. Med. Presse.* He observed in a female infant, four days old, a not inconsiderable hemorrhage from the vagina. The bleeding reappeared several times daily; after the third day the discharge assumed a reddish-brown, and later a chocolate color, and ceased totally when the infant was nine days old. At the same time there was noticed a swelling of the mammæ, and on pressure a milk-like fluid oozed from them, drop by drop. The general health of the case just reported did not apparently suffer at all in consequence of the bleeding.

Progress of Medical Science.

BIERMER ON CONTRACTED KIDNEY.—Professor Biermer (*Breslauer Ærztlich. Zeitsch.*, 1882, No. 1) points out that until 1853, when Dr. Wilks first showed that there existed a form of Bright's disease unattended by dropsy, the opinion of the German medical clinical teachers always held the contracted kidney to be the final stage of ordinary parenchymatous nephritis. That it may be occasionally seen in such cases is possible, although it is rare for patients to survive the effects of the processes which lead to its formation. Following Dr. Traube and Dr. George Johnson, Dr. Biermer insists, from a purely clinical point of view, upon the existence of a special form of renal inflammation, which may be properly described as genuine contraction of the kidney. The course and sequence of symptoms in such cases are too typical for them to be denied a special category. Beginning, without special cause, with polyuria and small quantities of albumen in urine of low specific gravity, a gradual but progressive wasting ensues, the complexion becomes sallow, the left ventricle of the heart becomes hypertrophied, the tension of the pulse becomes increased, dyspnœa follows, and disturbances of digestion or of vision take place, without a trace of dropsy having been observed. In the later stages, the evidences of uræmia are the chief symptoms, which may culminate in death.

It is hardly possible to believe that cases running such a course could have begun with parenchymatous nephritis; and hence, Dr. Biermer holds that the process from its commencement must have been a different one. He suggests that no special etiology can be associated with this form of disease. In none of his cases does he find any exciting cause except chills, and upon the importance of these he lays some stress.

Repeated chills and complaints of cold feet are common before the disease is recognizably established; and from this fact he is inclined to ascribe a good deal of the disease to exposure of the extremities in cold, underground dwellings, damp floors, etc., recognizing in the polyuria of the initial stages the agency of arterial congestion within the kidney, induced by these means. He points out, in passing, that the very occurrence of increased instead of diminished secretion of urine proves that the early affection of the kidney is not obstructive in its nature, *i.e.*, causes no narrowing of the lesser tubules.

In the later stages, three influences may be recognized as playing a part in the destructive processes in the walls of the vessels—the mechanical influence of the frequently increased tension within the vessel, the degenerative influence of frequent congestion, and the more subtle influence of impaired nutrition. To the second of these, viz., frequent congestion, one must look for the explanation of the occasional excess of albumen thrown off.

The form of contracted kidney described in association with atheroma of the arteries differs in many points from this genuine idiopathic nephritis atrophicans. In the atheromatous form, the symptoms of changes in the heart and arteries appear long before the albuminuria and the signs of renal contraction. In the genuine contracted kidney this order is exactly reversed. Histologically, also, there is a difference, the contracted kidney showing a marked overgrowth of connective tissue, the atheromatous form being simply atrophied, with certain epithelial changes.

Two other forms of contracted kidney may be recognized, viz., the contraction after parenchymatous nephritis, or the amyloid state, and the gouty kidney. The first of these, with or without amyloid change, is rarely seen. The gouty kidney, besides its diathetic origin, shows changes which are more purely atrophic, and often cystic or pyelitic. In its early stages, moreover, its symptoms are quite distinct, although less easily distinguished toward the close.

The course of a genuine contracted kidney is from the beginning insidious and chronic. The earlier stages have been already mentioned. The later stages may be divided into two periods—one, in which the concurrent hypertrophy of the heart maintains a sufficient compensation, and the other, in which it ceases to compensate properly, and in which the symptoms of uræmic poisoning are most prominent. Complications such as apoplexy, pneumonia, erysipelas, etc., are frequent; but, where none such occur, contraction may go on to an astounding extent.

Of the individual symptoms, the state of the urine is the most important. The proof of the presence of albumen in the urine is indispensable; but it must be remembered that the amount often varies greatly, and that it may sometimes be altogether absent for a short time. Bodily exercise and muscular effort favor the production of albuminuria, and Biermer has often produced it in suspected cases by these means. Microscopic examination generally shows a scarcity of solid elements, a few isolated hyaline cylinders, and at times, a little renal epithelium, but rarely any blood-corpuscles. The excessive secretion of urine is not accompanied by thirst.

The condition of the heart, of the arteries, and of the fundus oculi, are of decided importance in diagnosis; though neither of them, taken alone, is essential. A certain amount of hypertrophy of the left ventricle is almost always present, and high tension is maintained in the arteries, even, as some English observers have shown, during the diastole in extreme cases. Palpitation is frequently complained of. Retinal changes may or may not be present, and are very variable in their extent and severity. Disturbance of respiration is always present; dyspnœa is frequently the first subjective complaint. In the earlier stages, it is probably due to cardiac derangement, but later on the cause is generally uræmic. Occurring frequently in cases with pulmonary complications, its importance as diagnostic of renal disease may be overlooked. Cerebral symptoms are not usually present till the late uræmic stages. Early uræmic states may show themselves in headache, vomiting, etc.

Disturbance of digestion is sure to appear sooner or later. The general nutrition is always affected; indeed, it is never properly maintained in the presence of chronic renal disease. This fact serves to distinguish the organic renal mischief from the functional and innocuous albuminuria which has been described of late years. If any person have albuminuria for several months, and do not lose flesh, he certainly does not suffer from contracted kidney. Dropsy plays a negative part, and, if present to any extent, must be due to one of the other forms of chronic renal disease, and not to genuine contracted kidney.

Biermer closes his remarks with the statement that he knows of no effectual means of treatment for this disease. He speaks strongly as to the danger of checking the diuresis, and hence finds all astringents to be contra-indicated. Even tannin, which he would employ in parenchymatous nephritis, he objects to in this form of disease. Diuretics and tonics are to be used until the uræmic state is arrived at; and during that period only narcotics, as morphia and chloral, should be given, simply with a view to the temporary relief of the strugglings and sufferings of the patient.—*London Med. Record*, June 15, 1882.

Diphtheria of the Skin.—In a monograph with the above title, Dr. D. J. Viñetor Bellaserra sums up the subject in the following propositions: 1. Whether diphtheria attack the mucous membrane or the skin, it is essentially the same disease. 2. The different aspects which the local lesions present depend entirely on the tissues involved, and all the various manifestations are due to the same cause. 3. Diphtheria is transmissible by direct contact, and any part of the cutaneous surface deprived of its epidermis is susceptible to the poison. 4. It is generally believed that diphtheria depends upon the presence of minute organisms, but whether they are of animal or vegetable origin is not settled. 5. The cutaneous, false membrane may exist alone, and constitute the sole manifestation of the disease, but this is rare. 6. When the cutaneous manifestation has presented itself, general infection already exists. 7. Cutaneous diphtheria often assumes an excessively malignant form. 8. The cutaneous lesions are commonly followed by palatal or general paralysis. 9. Sudden death may occur from cardiac thrombosis. 10. The prognosis is grave. 11. Prophylaxis consists in perfect isolation in every case. 12. Blisters should never be employed in the treatment of any case of diphtheria. 13. In case of death all religious ceremonies in the presence of the body should be forbidden, and the corpse should be buried. 14. In the treatment of the local affection the cautery should be employed—sulphate of copper, nitrate of silver, the hot-iron, or the thermo-cautery.—*El Sentido Catilico en las Ciencias Médicas*, July 22, 1882.

Relative Stenosis of the Cardiac Orifices.—Dr. Richard Henkirch, in the *Berliner Klinische Wochenschrift* of June 12, 1882, advances a theoretical explanation of the transient heart-murmurs, so often heard, and for which no anatomical reason can be found. In a normal heart the size of the orifice multiplied by the velocity of the blood-current must equal the cubic contents of the heart cavity, otherwise, if the latter be greater, we have stenosis. Hitherto but one factor has been taken into account, viz.: the diameter of the orifice; but it is clear that if, with a normal exit, the capacity of the heart be increased, the former becomes relatively too small, and we have a relative stenosis. The auriculo-ventricular openings partake in the dilatation of the cavities—to such an extent, indeed, that the unchanged valves become too small and insufficiency results. But it is otherwise with the arterial orifices, which do not dilate as the ventricles enlarge, and hence become too small. As regards the third factor—the velocity of the blood-current—a certain relation exists between the capacity of the heart and the size of its orifices which permits of changes in the velocity of the current within certain limits. But when, through congenital defect or in consequence of pathological changes, the ventricle can barely empty itself, a slight increase in the velocity will produce a murmur. On the other hand, a pre-existing murmur may disappear upon retardation of the blood-current—witness, for instance, the disappearance of a systolic murmur after severe hemorrhage or in the death agony. We should make a distinction between organic and functional or clinical stenosis. Since excrescences and proliferations are so often found post-mortem, which gave rise to no murmurs during life, we cannot regard slight inflammatory exudations on the endocardium as a cause sufficient to account for all otherwise unexplained murmurs. In acute endocarditis, or during a high fever there may be a weakening of the muscular walls of the heart, and a consequent dilatation. Here the relation between the ventricle and its orifice is altered, and the latter becomes relatively stenosed. The sound produced is a faint blowing murmur, and since the left ventricle receives the greatest strain, it is the first to give way, and the murmur is heard loudest over the left heart. It is, of course, systolic, since it is caused by aortic stenosis. After copious hemorrhage loud, blowing, systolic murmurs often arise, sometimes several days after the occurrence. These cannot be produced by the irregular working of the valves, owing to the diminished amount of blood, for they do not supervene until some time after, when the volume of blood is already restored to the normal through absorption of water from the tissues. The intracardial blood-pressure is therefore nearly the same as before, but because of insufficient nutrition the muscular tone of the heart is lowered and dilatation ensues. When this condition exists, the orifice being relatively too small for the ventricle, only a part of the contents of the latter can pass out, the balance recoiling against the advancing blood-stream, and thus causing a murmur.

Decrease of Red Blood-Corpuscles during the Administration of Iodoform.—Dr. Ludwig Von Hoffer bases the following conclusions on the results of a few experiments made by him on rabbits and syphilitic human subjects: In rabbits a decrease in the number of the red blood-corpuscles and in the weight of the animal was observed commensurate with the dose of the drug. When the iodoform was withheld the falling away ceased and began again when it was readministered. In the case of syphilitic subjects, iodoform administered subcutaneously (in suspension in oil) for a few weeks causes, at first, an increase of the red globules, the syphilitic *hypoglobulia* being overcome. In the cases experimented upon the other signs of syphilis also receded. After a time the continuous administration of iodoform causes, as in the case of the rabbits, a decrease of weight and a lessening of the number of red globules.—*Wiener Medicinische Wochenschrift*, July 15, 1882.

Bilateral General Zoster.—Professor Tommaso de Amicis reports a very rare case of general bilateral herpes zoster in the *Giornale Internazionale delle Scienze Mediche*, part I., 1882. The patient, a woman twenty-seven years of age, about six weeks after the birth of her third child was seized with fever, preceded by a chill, and accompanied with abdominal pains, diarrhœa, and vomiting. Three days later she noticed a redness and puffiness of the hands, arms, and face, and the following day there appeared a vesicular eruption, disposed in groups, and accompanied with a smarting pain. The author thus de-

scribes the eruption as seen by him a few days later: The vesicles, ranging in size from a pin-head to a small pea, are in groups, surrounded by a hyperæmic zone, and contain an opaline fluid, which, in some cases, has become purulent. The eruption is perfectly symmetrical on the two sides of the body. Beginning at the posterior cervical region it surrounds the neck, and, enveloping the shoulders, passes down along the inner side of the arm and forearm, and covers the palm and the latero-dorsal aspect of the fingers. The back is entirely covered, except for a space extending about an inch on either side of the spinal column. The supra-mammary and spinal regions are nearly free from vesicles, though there are a few scattered over the breasts. In the lumbar region the eruption spreads down over the nates and, anteriorly, slightly on the abdomen, showing itself in various points in the inguino-crural region on either side. It then descends along the outer aspect of the thigh, leaving the inner side perfectly free. There are no vesicles on the legs, but they reappear at the malleoli, and run along the edges of the sole, with here and there a few points on the plantar aspect of the foot. The patient suffers from severe smarting pains, but complains of but little itching. The fever ranges from 101° to 103°, accompanied by headache and occasional colicky pains. In some regions the tactile sensibility is increased in the patches of eruption, in others the sound skin between the groups of vesicles is more sensitive. The eruption remained stationary for a couple of weeks, when it began to recede, and at the end of a month had entirely disappeared, without leaving any cicatrices.

Diastolic Heart-murmur without Valvular Lesion.—Dr. N. Weiss (*Wiener Medicinische Wochenschrift*, May 27, 1882) reports the case of a man in whom during life a diastolic murmur was heard at the apex. The murmur was heard continuously for four weeks before death. The other heart-sounds were normal with the exception of the second sound at the aortic valve, which was accentuated. The patient died of cancer of the pylorus. At the autopsy there was found a patch of recent endocarditis on the auricular surface of the aortic half of the bicuspid valve. There were also traces of old endocarditis at the bicuspid with consecutive valvular aneurism; endarteritis deformans of the aorta, with dilatation of the ascending portion; eccentric hypertrophy of the left ventricle; commencing pericarditis with milk spots at the apex and over the right ventricle. The pericarditis could not have caused the murmur, and there is hardly room to doubt that it was connected with the changes found at the mitral valve. The little aneurismal pouches on this valve were turned with their cups facing the auricle, and were also slightly roughened. There was, however, no disturbance of function caused by these changes, nor was there any stenosis of the venous opening into the auricle. Here, then, there was no valvular lesion in the ordinary clinical sense of the term, yet there was a persistent diastolic murmur at the mitral opening observed during several weeks preceding death.

Spontaneous Cow-pox.—Dr. José R. De Argumosa describes a case of spontaneous cow-pox, observed by him in the spring of the present year. A servant called his attention to the cow, saying that she was uneasy when milked and that he had noticed some pimples on her udder. The papules were a little raised, whitish in color, and surrounded with a very slightly inflamed areola. When a crust was formed he removed it and inoculated a heifer in fourteen places on the udder and belly. On the fourteenth day there were six well-formed papules. With the lymph from one of these the author then vaccinated a boy, fourteen years of age. On the sixth day there was slight inflammation, and on the eighth umbilical papules appeared. The following day they were more marked and the boy complained of headache. The axillary glands were swollen and very painful. The vesicles were of enormous size, surrounded by a large erysipelatous areola, and contained a quantity of transparent lymph. The temperature was 38.4° C. The symptoms increased alarmingly, and on the eleventh day the temperature rose to a maximum of 40.1° C. All the symptoms, however, gradually subsided, and in a few days the boy was perfectly well. Seventy-seven persons were afterward vaccinated, and the observer summarizes the results as follows: The period of incubation was larger than is ordinarily the case. The vesicles were larger and surrounded by a much wider areola, and the fever was greater in intensity and duration. The cow in whom the disease was discovered had been separated from other animals for several months, and as small-pox was prevalent in the neighborhood at the time, the author believes that the disease was acquired from man.—*Revista de Medicina y Cirurgia Prácticas*, July 7, 1882.

Traumatic Hæmato-Pericardium.—The patient, a man, twenty six years of age, was caught between two wagons, receiving a severe compression of the chest. He was at first rendered insensible, but after a few moments recovered consciousness and walked to his home. Here he began to cough up blood, and his condition becoming quite serious, he was sent to hospital. About twenty-four hours after receiving the injury he was seen by Dr. G. Tiling, the reporter of the case. He was then pale and weak, spitting up a little frothy blood; temperature slightly above normal; pulse 60. Râles could be heard on both sides of the chest. At the posterior and lower part of the right side there was a fine crepitation with a dull percussion-note, not absolutely flat, and vesicular breathing. The apex-beat of the heart was not perceptible to the eye, difficult to feel, and diffused. Area of dulness extending a finger's breadth beyond the right edge of the sternum. The heart-sounds were masked by various indescribable murmurs in this region, but clear and distinct at the second intercostal space. There were no signs of air in either pleural cavity, and only a small effusion on the right side as indicated. There was no air in the pericardium. There was no fracture of the ribs or sternum. After the third day the patient began to improve and went slowly on to recovery. The pulse continued slow, ranging from 54 to 76. On the tenth day the area of heart-dulness remained about the same, but the heart-sounds were strong and clear without murmurs. A diagnosis was made of hæmato-pericardium from contusion of the heart without fracture of the ribs or sternum.—*St. Petersburger Medicinische Wochenschrift*, May 29, 1882.

The Rest-Cure in Chorea is recommended by Dr. James E. Goodheart (*Lancet*). It is applicable to acute cases only. Several cases with favorable results are reported. The method is essentially that of Weir Mitchell. It is a somewhat heroic measure and could not be employed in many cases.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 23, 1882.

MEDICAL MEN AND THE TEMPERANCE QUESTION.

So much is being constantly said regarding the direful effects of alcoholic indulgence, that most persons are, we fear, but little affected by temperance statistics, however startling. To the medical profession the general question of selling and using alcohol has seemed to be a moral or political one, and rather outside of its domain.

Of late years, however, the effects of this agent upon the human organism have been studied with much exactness. The diseases which it will produce and the mortality which it occasions have become known with some degree of accuracy. And it has become recognized that in the study of preventive medicine the effects of alcohol must occupy a large share of the attention.

There has thus developed a medical and scientific aspect to the temperance question which did not exist twenty years ago, when the experiences of reformed drunkards were the chief staple of temperance oratory.

But for all this we very much doubt if the actual and direct influence of alcohol in increasing sickness and mortality is felt as it should be. We are quite sure that the summary of facts regarding this subject presented by Dr. Norman Kerr, at the last meeting of the British Medical Association (MEDICAL RECORD, September 9th), will strike the attention of many on account of its novelty. One man in every seven or eight hundred, he says, is yearly killed in England by the direct effects of alcohol. The deaths and sickness produced indirectly are at least three times more numerous. In the army, deaths are twice as numerous among drinkers as among abstainers. If this is so, and there seems no reason to doubt it, the prevention of the abuse of alcohol should be classed among the most important of the fields of work for the sanitarian.

We would enforce the view that alcoholic abuse is to be looked upon by medical men as a source of disease and death. That it demoralizes the character and produces misery and crime are arguments for the philanthropist to wield. But the physician, by dealing directly with the pathological side, and that alone, can do his share, and make that an effective one in lessening the evil.

Basing its views upon physiological and pathological data, the medical profession cannot take the ground of total abstinence, although individuals may hold to such an opinion for personal reasons. For the disease and death produced by moderate use of liquors is very slight, so far as scientific data at present show. The profession should, we believe, as a body strive to secure the substitution of light and pure alcoholic or of non-alcoholic drinks for those which now do so much physical injury.

The good which properly directed medical effort can do in helping the temperance cause has been strikingly shown in England during the past few years. There has been an enormous increase in the use of non-alcoholic table beverages, and a corresponding decrease in the consumption of malt liquors. The *British Medical Journal*, in a recent discussion of this subject, describes also the remarkable growth of coffee-taverns. These are places fitted up in the heart of the poorer quarters of London, where coffee, cocoa, etc., can be had for a small sum. Over one hundred of these have been opened in London alone, and their success is unquestioned. It would be worth the while to try them in American cities more extensively and carefully than has yet been done.

EXPERIMENTS IN THE PHYSIOLOGY AND PATHOLOGY OF MUCOUS MEMBRANES.

In a series of articles recently published, Professor M. J. Rossbach, of Würzburg, has contributed some original facts to the subject of the physiology and pathology of mucous membranes. His researches point, also, to certain new therapeutical methods in treating diseases of these tissues.

The experiments described were made chiefly upon cats. In these animals the trachea was opened and the appearance of the mucous membrane directly observed under various conditions.

The tracheal membrane was found to be covered uniformly with a thin layer of mucus. If this were removed by gently applying absorbent paper, the secretion returned within from one-half to two minutes, but it was never secreted in sufficient amount to form drops. In other words, the action appeared to cease, or nearly so, as soon as the membrane was completely covered. The secretion of mucus is intermittent, not constant, according to Professor Rossbach. He has hardly proved this point, however, since it is more probable that the secretion is a very slight but constant one, with exacerbations when any irritant is applied. Our author suggests that the mu-

cin is first formed from the epithelium, and is then washed off or dissolved out by the alkaline fluid from the blood, a view that is probable enough. As regards the functions of this lining layer of mucus, Rossbach opportunely expresses the view that it has a protective function against the entrance of atmospheric organisms into the blood. Such a theory is plausible, and happily fits into the present pathological fashion.

Mucus is secreted equally well after the membrane has been severed from all the nerve-centres and trunks. There are, however, vaso-motor nerves running to it from various cerebro-spinal nerves; the mucous secretion is in a certain relation, therefore, with the nerve-vascular system.

Experiments were made to discover the effect of various drugs and reagents upon the tracheal mucous membrane. A hot bread-poultice was applied, then withdrawn and an ice-bag substituted. The membrane at once became whitened and bloodless. In one or two minutes this pale appearance changed to blue, showing venous stasis, and at this time a copious secretion was poured out. Upon repeating the applications of hot and cold, the same phenomena were observed but they came on more slowly and were less marked.

Professor Rossbach's experimental studies with various drugs used in treating pulmonary or bronchial disease, lead to some conclusions that quite contradict ordinary views, if not ordinary experience. As regards the alkalies (carbonate of soda, chloride of ammonium, etc.), for example, Rossbach claims that they do not increase mucous secretion, but the reverse. He experimented by injecting these salts directly into the blood, then watching the mucous membrane. After such injections the mucus was secreted more slowly and in less amount. The favorable action of alkalies in bronchial disease is attributed to a diminution of congestion and lessened secretion which they produce. Rossbach could observe no effect from the direct application of alkalies, as in inhalations.

The direct pencilling of the membrane with astringent solutions, such as alum, tannin, nitrate of silver in four per cent. dilution, caused diminution of secretion and a clouding of the epithelium.

Experiments with oil of turpentine gave some interesting results. If air which had passed through turpentine were blown upon the mucous membrane the secretion was diminished or stopped. Direct application of turpentine in watery solution, however, caused an increased secretion with diminished amount of blood-supply. This substance is a most valuable one, therefore, says Rossbach, since it is at the same time an antiphlogistic and expectorant.

The chief direct stimulants of the mucous secretion were found to be apomorphine, emetin (from ipecac), and pilocarpin. Of these apomorphine is practically the best and most useful.

Of agents which lessen the secretion atropin was found to be most powerful, being able to check the function entirely. Morphine, on the other hand, reduced, by about one-fifth, the normal amount.

As a practical outcome of his experiments Rossbach cites a number of cases in which he has used the drugs above mentioned. In his opinion apomorphine is one of the best expectorants. Combinations of it with morphine are also effective.

Rossbach's views with regard to apomorphine are confirmed by Dr. M. Wertner, of Wartburg, who reports his experience in the *Pester Med. Chirug. Presse.* Jürgensen has also used it as an expectorant in catarrhal pneumonia.

THE PRESERVATION OF BOVINE VIRUS.

THE use of bovine virus in this country for vaccinating has on the whole been a success. Every year it has supplanted more largely the humanized virus. Two objections, however, have been raised, and with some force, against its general adoption. Its action is too severe, and the quality of the virus is extremely variable. Experience in New York amply confirms the latter objection especially.

The points thus made against the use of animal virus have received much attention abroad, where the question whether such virus should be recommended is still, in many places, unsettled.

Not long ago the French ambassador to the court at Berlin deemed it worth his diplomatic time to write a letter to the Academy of Medicine of Paris, informing that body of a certain discovery by which bovine virus could be kept active for a long time. Two German physicians, Drs. Reissner and Pissin, had, he said, claimed to have found such a method. A description of their procedures was given.

Dr. Reissner takes the lymph from a vaccinated heifer, mixes it with glycerine, and allows it to remain upon a glass plate for forty-eight hours. The plate is kept in a dryer such as is ordinarily used by chemists. The mass being finally desiccated, is pulverized, dried again, and then sealed in glass tubes. When used a little is placed in a watch-glass, and water or water and glycerine added.

Dr. Pissin's method is slightly different. He places the contents of five or ten vesicles in a watch-glass which contains about ten drops of glycerine. This is mixed with an equal amount of a one-half per cent. solution of salicylic acid. The whole is then deposited in glass tubes, which are carefully sealed.

Vaccine matter prepared in these ways has been used under the direction of Dr. R. Koch with very encouraging results, having been kept active for eighteen months. Dr. Reissner's method is considered somewhat the better, or at least the more convenient.

It is stated, on the other hand, by the editor of the *Gazette Medicale de Paris* that Dr. Hirschberg (not Samuel), of Posen, has not had so good results, but we are told, further, that this may have been due to unskilful manipulation.

At any rate, it would be worth the while to test these methods here, where bovine virus is so extensely used and where any method which ensured its trustworthiness would be of the highest importance.

Reviews and Notices of Books.

Atlas of Gynecology and Obstetrics. By Dr. E. Martin, Professor Gynecology, University Berlin, and Dr. J. P. Maygrier, Member de l'Academie Roy. de Med., etc. Explanatory text translated and edited, with additions, by Wm. A. Rothacker, M.D., Pathologist to the Cincinnati Hospital. Cincinnati, Ohio: A. E. Wilde & Co.

This large and beautifully printed atlas, giving life-size illustrations of diseases of women and of obstetrics, is mostly made up of Martin's celebrated "Atlas of Gynecology" and Maygrier's popular "Demonstrations of Midwifery." The size of the plates and their faithful reproduction are the distinctive features of the work. The range of subjects is wide and comprehensive, comprising a complete exposition of the anatomy of the womb, gross and microscopical, the relations of the organ to surrounding parts, the diseases affecting the genito-urinary apparatus in the female, including tumors, etc., the signs, course, and mechanism of labor and operative obstetrics generally. Of the five hundred and ten illustrations, thirty-five are colored, thus giving at a glance the different normal and abnormal appearances presented. The text to the gynecological portion is a translation of that contained in Martin's work, while the text to the plates on obstetrics was written specially for the atlas. It is an admirable atlas, and will doubtless find much favor among general practitioners who do much in gynecology and obstetrics.

Diseases of the Ear in Children. By Anton Von Troeltsch, M.D., Professor, University Würzburg, Translated by J. Orne Green, A.M., M.D., Aural Surgeon, Boston City Hospital. 8vo., pp. 165. New York: William Wood & Co. 1882.

This is a remarkably practical work on a class of ear diseases most commonly met with, and goes over the field designated in its title in a concise and masterly manner. The subjects are simply and naturally arranged. To the general practitioner it is almost an indispensable addition to his library.

Syphilis. By V. Cornil, Professor Faculty of Medicine, Paris. Translated, with notes and additions, by J. Henry C. Simes, M.D., Demonstrator of Pathological Histology, University Pennsylvania, and J. William White, M.D., Lecturer on Venereal Diseases, University Pennsylvania. 8vo. pp. 458. Philadelphia: Henry C. Lea's Son & Co. 1882.

Professor Cornil has perhaps studied syphilis from an anatomical standpoint more than any other syphilographer living, and his views, as given in the leçons which form the basis of the present work, will now, for the first time by our English-reading audiences, be appreciated in their full significance. Professor Cornil has gone over the field in a thorough and practical manner, and by his personal investigations, experiments, and study, has thrown new light upon many obscure points connected with the pathological histology of the chancre and its various constitutional lesions affecting skin, mucous membranes, bones, glandular organs, and nervous system. Interspersed with these are numerous clinical illustrations of salient points under discussion. The translators have given very substantial aid in this direction. Dr. James W. White has contributed an excellent note on syphilis of the teeth. The work is a valuable contribution to the literature of the subject, and will be found specially useful to the student who wishes to lay the proper and substantial groundwork for future studies.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland. Eighty-fourth Annual Session.

The Transactions of the Medico-Chirurgical Faculty of Maryland for the year 1882 comes to us in the usual style, and contains the usual amount of interesting material. In our exhaustive report of the meeting, made some months ago, we presented our readers with abstracts of such papers as were of interest and the discussions thereon. These papers are published in full in the present volume, as well as the official reports of the discussion.

Transactions of the Indiana State Medical Society, 1882. Thirty-second Annual Session, Indianapolis, 1882.

This yearly volume is more than ordinarily full of good papers. Notably among the latter are the following: "Case of Complete Transverse Rupture of Vagina at Junction of Uterus," by A. G. Preston, Green Castle; "Hot Water in Surgical Practice," by John R. Weist, M.D., Richmond; "Heredity and its Relations to Diseases," by J. Iutzi, M.D., Richmond; "Health Resorts in the United States," by E. S. Elder, M.D., Indianapolis; "Primary Cancer of the Lung," by G. W. H. Kemper, M.D., Muncie, and "Laceration of the Female Perineum," by H. V. Sweringen, Fort Wayne. The volume is of the usual style and size of its predecessors.

A Rationalistic Materialistic Definition of Insanity and Imbecility, with the Medical Jurisprudence of Legal Criminality. Founded upon Physiological, Psychological, and Clinical Observations. By Henry Howard, M.R.C.S., Eng. Montreal: Dawson Brothers. 1882.

Dr. Howard considers insanity "to be a physical disease, caused by a pathological change in the sensory nerves and organs of consciousness, or either, consequently loss of consciousness, increased reflex action, confusion of intellect, loss of intellect, necessarily loss of normal reason; insanity."

The quotation of the above might be considered sufficient criticism of the book. Yet it deserves a kinder treatment. Dr. Howard writes with a deep sincerity and earnestness, which claims our respect. The main points for which he is arguing also are, no doubt, correctly taken. There is, however, hardly a page in which he does not insert some physiological error, or exhibit a psychological crudeness. He gropes blindly toward his goal.

It strikes us also that Dr. Howard equips himself with much labor to prove what is already accepted. Certainly there are very few medical men

who deny that insanity is a physical disease. And so long as no one knows what matter or what essence is, there can be no harm in saying, as Dr. Howard does, that mind is one of the phenomena of matter, as we know it, remembering that with equal truth one can say that matter is a phenomenon of mind.

DOCTOR, WHAT SHALL I EAT? A Handbook of Diet in Disease for the Profession and the People. By CH. GATCHELL, M.D. Second edition. Chicago: Duncan Brothers. 1882.

THIS little book is quite well compiled and well arranged. It is better than one would infer from its awkward and infelicitous title.

THE MEDICAL DIGEST; or, Busy Practitioner's Vade Mecum. Being a Means of readily acquiring Information upon the Principal Contributions to Medical Science during the last Thirty-five Years. By RICHARD NEALE, M.D. Second edition. London: Ledger, Smith & Co. 1882.

THE first edition of this Digest was printed by the New Sydenham Society in 1877. It is now enlarged and brought down to date. It consists of a subject-index to all the leading English medical journals, including, in addition, one or two Scotch and American journals, and a few standard medical works. The number of journals and books indexed is large and well selected. The list includes, however, several monthly and quarterly periodicals devoted to abstracting foreign articles. The Digest, therefore, contains a reference to nearly everything of medical importance which has been published in the past thirty five years. The indexing is very thoroughly done, there being in almost all cases cross references. The reader can, without trouble, find all the articles upon any given subject published in the journals indexed. There are, we are informed, nearly ten thousand references and over one hundred and twenty thousand distinct entries.

The author says that the work has occupied him, on the average, *four hours per diem for thirty-five years*—a statement that compels us to look at the book with some awe as well as respect. The time which Dr. Neale has lost, the profession will gain. His book cannot fail to be of immense service to all practitioners, whether "busy" or not.

THE NATURAL HISTORY OF DOCTORS.—M. Colien, says *L'Union Médicale*, compares the different classes of the medical world to those of the ornithological world, and thinks that Cuvier's classification adapts itself perfectly to the disciples of Æsculapius, *e.g.*:

First Class.—The *Rapaces*. The eagle holds the first rank. Such are our great physicians, our great surgeons and specialists.

Second Class.—The *Passereax* (sparrows, etc.), which includes the medical journalists (*diarii*) and bookworms (*bibliophylaces*).

Third Class.—The *Grimpeurs* (climbers), who can hardly fly at all alone, but are very skilful in making use of the help of others.

Fourth Class.—The *Gallinaces*, of which the representatives are the army surgeon (*iatros cristatus militaris*) and navy surgeon (*iatros cristatus aquaticus*).

Sixth Class.—The *Palmipedes*, aquatic birds who live in water, upon water, and by water. Of these there is a sub-class, the *Saccharum lacti ferendes*, who live upon sugar of milk.

Correspondence.

CASE OF ACUTE ASCENDING PARALYSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I was called, July 1, 1882, to see Maggie M——, a healthy, robust, unmarried lady, thirty years of age, who, during her whole life, had not suffered from ill-health. I found her lying upon a lounge, feeling, as she expressed herself, quite comfortable, except that there was a bitter taste in her mouth and she could not move her lower limbs. As she said, her "knees gave way" upon trying to stand. She was entirely helpless from her knees down. Sensation was not impaired. She had had several chills, and was evidently suffering from the malarial influence which prevails in this region to a considerable extent. The arms and upper portions of the body were not affected. I did not consider it a serious matter, having lately met with malarious patients affected in much the same way, though in a minor degree. I regarded it as simply a novel concomitant of the bilious disorders of the season. By the next day the disease had made further progress, involving the whole of both limbs, including the hips, so that the patient was entirely unable to walk. Still, sensation was perfect, and the functions of the body above the hips complete. The greatest source of complaint, aside from inability to walk, was the excessive bitterness in the mouth, which continued to the end. Without following the case in detail throughout its course of eleven days, I will state that the paralysis was steadily progressive from below upward, affecting both sides of the body equally, except the face, the muscles of one side only being affected. The motion of the forearms remained more or less perfect throughout the disease. The case ran on until the tenth day without any modification of the symptoms, but on that day the muscles of deglutition and respiration became seriously affected, placing the life of the patient in imminent danger. These symptoms grew rapidly worse, and the patient died on the afternoon of the eleventh day of the disorder. The febrile symptoms manifested in the progress of the case were those of a remittent character, and were always moderate. There were two points of tenderness along the course of the spine—one at the beginning of the dorsal region, the other one at the junction of the lumbar with the sacral vertebræ.

My treatment consisted in the administration of antiperiodic doses of quinia, strychnia, and the use of counter-irritation to the spine. This was followed out for several days with the concurrence of Dr. C. B. Pearson and Dr. T. F. Stair, of Mazomanie, called in consultation. Subsequently, my friend, Dr. Cutler, of Dodgeville, saw the case with me, who recommended, in addition to counter-irritation, thorough mercurialization and iodism. His suggestions were carried out.

Perhaps physicians in longer practice may be enabled to recall cases of this kind frequently, but to me the circumstances surrounding the case are peculiar, and I have not been able in my reading to find anything analogous to it. It seems to me the obscurity (if it is such) lies particularly in the direction of the cause. I have tried to show in this imperfect statement of the case the presence of the distinctive characteristics of a mild form of bilious

remittent, the rapid progress to a fatal termination, the previous perfect health of the patient, the presence of similar symptoms—though much milder ones—in malarial cases occurring at the same time.

J. B. Stair, M.D.

Spring Green, Wis.

BORO-GLYCERIDE.

To the Editor of The Medical Record.

Dear Sir: I have read with interest your editorial in The Medical Record for September 2d, concerning boro-glyceride. Its antiseptic properties and usefulness in surgical dressings were first brought to my notice in the wards of the Charing Cross Hospital this summer. I had been watching with interest the use of iodoform in the German surgical wards during the winter, where it is used profusely.

In the Charing Cross Hospital I had the opportunity of *comparing* the carbolic iodoform and boro-glyceride surgical dressings. It is fair to say that the worst cases were given to boro-glyceride, but with the most gratifying results. In the boro-glyceride treatment you get *no increase of temperature*, in other words, no poisoning, as in the case of carbolic and iodoform treatment. The wounds have a healthy and cleanly appearance, healing rapidly, which is most satisfactory, and the whole condition of the patient seems to be better under this mode of treatment. Combined with vaseline, it makes an admirable dressing in minor surgical operations, ulcers, etc. In solution, it is valuable as an injection in vaginitis, otorrhœa, etc. Its introduction into surgery seems most fortunate and most satisfactory, and it will undoubtedly take the place of either carbolic acid or iodoform. A very superior preparation of boro-glyceride can be obtained of Messrs. Theodore Metcalf & Co., Boston.

I sincerely hope that the valuable properties of this new antiseptic will be appreciated by the profession.

Very truly yours,

W. Thornton Parker, M.D.

Jamaica Plain, Mass.

THE CLIMATE OF FLORIDA.

To the Editor of The Medical Record.

Sir: Dr. Haywood's experience, as given in The Record of August 12, conflicts decidedly with that of most medical men in this State. In my own case several years' residence in the highlands of Central Florida have relieved me of a harassing cough, night sweats, a hectic flush, anorexia, and from the invalid of one hundred and thirty pounds weight, dreading the cold, I now am able for continuous labor, weigh one hundred and sixty-six pounds, and have long ago discontinued the use of cod-liver oil, phosphites, etc.

Dr. Z. H. M——, of Apopka, Fla., has a similar experience. Coming from Georgia to find a temporary respite, year after year has passed away and the doctor now is the picture of rosy health in his old age.

Dr. C. J. K——, of Jacksonville, an old traveller, a scientific investigator, and widely known for his own case, has tried many climates and has fixed upon Florida as the best.

Twelve years ago Dr. McM——, of Charleston, S. C., brought his wife, a confirmed consumptive, to Gainesville, Fla., to spend what seemed a small remnant of life more comfortably. To-day she bids fair to reach the "three-score and ten," despite the "exceedingly debilitating" climate.

Col. J. H. R——, came from South Carolina as a winter resort, having all the symptoms of phthisis in an advanced stage. Now he is an active, comparatively healthy man, utterly unlike his former self.

I need not multiply examples, almost every neighborhood in this section can supply them, of the competent medical men who in their own cases are satisfied of the value of this climate as both preventive and curative of tuberculosis.

In this section of the State, high, dry, rolling pine land, and perfect drainage, in six years and in one thousand cases I have seen but four of pneumonia, and two of these traumatic. Can Dr. Haywood say as much even for Beaufort or Raleigh?

During the summer we have a mild form of malaria, but as to effect of such a climate upon phthisis I would refer him to Dr. Lawson, pp. 297, 389. Aitken, vol. i., p. 265.

These malarial attacks are easily subdued, and fatal cases are rare. Too many physicians allow their patients to remain in a cold, changeable climate until the lungs are a mass of tubercle, then send them to Florida too feeble to take out-door exercise, often with but little money to procure attentions or delicacies necessary, and among strangers the poor invalid becomes nostalgic and sinks rapidly, and then Florida is blamed. This ought not to be, but every season finds our hotels filled with cases that should be at home among friends, making ready for the rapidly approaching close of life.

There is, however, a positive curative agency in this climate for certain ailments, and to guide the profession, I beg to submit the results of many years of careful study both of cases and climatic factors.

These factors are location, soil, drainage, water, sunshine, temperature, humidity, and air-pressure. And with reference to a strip of elevated land, lying forty miles from either coast and extending from 28.30° to 30° latitude, I think no place east of the Rocky Mountains is better suited for the amelioration if not cure of incipient tuberculosis, asthma, catarrh, nervous complaints, and bronchitis.

The location—Almost insular, constantly traversed by warm breezes from the sea and gulf, in the track of trade winds, and the freshness tempered by miles of almost unbroken forest.

Soil.—Very sandy with but little humus, or animal remains; configuration broken, rotting, often eighty to one hundred and fifty feet elevation above the gulf. Drainage perfect, no stagnant pools or marshes.

Water.—In the main freestone, in wells twenty-five to sixty feet deep, with an average temperature of 65° F.

Timber.—The long-leafed pine, with little undergrowth, allowing free circulation of air.

Sunshine.—Twenty-two days of each month of almost clear skies, the remainder often partly available for out-door exercise, and during the winter the rains are usually at night, leaving the day cool and bright (see note). The rainy season begins in June and lasts till September. Often a week of showery days, then clear skies a week. During the rains the temperature falls to 72° F., and this season, in comparison with the torrid days of the north, is

quite endurable, and as these showers rarely last but a few hours, the remainder of the day is available for exercise or labor.

Temperature.—Unquestionably a climate allowing a loose easy costume with few wraps, and no requirements of hot, stove-heated, badly ventilated rooms, is best for weak lungs. The houses of this section are built for free ventilation—no stagnant air in cellars or close dirty bedrooms. Blizzards, northers; sudden changes, causing cold extremities, visceral congestions, or surface chilling, are extremely rare, and as they occur, if at all, in December or January, can easily be kept from harming.

The summer maximum is usually 96° F., and this for only a few hours. But 96° is not common. In 1880 it reached that point but four times in June, once in July, and once in August; this year twice in July and once in August.

The night temperature for the months from May to October is from 70° to 76°, and from October to May, 60° to 65°. The hot, sweltering nights so common in the North are unknown here. October, November, and till April are months comparable with the Indian summers of Pennsylvania—days dry, breezy, and bracing, the whole season enjoyable. (See Note.)

Humidity.—Much has been said of the dampness of Florida, but the observations of the Signal Service show nothing excessive in its humidity, and this section compares favorably with most health resorts, the annual mean for a long series of years being 69° against 73° at Menton, 68° at Nassau, 67° at St. Paul, Minn.

Air-pressure.—I have no doubt but that this is the most important factor of value in our climate—its remarkable equability of air-pressure. If we regard in the lung the pressure of the heart upon the mass of the blood as balanced against the air-pressure and strength of the blood-vessel walls, it is readily seen that in a diseased lung, a decrease of air-pressure tends to congestion, and at points of weakened tissues from any cause, if the air-pressure be sensibly diminished, hemorrhage may occur. Any physician will recall instances showing that the changeable months of spring and autumn occasion great distress to tuberculous patients, and the cold of January was not as fatal as the storms of March. A fall of even one-tenth inch mercury in the barometer produces a decided discomfort, and the descent of half an inch a temporary congestion, dyspnœa, headache, or neuralgic pains. Hence patients can often predict storms from their disagreeable sensation.

A climate offering the maximum of air-pressure and the minimum of change, with a genial temperature, leaves but little to be desired for patients requiring rest and warmth, and this section surely meets the wants of such cases. (See Note.)

A dozen invalids live near me, some hemorrhagic, some neuralgic, but all have experienced relief, and the majority of cases of rheumatism, asthma, bronchitis, and catarrh are alike favorably affected by this equability.

The practical deductions are readily apparent.

Northern invalids, in which the deposit of tubercle is incipient or limited; aged invalids requiring rest, warmth, and relaxation; neuralgic cases, nerve-worn patients, the whole range of uterine troubles resulting from congestions, all cases that grow better in the warm settled days of May or October, and get worse in November and March—these should be advised to try Florida, especially this section, with hope of betterment.

With discharging cavities, or fully tuberculized lungs, little aid can be given, though our 220 clear days, average air-pressure of 30.03 inches, and mean temperature of 71° will aid in pleasantly prolonging life.

Many when here neglect the most common sanitary laws, expose themselves recklessly to heat, rain, and dew, take fatiguing exercise, sit in draughts, eat to excess, and do not derive the benefit they should.

A little common sense would obviate this, and save much blame now given to Florida.

JAMES C. NEAL, M.D., PH.C.

ARCHER, FLORIDA, August 28, 1882.

NOTES.—*Temperature.* Mean, December and January, 55°; February 58°; March and November, 63°; April and October, 70°; May and September, 77°; June, 80°; July and August, 82°.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from September 9, 1882, to September 16, 1882.

WRIGHT, J. P., Surgeon. Granted leave of absence for one month, with permission to apply for an extension of one month, on Surgeon's certificate of disability. S. O. 181, Department of the Missouri, September 8, 1882.

MADDOX, T. J. C., Assistant Surgeon. To proceed from Fort Clark, Texas, via San Antonio and Larido, to Fort Brown, Texas, for duty. S. O. 96, Department of Texas, September 8, 1882.

TAYLOR, MORSE K., Assistant Surgeon. Relieved from duty as Attending Surgeon at Detroit, Mich. S. O. 157, Department of the East, September 9, 1882.

CORSON, JOSEPH K., Captain and Assistant Surgeon. Granted two months' leave of absence. S. O. 210, A. G. O., September 9, 1882.

SHUFELDT, ROBERT W., Captain and Assistant Surgeon, now awaiting orders, to report by letter to the Commanding General Department of the South, for assignment to duty. S. O. 209, A. G. O., September 8, 1882.

BACHE, DALLAS, Surgeon. Informed by Adjutant-General of acceptance of his certificate of disability of August 31, 1882. On sick leave from September 1 to 30, 1882.

HORTON, S. M., Major and Surgeon. Granted one month's leave on surgeon's certificate of disability. S. O. 96, Department of the Platte, September 11, 1882.

WRIGHT, J. P., Surgeon. Granted one month's leave of absence, with permission to apply for extension of one month, on Surgeon's certificate of disability. S. O. 181, Department of the Missouri, September 8, 1882.

THE SEA-SIDE SANITARY HOTEL OF THE FUTURE.— Anxious guest to hall-boy: "Boy, where are the water-closets?" "Hain't got any, sir; they breeds fever. Boat goes down the harbor every morning. Ladies at nine, gentlemen at ten." "Well, is dinner ready?" "No, sir. We always carbolize the dining-room before meals. Now they are spraying the waiters, sir." Impatiently: "Well, where is your ice-water?" "Don't have drinking-water now, sir. 'Tain't healthy. Yonder's our Labarraque mixture flavored to taste. Have a glass, sir?" Guest retires and takes a thymolized julep.

THE NEW YORK COLLEGE OF VETERINARY SURGEONS has removed from the former College building, No. 205 Lexington Avenue, to the College of Pharmacy in East Twenty-third Street, where the Fall session will open on October 4th, the lectures of the College of Pharmacy taking place in the evening, and those of the College of Veterinary Surgeons in the morning and afternoon. The arrangement is a convenient and fortunate one for both parties. The faculty remains unchanged; and, in addition to the regular corps of professors, a large staff of special lecturers has been secured by the efforts of President Rawson; and the veterinary students will also have access to the practical chemical course of the College of Pharmacy.

COTTAGE HOSPITALS.—Dr. Charles A. Hart, of Plainfield, N. J., writes: "I was very much interested, in a recent issue of THE RECORD, in the article on 'Cottage Hospitals,' but was disappointed at seeing no mention of the pioneer effort of the kind, in the establishment of the Muhlenberg Hospital of this place. The building in point of construction combines the latest known advances in hospital architecture, having a capacity for twenty-five patients. It has been in active running operation since last December, and has already given aid to over fifty patients. The cost of the building was about $5,000. The increasing usefulness is demonstrating itself daily, and before long will require additional force for its running."

SWALLOWING OF TWENTY NEEDLES BY A CHILD.— A boy, aged three, while playing with a needle-case, had swallowed twenty needles (5 ctms. long). Five days later, sixteen needles were discharged per anum, glued together by fæces. The remaining four came out, one by one, on the sixth and seventh days. There were no symptoms, except occasional abdominal pain, and no treatment.

SAMARITAN SCHOOLS.—Prof. Esmarch, the well-known surgeon of Kiel, recognizing the advantages of immediate attendance in cases of accidents, has instituted a number of schools in that city which are called Samaritan schools. They are composed of youth of both sexes who are so instructed that in case of accidents they can render every assistance necessary until the arrival of the physician. Prof. Esmarch has written a small work upon the subject, in which he exposes the various means to be employed under such circumstances.

HEMORRHAGE AFTER TONSILLOTOMY. — Lefferts (*Archiv. of Laryngol.*, Jan. 1) in five hundred tonsillotomies found: 1. A fatal hemorrhage very rare. 2. A dangerous one occasionally. 3. A serious one in both immediate and remote results not very unusual. 4. A moderate one requiring direct pressure and strong astringents to check it common. In the majority of cases no trouble is experienced.

PROGRESS OF HOMŒOPATHY.—At the recent meeting of the American Institute of Homœopathy, at Indianapolis, Dr. Talbot, of Boston, read a report showing that there are 7,000 homœopathic physicians and 278 institutions in the United States; four national societies report 1,067 members; twenty-six state societies, 1,783 members; one hundred and three local societies, of which sixty-six report 2,355 members; twenty-three general hospitals, of which eighteen report 1,268 beds. The cost and values of these hospitals are $1,106,000. Of twenty-nine dispensaries, twenty-seven reported having treated last year 1,469 patients; to these had been furnished 256,589 prescriptions. Twelve medical colleges have had 1,267 students, and graduated 412 physicians this year, and 1,680 since they were founded.

EXPERT TESTIMONY.—A case was recently tried in Chicago which brought up this question in a new phase. A member of the Eclectic society was expelled for violating its code of ethics by advertising a patent medicine. He brought a suit of criminal libel against the president of the society. During the proceedings several lay witnesses were called to testify to the virtues of the medicine. Their testimony was excluded on the ground that they were not experts, and consequently not capable, legally, of giving evidence on the subject. The point at issue in the case was not of special medical interest, but this decision is, as it gives legal sanction to what has been long recognized as a fact by the profession. In the war against patent medicines this decision may yet prove of value.—*Chicago Medical Review.*

RUSSIAN NAVY MEDICAL SERVICE.—Dr. Burch, the Director-General of the Medical Department of the Russian Navy, has been placed on trial for receiving bribes for promotions given to subordinates. Eighty-

six surgeons testified that Dr. Burch has not for many years made a promotion without receiving such a payment; in one instance the sum paid being three thousand one hundred rubles.—*Chicago Medical Review.*

A Peculiar Diagnosis.—A case of small-pox at Fort Worth, Texas, was diagnosed by the irregular practitioner in attendance as "erysipelas from the toes to the knees, measles from the knees to the waist, and seven-years itch from the waist to the top of the head." In consequence of this diagnosis several persons, who were allowed to visit the patient, contracted small-pox.—*Chicago Medical Review.*

Scurvy is on the increase in the British mercantile marine, though to no very alarming extent. The cases reported in 1880–81, were ninety-nine against seven in 1873, and eighteen in 1874.

Antiseptic Midwifery.—Dr. F. Barnes is said to deliver his hospital patients under the carbolic spray. This is the lunacy of Listerism.

The Ratio of Deafness to Population in Prussia, according to the last census, is 10.2 per 10,000, the total number being 27,794. This is an increase of about eighteen per cent. in the past decade. In 9,468 the deafness was congenital. Among Protestants the deafness amounts to .98 per cent., among Catholics to 1.09 per cent., among Jews to 1.438 per cent. The excess among the Jews is accounted for by their custom of intermarriage.

The Anti-Fat Dietary of Mr. Joseph Harass, by which he reduced his weight in nine months from 187 to 150 lbs. is as follows: Breakfast.—Vegetables, brown bread (toasted), water, with lemon-juice, and occasionally oatmeal. Dinner.—Vegetables, brown bread, water, and plain pudding. Supper.—Brown bread (toasted), stewed fruit, and water. No tea, coffee, cocoa, or milk, except skimmed, and only a trifle of butter.

Will Salting Kill Trichinæ?—M. Colin and other experimenters have claimed that salting will kill trichinæ. M. Fourment has just contributed evidence to the contrary. He took a piece of meat on April 19, 1881, from some American salted meats examined at the Havre docks and found infested. The meat was placed in a flask and imbedded in fine salt. It was then hermetically sealed and not opened till April 1, 1882. By this time the meat had undergone a year's salting carried to the highest degree, and if we add the time that must have elapsed since it was first put in salt in America (which could not be put at less than three months), the meat may be said to have been in salt for at least fifteen months. The meat was then cut up into small pieces, and these were placed in water, which was frequently changed to remove the salt, and remained for several hours in a temperature of 71° F. On April 4th, 5th, and 6th this was fed to a mouse, which died on the 7th, after presenting symptoms of diarrhœa. The intestine was evidently inflamed, and contained sexually developed trichinæ. A second and a third mouse were fed with more of the meat, and with exactly similar results in each case. Several other experiments were made. M. Fourment says that all show that the trichinæ were then certainly alive and capable of reproduction after fifteen months of salting; and it is consequently manifest that salting does not surely and rapidly destroy these parasites. They may die in salted meats as well as in any other situation, and thus explain the negative experiments published by distinguished observers; but they may also live a considerable time without our being able to determine the length of the period after which death necessarily follows latent life. But, although salting is thus an uncertain remedy, there need be no danger whatever from trichinosis if only the meat be properly cooked. In no single case—and there have been numerous experiments made—has heat failed to entirely destroy these parasites. Fjord, in Sweden, and Krabbe, in Germany, have both proved that a temperature of 129° F. kills trichinæ if maintained for fifteen minutes, while 158° F. has been shown by many experiments to kill instantaneously. Only those who neglect the precaution of thorough cooking—absolutely necessary in the case of all pig meat and sausages—need be under any fear of these parasites.

State Boards of Health.—Only nine States are now without a State Board of Health. These are the following: Florida, Kansas, Maine, Missouri, Nebraska, Nevada, Ohio, Pennsylvania, and Vermont.—*Dr. Gihon in Am. Med. Association.*

Operating for Elephantiasis.—Dr. George A. Turner, for twelve years a medical missionary in the Samoan Islands, has published in the *Medical Abstract*, a report of one hundred and thirty-eight cases of amputation of the scrotum made by himself, for elephantiasis Arabum, of which number only two died. There is nothing about his mode of operating which can be regarded as new, except his use of a large clamp to restrain the hemorrhage during the operation. His success was, however, remarkable.

Hasuer of Prague.—Let me devote a little space to Hasuer, the oculist. His name is familiar only to the students of ophthalmological literature, at home, and yet I suppose he is the most expert and rapid operator, perhaps, of the present century. May 16th is the day allotted in the calendar to St. John Nepomuck, the patron saint of Bohemia. On this day the halt, the maim, and the blind come in from all the surrounding country for treatment. Among this motley crowd are a great many cataract cases, and on one of these occasions, having his patients all made ready, Hasuer is known to have operated on *twenty-three eyes in one hour.* I have seen him several times, and can testify to the wonderful rapidity and certainty of his movements. I saw him one day remove two cataracts from different patients in different rooms, and also operate on both sides for strabismus, *within six minutes.* Of course no anæsthetic was used, and all the dressing was left to the assistants. Hasuer has his own method of extracting cataract. He uses a Beers knife, makes an incision closely corresponding to the Graefe cut, and then, instead of an *iridectomy*, he performs an *iridotomy.* Most of his results are wonderfully good. Surely the method is deserving a trial on your side of the ocean.—*Roswell Park in Chicago Medical Journal and Express.*

The "Gonococcus."—Neisser, in Breslau, who in 1879 published the discovery of a micrococcus which was to be found in every case of specific blenorrhœa either of urethra or of eye, but nowhere else, has recently recorded his conviction that this "gonococcus," as he christens it, is the specific agent in producing the disease; and quotes Aufrecht, Ehrlich, and Gaffkey, the ophthalmologists Leber, Sattler, and Hirschberg in support of his statements. But until recently the *experimentum crucis*—successful inocu-

lation of the micrococci—had never been performed from the simple fact that animals are not susceptible to the gonorrhœal contagion, and human subjects have always preferred to acquire theirs in another way. Recently, however, Bokai, in Pesth, was so fortunate as to find six philanthropic students who placed their urethras at the disposal of science. With the "gonococci" which Bokai had cultivated artificially from gonorrhœal discharge, the six were inoculated; and three had the satisfaction of exhibiting a week later a classical gonorrhœa. For one somewhat familiar with the natural history of medical students, the experiment would have been far more convincing if the dauntless three had been kept in solitary confinement for a week before and after the inoculation.—*W. T. Belfield in Chicago Medical Journal and Examiner.*

Prague as a Medical Centre.—In every respect, then, Prague deserves the attention of any one going abroad to study. Everything is cheap, even whatever private instruction a man may want. I think no one ought to study in Europe until he has done some work and some practice at home; but to such I can most cordially commend Prague, both as a place where he will be treated much better in every respect than in Vienna, and as a field for study which compares most favorably with Berlin and Vienna, and perhaps ranks next to them.—*Roswell Park in Chicago Medical Journal and Examiner.*

Woman's Hospital of the State of Illinois.—The following is the arrangement of the staff since the recent organization: Dr. W. H. Byford, Dr. J. H. Etheridge, Dr. Daniel T. Nelson, Dr. H. P. Merriman, Dr. E. O. F. Roler, Dr. E. Warren Sawyer, Dr. A. M. Davenport. Consulting Physicians: Dr. J. Ramsey Flood, Dr. D. R. Brower.

Chloride not Chlorate of Potassium is the specific for mercurial stomatitis. As pointed out by Professor Wertheim recently, the chlorate is very generally prescribed. The chloride can be used in saturated solution for the above trouble. It is less irritating than the chlorate.

The Medical Chronicle is the title of a new monthly journal edited by Dr. George H. Rohé and published in Baltimore. It is the only medical monthly in that State. It presents a good appearance and makes the one hundred and eighty-fifth American medical journal and the seven hundred and eighty-seventh medical journal in the world.

A New Treatment for Small-Pox.—Some months ago Dr. Ducastel reported a new method of treating small-pox. It consisted in the administration of a mixture containing opium and ether, of a second mixture containing perchloride of iron, of the hypodermic injection of ether, and the administration of alcohol. Since May 1st, Dr. Dreyfus-Brisac has been in charge of some small-pox wards, at the Hospital St. Antoine, where he has had an opportunity of testing its value. His report is published in the current number of the *Gazette Hebdomadaire.* The treatment was at first carried out in its entirety, but after a time the perchloride of iron was omitted except in hemorrhagic cases. The injections of ether were disagreeable, but not enough to cause any of the patients to refuse them. Sometimes they caused a painful inflammatory induration, which occasionally terminated in a purulent collection, requiring incision, or in a small superficial sore which heals up rapidly. The effect of the treatment on the general intoxication remains problematic, but its influence on the eruption is undeniable. The papules on the mucous surfaces as well as those on the skin abort. Small-pox is transformed practically into varioloid, and the serious complications of the third period of the disease scarcely ever occur. In many of the cases a severe eruption of boils, without any evil consequence, occurs during convalescence. Dr. Dreyfus-Brissac has always endeavored to carry out the treatment with opium and ether, but he thinks that the former plays the more important part, for when the mixture, as occasionally happens, is rejected by the stomach, and the treatment is practically reduced to the hypodermic injection of ether, the result is far from being as satisfactory as with the mixed medication.

Bromide of Potassium in Diabetes.—M. Felizet, a Paris surgeon, claims to have cured fifteen cases of diabetes by the use of bromide of potassium. He reports experiments showing its favorable action in artificial diabetes produced in animals. Others have not been so successful as M. Felizet.

Composition of Commercial Foods.—In the *Centralbl. f. allgem. Gesundheitspflege* Stütze records the results of an analysis of a number of commercial foods, breads, biscuits, prepared meal, etc. We cite a few of these:

	Digestible albumen.	Fat.	Carbohydrate.	Water.	Salts.	Alcohol.	Carbohydrate with extractive glycerine, etc.	Extractive (creatin, etc.).
Prepared oatmeal....	9.12	7.10	72.51	10.3	0.95			
Nestle's Food.....	9.9	5.16	79.30	4.17	1.4			1
Fresh white bread...	7.20	0.28	60.76	30.2	1.48			i
Hoff's malt extract ..	0.28	..	...	91.29	0.13	1.20	7.10	.
Linck's malt extract.	2.50	..	63.46	33.11	0.93			
Cacao (Lobeck's)....	4.16	33.4(!)	52.00	6.55	3.78			
Ordinary lean beef...	18.53	3.45	..	74.26	1.17	..	..	2.59
Liebig's extract of meat	3.40	..	..	19.57	23.18	..	..	53.85
Anglo-Swiss condensed milk.....	8.79	10.45	54.22	24.79	1.75			

A pound of lean beef contains about as much digestible albumen as fifteen hen's eggs. The following instructive table shows the change in making soup by boiling lean beef in water with salt for four hours.

	Left over in the soup.	Remaining in the meat.
Digestible albumen.....	1.51	17.02
Fat.....	0.52	2.93
Extractive (chiefly creatin)....	2.29	0.30
Salts.....	0.82	0.35
Phosphoric acid	0.318	0.187

Patent Medicines and Quack Nostrums.—Dr. W. W. Hebbard, of Boston, Mass., writes: "Boards of health and newspaper experts are dealing out cautions and suggestions to the people about unhealthy water, poorly ventilated buildings, malarial atmospheres, infectious diseases, etc., insisting that the health of the community demands the solicitude of citizens and the attention of officials to these important facts. And I agree with them, knowing and publicly teaching so long that many fatal diseases are traceable to these malign influences; but in the name of public safety, to say nothing of medical honor and professional rights, why is nothing said of the widespread and deadly influences of patent medicines and quack nostrums? Small-

pox, cholera, scarlet fever, typhus, diphtheria, anæmia, marasmus, consumption, heart diseases, etc., owe their origin and their fatal ends more to swallowing '*miraculous*' nostrums than they do to bad atmospheres and poor water. Alas! because no immediate bad results are experienced, the poor victims (their number is legion) continue to swallow these 'wonderful discoveries,' and by and by wonder that they are so 'kinder gin out like,' and so keep on dosing, just the same as 'old tipplers of the bottle' do, to stimulate their worn-out energies, until the whole body is emaciated, the throat filling with phlegm, the sight dimmed, the ears 'dull of hearing,' the chest oppressed, cough sepulchral; and now these wretches, seeing the pale king smiling coldly upon them, appeal to Divine Providence and—*send for a physician*, and die declaring that they have no faith in doctors! Congress ought to be ashamed of so ignorant, so infamous a law that encourages and sanctions the sharpers whose 'wonderful discoveries' are robbing suffering humanity, poisoning the human system, and demoralizing the medical profession. Medical conventions should be held for the sole purpose of repealing this law at once. I am almost ashamed of my own profession that it is so dilatory and negligent in saving itself from the terrible vortex into which an ignorant Congress and sharpers are plunging it. I am more than ashamed that our State medical associations do not do their utmost to force every pretended 'discovery,' of whatever name, to submit to a board of at least four of the best physicians before said 'discoveries' or any nostrums should be allowed to go into a human stomach. Still farther, I am almost astounded that all the States do not follow the example of New York, New Hampshire, and others, in putting a stop to any one practising medicine who is not a graduate in regular standing, or a licentiate, that thus we may be protected from notorious frauds and poisonous dosing, and an additional step inaugurated toward the much-needed reform."

Hydrophobia and Dog-muzzles.—In Bordeaux, between 1876–78, when dogs were muzzled, there were 5 mad-dogs which bit 52 other dogs, 1 cat, and 1 man. Between 1871–81, when muzzles were removed, there were 32 dogs which bit 209 animals and 4 persons. The value of muzzling the dogs is clearly shown.

Failure of the Chromic Gut.—Professor Spaeth, of Vienna, performed Cæsarean section and sewed up the uterine wound with five deep and four superficial catgut stitches, largest size of Lister's antiseptic chromic acid ligature. The woman died forty-eight hours after, of peritonitis. The autopsy was surprising in its revelations. Every catgut suture in the uterine tissue was found untied and straightened out while the wound was open and gaping, the lochial discharges having escaped into the peritoneal cavity. The original knots in the catgut had been tied with especial care by Professor Weinlechner.—*Philadelphia Medical Times.*

Doctors' Signs.—The *Canadian Journal of Medical Sciences* laments the gorgeousness of doctors' signs in Toronto. A while ago a modern door-plate was all that was thought necessary. Suddenly an enterprising medico exhibited a fanlight adorned with gilt letters over his door. The horror-struck profession first protested, then endured, then embraced the new style. Of late even this has been "improved upon." "At first simply the name appeared, and perhaps the street number; now we have 'office hours,' covering immense spaces, beautifully colored, in some cases; in others a good portion of the alphabet, in capital letters, after the name. Sometimes tin plates adorn various parts of the doctors' abodes, being especially profuse about the corners of the houses and fences. Enterprise has not, however, stopped here, and we have occasionally added a street lamp, or a huge gray stone slab, fashioned after the model of a modern tombstone, and decorated with the doctor's name."

These big and glittering signs that stretch across the door and force the passer-by to look, are the mark of the tradesman. They show a lowering of professional self-respect.

As a rule, the bigger the doctor the smaller the sign—and *vice-versa*.

Sciatica.—Mr. Jonathan Hutchinson says, somewhat dogmatically, that in nineteen cases out of twenty where sciatica is diagnosed the sciatic nerve is not affected at all. The cases are simply those of rheumatic or gouty arthritis or peri-arthritis of the hip.

Lead Colic.—M. Bernutz has been experimenting at La Charité with Malherbe's method of treating lead colic, a mode of treatment resuscitated by Picot, of Bordeaux.

Thirty years ago Malherbe, basing his opinion upon a long series of cases, advocated the use of belladonna in massive doses in the treatment of lead colic. He found the tolerance for this drug was in direct proportion to the intensity of the lead poisoning. Malherbe's plan was to give five centigrammes, about gr. viii. ss., of extract belladonnæ every half hour, until twenty or twenty-five centigrammes had been given. Concurrently he gave a purgative, as two drops of croton oil.

In M. Picot's observations the cure has been prompt, the constipation being overcome after the first day, and the colic immediately calmed. M. Bernutz has had to wait longer, and in some cases was obliged the next day to recommence the treatment; occasionally there were slight signs of atropinism.—*Gaz. des Hôp.*

Mechanical Treatment of Cicatrices.—Unna has found (abstract in *Viertelj. für Derm. und Syph.*) that the cicatrices of small-pox, after ulceration, are much improved in appearance by daily rubbing with fine sand. A small sponge soaked with soap lather is dipped in the powder collected from the débris of marble, and is then steadily rubbed over the cicatrix. The resulting improvement is naturally attributed to the stimulating effect of the mechanical irritation.

Stealing Medical Advice.—It is very well known that although medical advice is made much sport of by certain of the laity, it is a practice among some to get such advice surreptitiously at an ordinary social interview whenever they can. The most innocent conversation sometimes conceals an insidious demand, or ends in a direct request for a medical opinion. One day a physician met in the street a gentleman who was accustomed to annoy him in this way. The doctor was stopped and a number of physical troubles were rehearsed. "Great heavens!" said our Æsculapius in affected alarm, "is that the case? Let me see your tongue." The would-be patient looked around suspiciously, then

opened his mouth with some reluctance. "I tell you," said the doctor, with apparent irritation, "put out your tongue. How can I make a diagnosis if I only see the tip? There, hold still! Further! Now close your eyes." The patient, conquered, shut his eyes tightly and thrust out his tongue to the utmost. The doctor stepped around the corner quick as a flash, and was troubled no more for advice *gratis*.

CARBOLIC ACID, according to Dr. Robert J. Lee, is the only antiseptic that can be volatilized in a definite and constant manner. This is a most important fact in treatment, and deserving attention. If a solution of one part of carbolic acid in eighty of water be distilled under slight pressure, the vapor will contain the same proportion of the acid as the solution during the process of boiling; so that we can obtain vapor of any strength and diffuse it in the atmosphere. Other antiseptics are often too volatile, as, for example, thymol, which comes off very rapidly from the boiling water, as does also benzoic acid, so that they are not convenient for inhaling.

FOREIGN BODIES IN THE ALIMENTARY CANAL.—Dr. T. C. Wallace, of Cambridge, N. Y., writes: "The article of Dr. Field on 'Foreign Bodies in the Alimentary Canal,' in the last number of THE RECORD, prompts me to relate the following: On the 6th inst., at 10 A.M., a gentleman living about a mile distant from this village came to my house, and with intense (but natural) anxiety informed me that a few minutes previously his little son, aged six years, had swallowed a shawl-pin. I directed him to trust the case entirely to nature, so long as no unfavorable symptoms arose, and expressly forbade the administration of any cathartic medicine. On the morning of the 9th inst. careful examination of the fæces revealed the pin. During its transit from mouth to anus there was not the slightest constitutional disturbance or unpleasant symptom. The pin was about three inches in length, its head was a black ball about the size of a large marrowfat pea, and the point very sharp."

APPROVAL OF THE NEW CODE.—At the semi-annual meeting of the Clinton County Medical Society, held at Plattsburg, N. Y., July 11th, the provisions of the new code of ethics regarding consultations were referred to a special committee, who promptly reported the following:

"*Resolved*, That we utterly repudiate the code of medical ethics adopted by the New York State Medical Society in February last."

One member inquired whether the adoption of the resolution would be followed by discipline in case the members should fail to comply with the old code.

Another inquired whether the resolution was intended to cover the whole or only part of the code.

The committee then changed the resolution so as to make it apply only to consultations. Ample opportunity was afforded for remarks; no one, however, appeared willing to advocate the adoption of the resolution.

Dr. Nichols then expressed, in strong terms, his disapproval of its provisions. He read portions of the old code having reference to consultations, and stated that this requirement was termed "*putting up the bars*," and followed by reading the section of the new code bearing on the same subject, which, he said, was called "*letting down the bars*." The doctor alleged that in former times it might have seemed necessary, for the better protection of the profession, to enact and enforce inhibitory provisions such as the old code established. He was fully convinced, however, that the intelligence and liberality of the medical men of the present day was such as to render all rules involving liberty of opinion and action unnecessary and harmful. The dark age of medicine was passing away. Medical men may now be safely allowed the utmost freedom in the matter of professional consultations.

The doctor described the operation of the medical laws in force in the Canadian Provinces, which, after a trial of twelve years, prove that the barriers embodied in the old code are worse than useless. He was proud of the New York State Medical Society, and was pleased to know that it was the first to take this bold step in defence of the right, and he for one would earnestly support the Society, and would endeavor to aid, in every way in his power, the adoption of similar liberal provisions and principles by medical associations throughout the country. The following was then proposed as a substitute for the foregoing resolution:

"*Resolved*, That we cordially approve the code of medical ethics adopted by the New York State Medical Society at its annual meeting held at Albany, February 7, 1882."

The resolution was promptly adopted by a vote of seven in the affirmative to five in the negative.

THE PROFESSORS OF OBSTETRICS IN ITALY.—Some months ago Dr. V. Balocchi, the distinguished Professor of Obstetrics at the University of Florence, died. Professor Chiara, of Milan, has been nominated in his place. Professor Porro, of Pavia, has been called to Chiara's place at Milan. Drs. Mangiagalli and Negri, who were Chiara's assistants in Milan, have been elected to the Obstetrical Professorships respectively in Sassari and Novare.

DR. MOLSON, who was associated with Dr. Ross in the editorial management of the *Canada Medical and Surgical Journal*, has resigned. His place is filled by Dr. Roddick.

THE TRI STATE MEDICAL SOCIETY of Kentucky, Illinois, and Indiana will hold its eighth annual meeting in Terre Haute, Ind., on September 26, 27, and 28, 1882.

THE SIGNIFICANCE OF CEREBRAL ASYMETRY.—Dr. Layton quotes (*N. O. Medical and Surgical Journal*) the following from J. A. Fort's "Anatomie et Dissection": "Every one knows that after the death of the celebrated Bichat, one hemisphere was discovered to be in a state of almost complete atrophy, which appeared to be by no means of recent origin. Who would venture to deny the mental capacity of the illustrious anatomist, his lively imagination, and that spirit of generalization which has immortalized his name?"

TIGHT TROUSERS AND SEXUAL HYGIENE.—That the present style of pointed shoes develop corns every one will admit, but it is reserved for Dr. John I. Ligget, in our esteemed contemporary, the *Medical Gazette*, to show that the tight pants of the period produce a constant erethysm and lead to sexual excess. It will certainly be painful for the physician, as he watches the dapper youths who promenade our Avenue, to think that they are all more or less in a state of hyper-sensitiveness as regards the reproductive parts. We hope that Dr. L. is mistaken, and think that he has probably fallen in with gentlemen who wore misfits.

THE AMERICAN PUBLIC HEALTH ASSOCIATION meets at Indianapolis in October next.

THE BRITISH NAVAL MEDICAL DEPARTMENT has furnished every sailor and marine in the expedition to Egypt with a charcoal portable filter filled with caoutchouc tubes.

SYPHILIS TREATED WITH AMMONIO-MERCURIC PEPTONE.—M. Martineau has treated six hundred syphilitic patients by subcutaneous injections of ammonio-mercuric peptone. He has made eleven thousand injections in all, and has never had any accident, neither abscess, stomatitis, salivation, or intestinal disorder.

ASSES' MILK.—Professor Parrot, on the basis of the experience of the extensive nursery of the Hospice des Enfants Assistés of Paris, considers demonstrated the superiority of asses' milk over that of other animals in the hand-feeding of infants. M. Parrot has seen this milk bring about the veritable resurrection of infants. He formulates his practical conclusions in the following propositions: In the absence of a good nurse, a milch ass is the best substitute for infants. Its sober character, the tolerance which it has of stable-life, especially also the chemical constitution of its milk, which very closely approximates to that of the mother, place it first among animals which can be utilized for artificial feeding of infants. After it come in order the mare, the goat, and the cow. A she ass in full milk can only satisfactorily nourish three infants of the average age of five months. In places where the goat can live free, and find the food which it likes, it may be substituted without inconvenience for the ass. Asses' milk should play a large part in the treatment of children's diseases. It is particularly indicated in gastro-intestinal affections. Exceptionally, it will replace with advantage the mother's milk. All public institutions destined for the maintenance of new-born children and young infants, healthy or diseased, should be provided with arrangements for keeping, in proportion to need, asses and goats.—*Brit. Med. Journal.*

DESCRIPTION OF THE TOY PISTOL.—In *Walsh's Retrospect* there appeared last summer a description of the toy pistol, with the comments of a Baltimore physician upon the cause of its destructiveness:

"This pistol is about four inches in length and explodes a blank cartridge in a metallic case, with a pasteboard or other thick paper wad, but carries no ball or shot in the cartridge. In order to insert the cartridge the breech of the barrel is raised by pressing on the finger-piece forward of the trigger; but to do this the boy takes hold of the barrel with his left hand, the muzzle pressing against the palm of the hand, near the ball of the thumb frequently, and raises the hammer with his right hand. In loading, however, unless the utmost care is exercised, the hammer slips from the finger and explodes the cartridge, while the barrel is held against the palm of the left hand. The fulminating powder, the wad, or the metallic case of the cartridge inflicts the wound, which is often so slight that a physician is not called in, even if the boy does not, Spartan like, conceal his wounds from his parents, until he is past relief."

Dr. N. H. Clendinen, extracted from the palm of a boy a thick pasteboard wad which had been driven there by a toy pistol. The hand was much swollen, and had been poulticed and otherwise treated in vain, until the wad was removed. Dr. Clendinen thinks that the wad is the cause of most of the cases of tetanus that have occurred from these wounds. Yet the profession in Baltimore are divided in opinion regarding the cause; some suspect the fulminating powder used in the manufacture of the cartridges, and others that atmospheric conditions have some unfavorable effect upon the wounds. In one fatal case the wound was only a slight abrasion of the skin.

DEATH OF DR. JOHN B. LEAL.—We regret to announce the death of Dr. John B. Leal, an eminent physician of Paterson, N. J. Dr. Leal was born in Delhi, Del., in 1827. He graduated in medicine at Pittsfield, Mass. He was surgeon in the Union army during the war of the rebellion, and there did excellent service, being at one time Medical Director in the Department of the South. Dr. Leal came to Paterson in 1867, and lived there during the remainder of his life. He was very highly esteemed by the public and profession of that city.

LAWN TENNIS ARM.—For this affection a correspondent of the *Lancet* recommends chaulmoogra oil carefully rubbed into the arm night and morning. This oil, he states, is now generally used by men after their first day's hunting, and also by bicyclists after their first day's long ride, because they find that it entirely prevents any irritation of the skin or stiffness if it is well rubbed in before they retire to bed.

ACUTE CONJUNCTIVITIS CAUSED BY THE ELECTRIC LIGHT.—Dr. W. C. Rockliffe reports in the *Lancet* the case of a man, aged twenty-eight, who was accustomed daily to adjust the carbon points of a 3,000 candle-power electric light. He did not use colored glasses, and stated that every day for a quarter of an hour there was dimness of vision after the lighting. On one occasion, after regaining vision as usual, he felt pain, lachrymation, rapidly increasing photophobia. During the night he suffered intense agony. By the next day there was a fully developed conjunctivitis.

THE DIMINUTION IN MORTALITY AFTER AMPUTATIONS during late years is shown by statistics of the Glasgow Royal Infirmary, recently published in the *Lancet* by Dr. M. Thomas. The per cent. of mortality given by Sir James Simpson as existing previous to 1869 was 39.1. Since 1868, the average mortality has been 25.5 per cent., or 212 deaths in 822 operations.

The decrease in the case of the four major amputations is shown by the following table:

Thigh cases, 380; deaths, 113; mortality, 29.7 per cent. against 46.2 per cent. previous to 1868. Leg cases, 182; deaths, 54; mortality, 29.6 against 44.0. Arm cases, 167; deaths, 33; mortality, 19.7 against 35.4. Forearm cases, 93; deaths, 12; mortality, 12.9 against 11.7.

There has been an increase of 19 per cent. in the annual number of operations. The mortality cannot be reduced to that of country cottage hospitals because such bad cases are sent in for operation.

A MOLECULE OF WATER, according to Dr. Heen, measures in diameter 0.000,000,075 millimetre. A drop of water measuring one cubic millimetre would contain twenty-five trillions of molecules.

THE CHEMICAL CAUSE OF LIFE.—Up to within a few years physiology did not suspect that there was any chemical difference between dead and living protoplasm. Many still will say there is none. But re-

cent researches, beginning with an article of Pflüger's in 1875, point strongly in an opposite direction. One of the ablest essays in the affirmative was written last year by Dr. Oscar Loew and Dr. Bokorny, and published in Munich. The result of their investigation goes to show that living protoplasm owes its property of life to the presence of aldehyde groups which are characterized by intensely active atomic movement. When death takes place it is coeval with and caused by a transformation of these aldehyde groups into amyd groups, with diminished molecular motion, thus leading to cessation of action.—*Medical Press.*

Appointments in Harvard Medical College.—At the annual meeting of the Board of Overseers of Harvard University, September 13, 1882, Dr. David William Cheever was appointed Professor of Surgery; Dr. Charles P. Lyman, Professor of Veterinary Medicine.

The Yellow Fever Epidemic.—The following is a summary of the progress of the yellow fever at Brownsville during the week ending September 16th, furnished by the Surgeon-General, Marine Hospital Service, compiled from official reports:

Date.	Cases.	Deaths.
September 10	58	None.
September 11	47	1
September 12	31	3
September 13	32	None.
September 14	24	None.
September 15	18	2
September 16	22	None.
Total	232	6
Previously reported	1,539	88
Grand total, to include Sept. 16.	1,771	94

Since September 16th, the average daily number has continued to be less than it was a week ago.

Official reports from Pensacola have been received by the Surgeon-General up to and including September 12th, as follows:

Date.	Cases.	Deaths.
August 28	9	1
August 29	2	None.
August 30	3	1
August 31	4	None.
September 1	1	2
September 2	None.	1
September 3	None.	None.
September 4	1	2
September 5	1	None.
September 6	None.	1
September 7	13	None.
September 8	12	2
September 9	16	2
September 10	10	2
September 11	20	3
September 12	22	2
Total during epidemic	114	19

Since the twelfth, the number of cases has kept at about twenty daily. On the eighteenth, the number was twenty-seven, and the prospects were bad. The deaths, however, have been few.

Poisoning of an Infant.—Dr. G. Frank Lydston, of Chicago, writes: "I notice in The Record of September 2d a remarkable case of fatal poisoning in an infant as a result of the administration of a single drop of laudanum, and it suggests to me a case of my own, in which I very nearly experienced a similar accident. The case was that of an infant, about a week old, born at the Charity Hospital, New York. The nurse called my attention to the fact that the stools of the child contained a quantity of blood, which began to appear in slight amount and gradually increased. As the child had had some diarrhœa, I concluded that the trouble was of a dysenteric nature, and accordingly gave the child a drop of tr. opii with two drops of castor-oil, with the result of producing the symptoms of opium-poisoning to a marked degree, the surface being cold, the pulse feeble, and respiration very slow and shallow. The pupils were contracted and the child comatose, being aroused with difficulty. By slapping the surface smartly, and the free use of the cold douche, I succeeded, after a hard night's work, in restoring the infant. The experience gained was very valuable, as it served to impress me very forcibly with a point with which I was already familiar, viz., the marked intolerance of children for opium. The most singular feature of the case is, that upon careful examination—the diarrhœa having stopped and the hemorrhage still persisting—I found the source of the bleeding to be the vagina. There was no lesion visible, but the vaginal mucous membrane was considerably congested. The hemorrhage persisted for four days, and then ceased as gradually as it began. The child seemed otherwise perfectly healthy. The blood had one peculiar quality, in that it showed no disposition to clot, resembling in that respect normal menstrual blood. There were no evidences of precocious development. I attempted to detain the child for a time, but it was removed from the hospital, and I could learn nothing of its subsequent history."

A New Veterinary School will be opened in Harvard University this fall. The regular course of the veterinary students will be three years. The subsidiary branches to be studied by the veterinary aspirant are taught in the other departments of the university, while preparations will be made for the theoretical and practical instruction in the veterinary art.

Multiple Sarcoma of the Skin.—A case of this very rare disease occurred in Neumann's clinic at Vienna lately. It is described by a correspondent of the *Maryland Medical Journal.* A Russian Jew, aged thirty-four, and apparently in excellent health, appeared, having on his abdomen an erythema which upon further investigation was found to be lumpy. His abdomen looked as if covered with large varicose veins. Upon turning him around, under the right scapular, there was a half-moon shaped tumor, about the size of a large watch, raised above the surface of the skin an eighth of an inch. There was no ulceration. The color was a light brown, and the surface had the appearance of normal skin when viewed under a magnifying glass. This was the only tumor projecting above the skin. Various lumps could be felt on the abdomen, which were quite hard and varving in size. The disease was seven years old. Leprosy, syphilis, and sarcoma cutis, were the three possible diseases, and as the two former were excluded, both Neumann and Kaposi settled upon the latter, making a diagnosis of multiple sarcoma of the skin. Such cases are very rare, Neumann only having seen three in the course of his large experience.

Original Communications.

CUTANEOUS IRRITATION AND THE PULSE.[1]

By SARAH E. POST, M.D.,
NEW YORK.

The following memoranda record an effect of general cutaneous faradization. The patient having been disrobed, enveloped in blankets, and in the recumbent position, application was made to each posterior lateral half, and last to the anterior surface of the body.

The electrodes used were the brush and the curved plate, figured in The Record, p. 724, June 25, 1881. The warmed plate was apposed to a part of slight sensibility, usually some portion of the thigh, while the brush, with a short but deliberate motion, was passed forward and backward over the regions indicated, force enough being used to thoroughly redden the skin. The electrodes were not moistened. The skin was dry but not powdered. The motion of the brush was accompanied by a low-pitched humming sound. The duration of the application varied between fifteen and forty-five minutes. The current was stronger than that usually employed for the production of contractions, never, however, being sufficiently strong to cause pain.

The principal precaution was the avoidance of shock. We did not attack too precipitately a painful or sensitive point, but hovered in its neighborhood, or passed the brush over it quickly and in one direction until thorough counter-irritation could be comfortably borne.

The patient did not talk during the application, and did not watch the process while the record was being made.

In general terms, where the slowing amounted to seven per cent. drowsiness usually appeared, the face would become pale, and the hands and feet would become warm. With these symptoms coexisted a general tonic effect.

Case I.—Lady, thirty-five years of age, 160 pounds. Has cold feet, erythematous blotches over body and limbs. Mental depression marked.

Observation.	Pulse before.	Pulse after.	Observation.	Pulse before.	Pulse after.

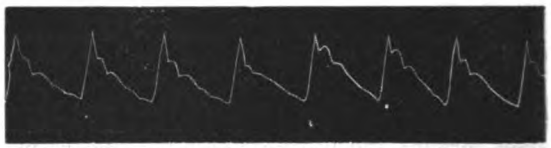
3	66	62	8	72	64
4	72	60	9	66	60
5	68	62	10	54	52

Average pulse, 66.
Average slowing equals 11.80 per cent.

The total average slowing amounts to 8.31 per cent. of the primary count.

To determine changes in character, the radial pulse was sphygmographed in four cases before and at the end of the application, also at the end of the separate periods devoted to the back, to the limbs, and to the abdomen. At the end of the application, in two increased, in one decreased, and in one case unaltered arterial tension was obtained. The increased number of observations showed in the two cases increased tension, also after the application to the back; a diminished tension after the application to the limbs, and again an increase after the application to the abdomen, changes which are registered in Traces 1 to 4.



No. 1.—Pressure 12; taken before the application.

No. 2.—Pressure 12; after application to back.

No. 3.—Pressure 12; after application to limbs.[1]

No. 4.—Pressure 10; after application to abdomen.

The case which presented the diminished tension at the end of the application showed also after the application to the back increased tension, which was soon lost, and did not reappear during the subsequent stages of the treatment. It may be remarked that the former two cases were spare women, while the latter were corpulent with an especially deep deposit of fat in the abdominal walls. The remaining case with a diminished frequency, amounting to 12 per cent., showed, at the end of the separate periods, only so slight alteration in the character of the pulse as might be due to a modified adjustment of the instrument. So long a time, however, intervened between the observations that a very rapid reaction might easily have escaped unnoted.

In general terms increased tension was observed after applications to the back and to the abdomen, a fall or unaltered tension being present in each case after application to the limbs.

To determine the relation between these condi-

[1] Pond's sphygmograph was used. This instrument propels the card at a rate of about one inch in three seconds.

tions and the one previously noted, observations were made with the following result:

Case.	Pulse before app.	After app. to back.	After app. to limbs.	After app. to abdomen.
3.....	72	84	84	76
7.....	64	60	64	66
8.....	70	64	64	66
9.....	92	80	80	80
10.....	54	52	52	52

It will be seen that in five unselected cases the slowing had place only during periods when the rise in pressure is most apt to occur.

Concerning the mechanism of these phenomena, slowing of the pulse under the circumstances noted might be considered due to the enforced quietude or to the supine position; the patients were, however, recumbent several minutes previous to the first count, the original pulse was, in the majority of cases, not rapid, while from the simple subsidence of excitement the peculiar modifications in character would not have occurred.

Stimulation of a sensitive nerve may by direct reflection slow the heart. Such slowing is obtained from crushing the foot or touching the inflamed peritoneum of the frog.[1]

In the cases before us, however, the sensory impulse was agreeable to the patient, while in the instances quoted slowing was the concomitant of severe pain.

By exclusion and from the coincidence in the time of their production we consider the increased blood-pressure itself the sufficient[2] and probable cause for the diminished frequency of the heart. With regard to the method of its action, Marcy has supposed the heart to beat the more slowly as it has the greater difficulty in emptying itself.[3] Loaded muscle, however, contracts with the greater energy[4] while the excised heart of the frog beats the more rapidly with increase of endocardial pressure.[5]

Bernstein observed the slowing to be absent if the vagi had been previously divided,[6] and hence supposes it to be due to an impulse travelling that nerve—a conclusion supported by a number of other investigators.

Francois Franck has obtained slowing from an increased pressure which affected the brain alone.[7]

The increased pressure is supposed to be due to increased general or local arterial tone. Dr. Ott has said that all of the arteries of the body are contracted excepting those of the surface irritated.[8] This conclusion is not universally true. Dr. Brown-Séquard obtained from pinching one hand contraction of the vessels in only the opposing limb.[9] Similar observations have been made by Van der Beke Callenfels upon the rabbit,[10] and by Dr. Putnam upon the frog.[11]

A limited reflex is assumed in the cases before us from the coincidently warmed extremities. Heidenhain, with a similar result, supposes the vessels of the skin to have been relaxed and the contraction to have occurred in internal organs with the effect of an outward wave.[12]

To consider the slowing produced by the increased pressure explains also the coincident drowsiness, according to Dr. Jewell's theory, that sleep may be induced by a sudden change in the circulation of the brain;[13] also, the occurrence of the sleep in some cases during the application, and in others at its end, is accounted for as the increased or the diminished pressure is its determining cause.

That applications which produce a considerable slowing of the pulse have a general tonic effect has been referred to. A similar relation has been noted by other observers. Dr. Putnam-Jacobi has associated the benefit of massage and the cold pack with the slowing of the pulse which they produce.[14]

Drs. Beard and Rockwell have indicated the same coincidence by an expressive phrase, "the tonic and sedative effect."[15]

Massage and the cold pack cause also increased elimination of urea,[16] indicating increased destruction of circulating albumen or increased appropriation of food.[17]

Similar mild irritants, as salt baths, etc., cause increased elimination of CO_2, with also a nutritive influence shown by an immediately increased consumption of oxygen.[18]

These results, immediate and remote, with their relation to the slowed pulse, would a few years ago have been explained by the agency of the conditions which I have placed before you in this essay. Increased blood-pressure, with its increased rapidity of current, being supposed to increase the supply of oxygen, which in its turn determined the metamorphoses of the body.

Pflüger and his pupils, however, most emphatically deny this agency. Pettenkofer and Voit also find the quantity of the excretions quite independent of the coincident supply of oxygen.[19]

Pflüger says, "The regulation of the supply of oxygen consumed is determined by the cells themselves, not by the oxygen capacity of the blood, not by the tension of the aortic system, not by the swiftness of the current, not by the character of the heart's action, and not by the character of the respiration."[20]

Roehrig and Zuntz find O and CO_2 diminished by a dose of curare insufficient to affect either the respiration or the pulse, and hence suppose nutrition to be controlled by special nerves, which run in the motor paths.[21]

Dr. Ott has obtained also hypnotic and other phenomena which cannot be explained by the circulatory conditions.[22]

In deference to these deductions after having allowed for the influence of sleep, for the influence of the improved function of the skin, for the influence of the dissipated stasis in internal parts, and for the influence of an increased nutritive supply,[23] we may suppose that our cutaneous irritant

affected reflexly not only the vascular, but other systems of nerves.

Dr. Naumann, in 1863, proposed the effect of cutaneous irritants upon the pulse, as a basis for their classification, dividing them into the comparatively mild, or those producing a "hypersthenic" effect, and the painfully strong or those producing a "hyposthenic" effect.[1] With the former he obtained an increase in the arterial blood-pressure, with an increased frequency and force of the heart. With the latter a diminished pressure and a diminished frequency, averaging 4 per cent., preceded by an increase in both, the location of the application being immaterial to the result.

Drs. Nothnagel and Rossbach accept this classification in a late edition of their therapeutical work.[2]

The authors then assign our ordinary counter-irritating agents to this second class, mustard and cantharides heading the list.

Now it has occurred to me to have from applications more than usually severe cutis anserina, with the acceleration of which these gentlemen speak, a relation which requires the existence of a grade of irritant milder than either with which Dr. Naumann experimented, yet possessed of marked hæmodynamic influence.

Acceleration and increased pressure are considered independent when produced by peripheral stimulation.[3] To exclude the former has been my effort in these experiments. That we are able to entirely avoid acceleration while increasing blood-pressure from a cutaneous irritant, I am not fully assured. To demonstrate the fact would require a continuously running graphic apparatus. Its minimum, however, appears to depend upon the skill of the operator in the avoidance of shock.

The warmed electrodes also have in this connection their recommendation and their defence.

Further, the rise in blood-pressure is greater and more constant from tactile irritation of the skin than from that which would produce pain.[4]

To avoid abruptness and unpleasant severity is therefore essential, both for the exclusion of acceleration and for the production of the increased pressure which determines the diminished frequency of the heart.

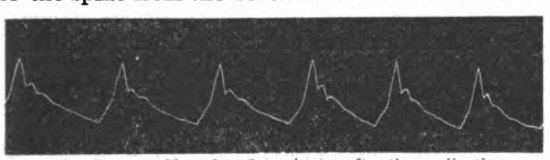
In recapitulation it is submitted to you:

First.—That we have obtained a diminished frequency, which occurs in the case of the already slow, as well as in that of the previously rapid pulse.

Second.—That this diminished frequency is a result of increased arterial blood-pressure, determined by the reflection of a stimulus to cutaneous nerves.

Third.—That the stimulus which produced it is milder than that necessary permanently to excite the pulse.

The following sphygmographic traces record an effect of mustard. To Case X. a plaster three inches broad was applied over and equally upon each side of the spine from the seventh cervical to the tenth dorsal vertebra. Trace 6 shows at the end of ten minutes, by the additional pressure necessary for its development and by the increased prominence of the tidal wave, increased tension, Trace 7 diminished tension, and Trace 8, at the end of twenty minutes, again an increase which gradually subsided. At the end of thirty-five minutes the plaster was removed.

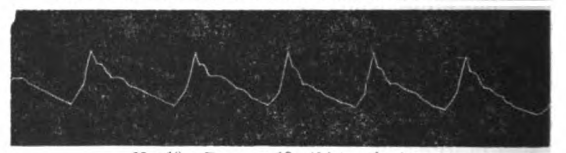


No. 5.—Pressure 10; taken five minutes after the application.

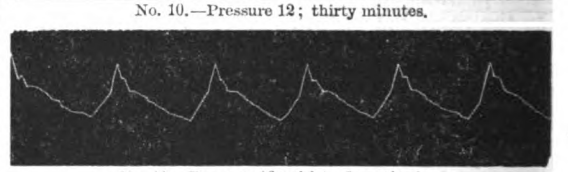
No. 6.—Pressure 14; at the end of ten minutes.

No. 7.—Pressure 10; fifteen minutes.

No. 9.—Pressure 12; twenty-five minutes; patient asleep.



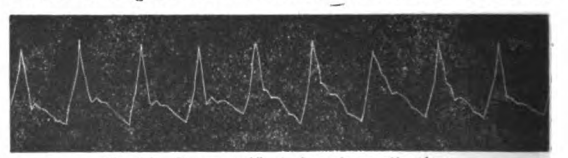
No. 10.—Pressure 12; thirty minutes.



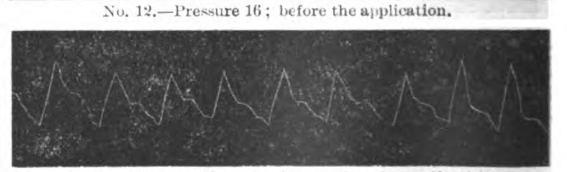
No. 11.—Pressure 12; thirty-five minutes.

As compared with the Traces which immediately precede, diminished frequency may be detected in Trace 7 and in Trace 9, while Trace 8, which shows the most marked tension shows also acceleration of the pulse. Drowsiness occurred as from the faradic brush. Trace 9 was taken while the patient was asleep. It is incidentally of interest that upon the removal of the paste the subject remarked, "It again burns." Again the instrument registered increased tension and again the patient slept.

The next application was similar, and made to a healthy young woman of twenty-four years. Its effect is registered in Traces 12 to 24. An acne



No. 12.—Pressure 16; before the application.



No. 13.—Pressure 16; five minutes after the application.

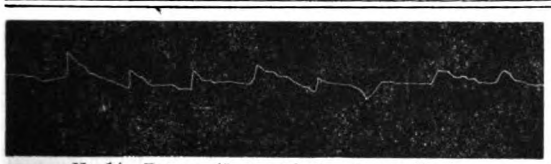
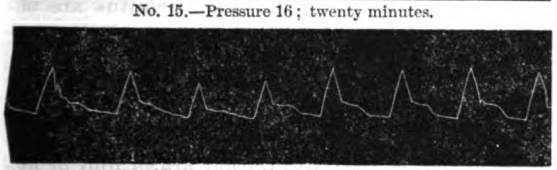
[3] Hermann's Hdb. der Phys., Bd. iv., Th. 1, S. 392.
[4] Ibid., S. 431. Heidenhain: Pflüger's Archives, Bd. xvi., S. 47.

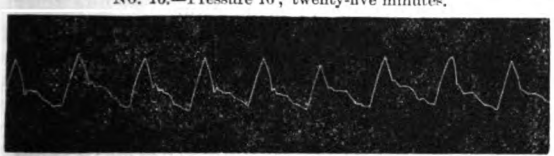


No. 14.—Pressure 10; ten minutes after application.

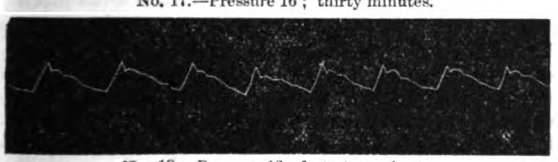
No. 15.—Pressure 16; twenty minutes.



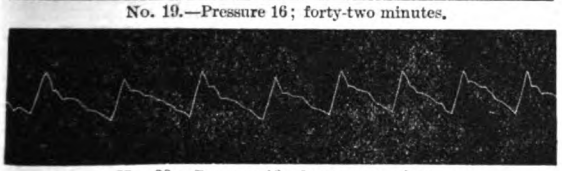
No. 16.—Pressure 16; twenty-five minutes.



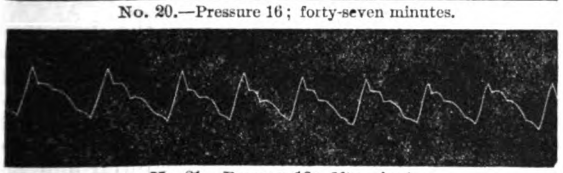
No. 17.—Pressure 16; thirty minutes.



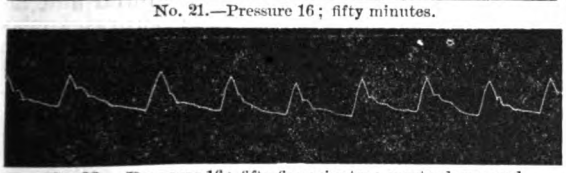
No. 19.—Pressure 16; forty-two minutes.



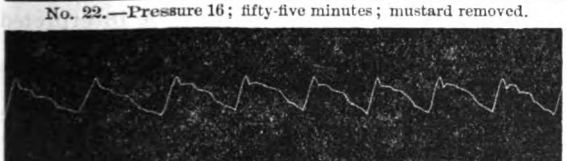
No. 20.—Pressure 16; forty-seven minutes.



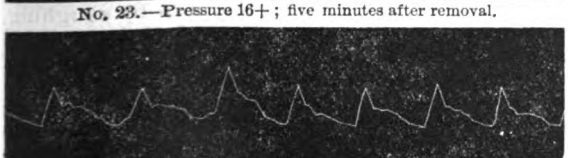
No. 21.—Pressure 16; fifty minutes.



No. 22.—Pressure 16; fifty-five minutes; mustard removed.



No. 23.—Pressure 16+; five minutes after removal.



No. 24.—Pressure 16; ten minutes after removal.

pustule upon the part caused an immediate and severe burning pain. Four periods of increased tension may be discerned, one shown in Trace 15, one rising in Trace 17, reaching its maximum in Trace 18, and subsiding in Traces 19 and 20; another in Trace 21, and again another, upon the removal of the paste, is shown in Trace 23. Upon myself these periods of increased tension coincided with distinct periods of burning when a new focus of irritation would appear to be set up.

Comparative slowing may be found in Traces 14, 16, 20, 22, and 24, while the increased tension was in each instance clearly accompanied by acceleration of the pulse.

The mustard used was of the commercial variety, was mixed with vinegar, and was not retained longer than could with equanimity be borne.

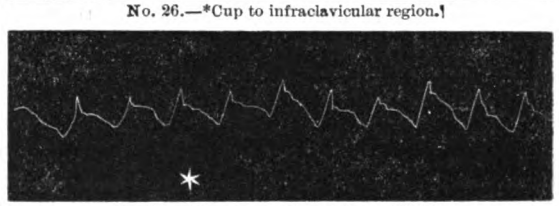
The redness was marked and in both cases persisted for several days. In Case XI. complete desquamation of the epidermis occurred.

In the foregoing diagrams we have increased pressure with acceleration followed by diminished pressure with diminished frequency and somewhat diminished force of the heart. This is Dr. Naumann's description of his hyposthenic effect, yet the irritant which produced this result, while more severe than the faradism previously employed, is yet milder than that which produces permanent acceleration of the pulse. From increasing its strength beyond the point of tolerance wildly excited heart's action occurred.

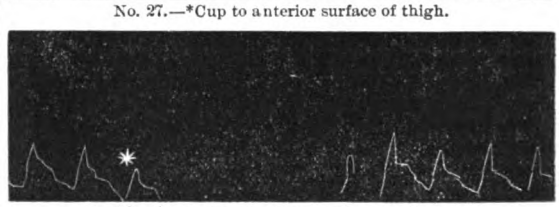
The remaining Traces register an effect of dry cups, upon Case XI., two weeks after the preceding experiment. At the instant indicated in Trace 25,

No. 25.—*Cup to interscapular region.

No. 26.—*Cup to infraclavicular region.



No. 27.—*Cup to anterior surface of thigh.



No. 28.—*Cup to back after previous applications.

an application was made to the right interscapular region, as indicated in Trace 26, to the right in-

fraclavicular region, and, as indicated in Trace 27, to the anterior surface of the thigh.

An immediate rise in tension is indicated with the application to the back and to the chest, while that to the limbs produced no perceptible change.

Trace 28 records the effect of the same application to the back at the end of the same sitting, six or eight cups having been previously applied. It will be seen that a fall, instead of a rise in arterial blood-pressure occurred. This effect is similar to that obtained from the prolonged stimulation of a sensitive trunk.[1]

Slight acceleration coincident with the increased tension may be seen; while in another case from cups to the spine repeatedly resulted pallor and drowsiness similar to that from the faradic brush.

113 East Thirty-first Street.

BRONCHITIS AND INTERPLEURAL PLASTIC EXUDATION.

By D. M. CAMMANN, M.D.,

late attending physician to new york dispensary (heart and lungs).

It is probable that many cases of plastic exudation within the pleural are diagnosed and treated as cases of bronchitis. In the following paper it is my purpose to consider some of the signs which will assist in the differentiating of the two diseases. The correct interpretation of the physical signs in these cases is of such importance as regards treatment that the differential diagnosis should be carefully studied. On the one hand, those cases treated for bronchitis may have fresh exudation of plastic matter from time to time which becomes organized, contracts, binds the lung to the chest-wall, and ends in fibroid or tubercular phthisis. On the other hand, in the majority of the cases properly treated, the plastic matter will be absorbed, or, if absorption does not occur, the patient may be put in the best condition to avoid danger from old, and to guard against the approach of new adhesions.

Many cases of acute bronchitis cannot be recognized by the physical signs. Respiration is normal, and there are no râles. These cases can usually be diagnosed from the history. The patient says he has taken cold, or the case may have begun with a sore throat, and the inflammation extended to the bronchi. Cough is more or less troublesome; the expectoration is mucous or muco-purulent; the temperature is a degree or two above normal; the patient does not look or feel very sick.

In other cases the respiration is modified. The bronchial element of the respiratory sound is exaggerated, and the respiration is harsh. This harshness is most marked in inspiration, but may also be observed with expiration of less intensity and lower pitch. It is most evident where the bronchi most nearly approach the chest-wall, or where the chest-wall is thinnest, as in the interscapular or the infrascapular regions. The most careful search at each examination may fail to discover râles. The percussion note is normal.

In a third class of cases râles and rhonchi are present, and it is in these cases that the greatest care is requisite to reach a correct diagnosis. Bronchitis may alone be present, or it may be accompanied by plastic exudation, or plastic exudation may have been the initial lesion and be accompanied by a bronchorrhœa.

Coarse and sibilant and sonorous râles and rhonchi may be heard. One or all of these râles are present, and they may be few and scattered over the chest, or confined to certain regions, or change from place to place, or they may be abundant over both lungs. They are more or less distant from the ear, and, unless very abundant, usually change position or disappear on violent coughing. The respiration may be harsh, or occasionally the abundance of the râles and rhonchi will somewhat obscure the respiration.

The percussion note and vocal fremitus are unchanged. A small proportion only of all cases of bronchitis come under this class.

I am satisfied, after examining a large number of cases, that, after excluding cases of plastic exudation within the pleura, the number of cases in which there are no physical signs, or in which the only physical sign is harsh respiration, are as four or five to one, or in even larger proportion.

The physical signs of chronic are the same as of acute bronchitis. As a clinical fact, however, we rarely have chronic bronchitis uncomplicated with plastic exudation. The sympathy between the bronchi and pleuræ is intimate, and a morbid condition of the one frequently induces a morbid change in the other.

Having briefly reviewed the physical signs of bronchitis, the differential diagnosis from plastic exudation may be properly considered, and it may not be inappropriate in this connection to give some cases of the latter morbid condition when the difference between the two diseases may be clearly understood by contrasting cases of each.

The examinations were made by Dr. J. R. Leaming.

Case I.—Mr. L——. In the right infraclavicular region a shower of small râles are heard in inspiration, and this condition is still more marked below. Toward the mediastinum a few distant râles are heard.

In the left infraclavicular region the broncho-respiratory murmur is harsh and expiration prolonged. The motion of the heart is restrained, and a few dry râles are heard in inspiration and expiration. The pericardium is bound to the lung and chest-wall. Over the left side, behind, the lung fills well. Râles are heard in the suprascapular and interscapular regions. In the right suprascapular region the lung does not fill as well as on the left side. Expiration is prolonged, and râles are heard in inspiration and expiration. In the interscapular space loud râles are heard. Over the lower portion of the lung some râles are heard and the motion of the lung is restrained.

The physical signs in this case may be interpreted to mean that pretty extensive interpleural plastic exudation existed, and that such an interpretation is correct has been shown by post mortem examinations[1] in similar cases on man and animals. The shower of small râles heard in front were proved to be interpleural by being directly under the ear. Such râles are not changed in position by coughing, and although they may vary somewhat in position and character from day to day by the absorption of old, and the exudation of fresh plastic matter, and by the adhesions becoming drier or moister, they

[1] Hermann's Hdb. der Phys., Bd. iv., Th. 1, S. 4.

[1] Vide Physical Signs of Interpleural Pathological Processes, by Dr. J. R. Leaming, Medical Record; and Endemic Pleuro-Pneumonia, by Dr. Leaming, Medical Gazette, February 7, 1880.

often remain without change for a considerable time. The râles heard along the mediastinum were due to exudation on the mediastinal pleura. They were more or less distant, but followed the course of the mediastinum and were not altered in position or character by coughing. In this case bronchorrhœa existed from the interference to the circulation caused by the pleurisy, and the harsh respiration may have been partly due to this and partly to the better conveyance of the bronchial sound by the adhesions between the costal and pulmonary pleuræ. Prolonged expiration may be caused by loss of resiliency of lung-tissue or by mechanical obstruction. Now, the mechanical obstruction of plastic exudation is probably sufficient to account for the prolonged expiration in this case. The dry râles heard over the heart were due to old adhesions. When adhesions are old and dry the râles become dry and creaking, or leathery. Over the right lung, behind, the signs of pleuritic exudation were evident; the râles superficial and always in the same position; the prolonged expiration and the restrained action of the lung, the lower border varying little in position with respiration.

In the next case, on a previous examination, to the one recorded, extensive plastic exudation was found on the right side and to a less extent on the left side, but up to that time there had been no cough. This has been noted in other cases, and as cough is a symptom of bronchitis, its absence may sometimes assist in forming a differential diagnosis.

Case II.—Mr. B——. In right infraclavicular region respiration is harsh and divided by heart-beat; slight leather-creaking râles in inspiration and expiration; harsh râles on coughing; percussion note flattened and raised in pitch. In the mammary region some soft râles, distant from the ear, and harsh respiration are heard; the lower portion of the lung is restrained, and at end of inspiration and beginning of expiration are creaking râles. In right suprascapular region inspiration and expiration are a little harsh, and the true respiratory murmur is scarcely heard. In interscapular space respiration is harsh and expiration a little prolonged, and dry râles are heard.

In the infrascapular region the lung is free and respiration good. Over the right side, behind, the percussion note is raised in pitch. On the left infraclavicular region the respiration is good. Below the heart the lung is restrained and the respiration interrupted. Over the left suprascapular region soft râles are heard. The respiration and percussion note are good.

The interruptions to the respiration in this case were synchronous with the movements of the heart, and were probably due to adhesions between the pericardium and pleura, which, stretched and relaxed by the contraction and relaxation of the heart, produced cog-wheel respiration at this point. The leather-creaking râles were caused by the presence of old adhesions, as were those also heard over the lower part of the lung. The flattening of the percussion note in the right infraclavicular region was due to thickened pleura. The feeble, true respiratory murmur in the right suprascapular region indicated interference with the free expansion of the lung, and was due to confinement of the lung by pleuritic adhesions, or to the lung itself having become involved. The raised pitch of the percussion note on the right side. behind, was evidently due to thickened pleura. The soft râles heard in front and behind were due either to fresh adhesions or to the moistening of old adhesions.

Case III.—Mr. E——. In right infraclavicular region there are creaking and râles and restrained motion. Beyond the interpleural complications true respiratory murmur is heard. To outer side of mammary region there is a little sibilus in inspiration and expiration. The lung is restrained at the lower part. In the left infraclavicular region the true respiratory murmur is feeble. Hard and dry râles are heard in this region, along the mediastinum in the mammary region, at outer side of mammary region, and over lower part of the lung. Percussion note under the right clavicle is flattened; on the left side it is flattened and a little more raised in pitch than on the right. In left suprascapular region tearing and creaking noises are heard at the end of inspiration. True respiratory and broncho-respiratory murmurs are heard. In interscapular region râles are heard. Lung a little freer than in front. In infrascapular region more movement than in front; cog-wheel respiration. In right suprascapular and interscapular regions râles are heard in inspiration, musical in the beginning and tearing at the end. Motion of lung near the base limited. Percussion note in right suprascapular region somewhat flat.

In this case the raised pitch of the percussion note and the creaking and râles heard with the respiration showed the presence of the thickened pleura and old pleuritic adhesions; but the true respiratory murmur clearly heard beyond the pleuritic exudation gave evidence that the lung was not yet involved. The presence in the right suprascapular and interscapular regions of râles, musical in the beginning, as the adhesions were put on the stretch, and tearing at the end, is an interesting fact.

Many more cases might be taken from my note-book, but it is perhaps unnecessary to do more than conclude with a synopsis of the physical signs of bronchitis and interpleural plastic exudation.

In bronchitis there may be no physical signs, no harsh respiration,[1] or coarse, sibilant, and sonorous râles. Sibilant and sonorous râles are almost always interbronchial. Coarse râles, when interbronchial, are distant from the ear, and change position from time to time. The percussion note is not raised in pitch and vocal resonance is not increased.

In interpleural plastic exudation there may be crepitant, subcrepitant, coarse, large gurgling, soft tearing, harsh and creaking râles and rhonchi. Fine râles are always interpleural; coarse râles, when interpleural, are directly under the ear and do not change position. Pleuritic râles disappear from extreme stretching of adhesions, from the exudation of fresh plastic matter binding the lung to the chest-wall and preventing motion, or from the rapid absorption of the plastic material. The respiration may be harsh or interrupted, or the expiration may be prolonged. The percussion note may be dull, flat, parchment-like, wooden, raised in pitch. Vocal fremitus may be increased. Respiration may be feeble from lack of expansion of the confined lung.

The Japanese Government has lately drafted new regulations for marriages. According to these, no man in the empire will henceforth be permitted to marry before arriving at the age of twenty. Women, however, are to be privileged to marry at eighteen.

---

[1] Harsh respiration may be produced by rapid breathing, and this source of error should be eliminated.

MR. SHAW'S VIEW OF THE CAUSE OF ROTATION IN LATERAL CURVATURE OF THE SPINE.

By A. B. JUDSON, M.D.,

ORTHOPEDIC SURGEON TO THE OUT-PATIENT DEPARTMENT OF THE NEW YORK HOSPITAL.

In his valuable lectures on "Curvature of the Spine," Mr. William Adams says: "Dr. Judson's view of the cause and mode of production of rotation does not materially differ from that of Mr. A. Shaw."[1] With a high regard for the opinion of Mr. Adams in all questions relating to spinal curvatures, I desire to point out what I conceive to be the difference between the two views referred to in the above quotation, and to present certain grave objections to the view which he has adopted.

Mr. Shaw's view is set forth by Mr. Adams in the following words: "According to this explanation, rotation of the bodies of the vertebræ is assumed to take place at the commencement of spinal curvature, and previous to any lateral deviation traceable externally. It is supposed to be directly caused by the weight of the body being thrown upon the oblique articulating processes, which are situated posterior to the bodies of the vertebræ, as well as laterally, and naturally resist and limit the lateral flexion of the spinal column. Hence, when the pelvis is tilted from any cause, such as standing on one leg, sitting in a bad position, etc., the body is thrown to one side. In this attitude, these processes resist the lateral inclination, in combination with such muscles as, in the position of the body assumed, are called into play. If, however, this faulty position be long continued, the oblique articulating processes are no longer able to resist the superincumbent weight of the body, and gradually become altered in form, so that the position becomes fixed and permanent.

"As the oblique articulating processes yield to the pressure thrown upon them, so the bodies of the vertebræ deviate laterally, as shown in diagram, Fig. 23; or as Mr. Shaw has more correctly described it, wheel partly round, the centre of motion being fixed in the articulations between the oblique articulating processes which are situated posteriorly, as well as laterally, in respect to the bodies of the vertebræ."[2]

The explanation offered by me is worded as follows: "The distinguishing feature of the explanation of rotation here proposed is the recognition of the fact, heretofore overlooked, so far as I am aware, that the posterior portion of the vertebral column, being a part of the dorsal parietes of the chest and abdomen, is confined in the median plane of the trunk, while the anterior portion of the column, projecting into the thoracic and abdominal cavities, and devoid of lateral attachments, is at liberty to, and physiologically does, move to the right and left of the median plane.

"When the median plane of the trunk curves to the right or the left, under the vertical pressure which is the direct cause of lateral curvature, their freedom from control allows the bodies of the vertebræ to fall away from the median plane, to the right or the left, while the posterior portions of the column are held in the median plane by their muscular and fibrous attachments. This deportment of the two components of a vertebra, its anterior and posterior portions, is rotation in the vertebra as a whole."[1]

Continued observations have confirmed my opinion that this view is correct and has important practical relations.

The two views above set forth are, indeed, alike, in that they both recognize, in common with several other theories that have been proposed, the fact that rotation is dependent, as lateral curvature itself is, on the vertical pressure of the superincumbent weight, or the pressure exerted by muscular action in the direction of the axis of the trunk. They differ, however, in that in the former rotation is said to be caused, under this vertical or axial pressure, by a change in the form of the articular processes which disables them from preventing a wide lateral excursion of the anterior part of the vertebral column, while in the latter it is said to be caused, under this axial pressure, by the fact that the anterior part of the vertebral column is anatomically devoid of impediments to a wide lateral mobility.

An interesting and important feature of the difference between these two views is, that in the former rotation is said to be a purely pathological phenomenon, dependent on morbid changes in the articular processes, while in the latter it is said to be a physiological phenomenon, necessarily accompanying every lateral bending of the normal spine, and becoming a pathological feature only when it becomes excessive and permanent, thus resembling lateral curvature itself, which is one of the functions of the healthy spine and only comes to be considered a disease after it has assumed a morbid degree and permanence.

As an illustration of the rotatory flexibility of the normal spinal column, it may be said that it is not improbable that the remarkable apparent deflection of the assassin's bullet in the case of the late President Garfield was due to a rotation of the lumbar vertebræ. A strong inclination of the President's body toward the left, between the first and second shots, in response to the threatening attitude of his assailant, who stood behind and to the right, would have produced a lateral bending of the spine, with a convexity toward the right, and with a rotation of the bodies of the vertebræ still further toward the right, thus bringing the body of the first lumbar vertebra within the range of the bullet, which entered the trunk in an antero-posterior direction (as shown by the arrow in the figure below) a short distance to the right of the median line. It may be demonstrated in the living model that rotation is an incident of physiological or normal lateral curvature. A strong lateral bending of the trunk, erect or lying prone, will cause the transverse processes of the lumbar and lower dorsal regions to become prominent on the side of the convexity and to recede on the side of the concavity.

With great respect for the authority of Mr. Shaw and the highest regard for the valuable labors of his useful and honorable life, I have been unable to accept his view of the cause of rotation. I have even been led to conclude that rotation takes place in spite of, rather than in consequence of the yielding the articular processes. I reach this conclusion by a consideration of Fig. 23 of "Mr. Adams' Lectures,"[2] and Fig. 2 of my paper.[3] For purposes of

[1] Second edition, London, 1882, p. 152. See also THE MEDICAL RECORD, April 29, 1882, p. 466.
[2] Op. cit., p. 142.

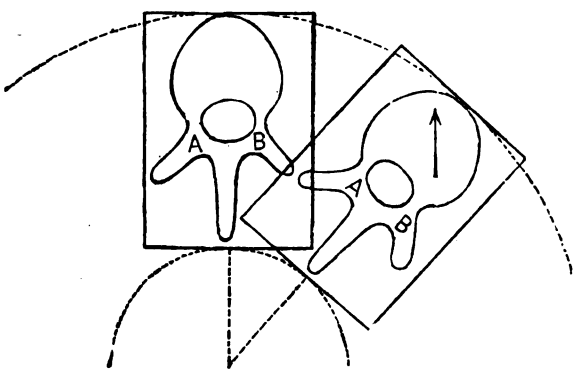
[3] Op. cit., p. 325.

illustration, these figures are virtually the same. I use mine simply because its lines are less involved. In this figure A and B represent the position of the articular processes. Those at A lie in the concavity of the curve, and are, therefore, subject to alteration in form by reason of the superincumbent weight. If rotation were determined by the yielding of these articular processes, it would take place from right to left in the above diagram, or in the direction toward which the body of the vertebra would naturally move, in obedience to the yielding of the articular processes at A. The rotation seen in the diagram is a movement which would be imparted to the vertebra by the advance rather than the yielding of the articular processes at A. Rotation in lateral curvature thus appears to take place against rather than in consequence of the supposed influence of the change in the shape of the articular processes.



Horizontal Section of a Vertebra in Lateral Curvature, with the Convexity toward the Right.

Another important point of difference between the two views under consideration is that, in the former rotation is said to be caused, under the pressure referred to above, by agencies residing in the vertebræ themselves, while in the latter it is said to be caused, under this pressure, by a foreign agent, viz., the limitation of lateral motion in the spinous processes by reason of their involvement in the parietes. In Mr. Shaw's view, rotation is the result of the yielding of the articular processes on that side of the column which is directed toward the concavity of the curvature. Herein lies a fallacy. Take, for instance, the superior articular process of the left side of the ninth dorsal vertebra in a case of lateral curvature toward the right. From pressure and absorption the articulating surface of this process, looking upward and backward, has yielded so as to allow the left side of the eighth vertebra to advance, which would be equivalent to rotation of the eighth vertebra toward the right. But, while this movement is taking place in the eighth vertebra, the yielding of the above-mentioned process would also, *pari passu*, allow the left side of the ninth to recede, which would be equivalent to rotation of the ninth vertebra toward the left. Thus, by the yielding of this articular process, rotation occurs toward the right in one vertebra, toward the left in a contiguous vertebra, but neither toward the right nor the left in the vertebral column at this point. Again, as the inferior articular processes are subject to pressure and absorption as well as the superior, while the ninth dorsal vertebra, as above described, is rotating toward the left in obedience to the yielding of its superior articular process it will also be rotating toward the right in response to the yielding of its inferior articular process, so that the vertebra in question must at the same time rotate toward the right and toward the left—an evident impossibility.

It has been said by an acute observer, Mr. Adams himself,[1] that the great majority of pathological doctrines prove to be erroneous when tested by the experience of thirty years' scientific inquiry. Mr. Shaw's view, having been published in 1832, has survived fifty years. It must, however, be finally laid aside if the objections to its validity above presented are well founded.

DRY CUPPING AND REST

Considered as Means of Relief in a Case of Locomotor Ataxia.

By HENRY M. LYMAN, A.M., M.D.,

Professor of Physiology and of Diseases of the Nervous System, Rush Medical College, Chicago, Ill.

In the early part of the winter of 1879–80, I was consulted by Mr. D——, a gentleman, then about thirty-eight years of age, a wholesale dry goods salesman, who was suffering with well-marked symptoms of locomotor ataxia. A single man, well-formed and vigorous in his general appearance, he could trace his disorder to no hereditary cause. He was, and always had been, exceedingly temperate and correct in all his habits, and had never experienced any severe sickness. He had never had either syphilis or gonorrhœa, or rheumatism. Shortly after the great Chicago fire in 1871, at which time he had been severely overworked, he began to suffer with lancinating pains and with paroxysms of painful micturition. For this he was treated at great length by an eminent genito-urinary specialist, who considered it a case of spasmodic stricture of the urethra. Treatment with bougies, etc., failed to give any relief, and was finally discontinued. For a number of years the patient continued his usual occupations with the greatest diligence and prosperity, and with the exception of the pains just mentioned he seemed to enjoy excellent health. During the course of the year 1879, he began to experience a certain degree of unsteadiness when walking, especially in the dark. After consulting a number of other physicians, he called at my office, and requested an examination. I found him presenting the usual symptoms of progressive locomotor ataxia—lightning pains, anæsthetic, paresthetic, and analgesic patches upon the surface of the limbs, absence of the tendinous reflexes, ataxic gait, diminution of the power of co-ordination in the muscles of the upper extremities, cracking of the joints, paroxysms of hyperæsthesia affecting the mucous surfaces of the mouth and pharynx, unequal contraction of the pupils, weakened power of accommodation, progressing atrophy of the optic papillæ, and failure of sexual appetite. I advised the use of ergot, which was shortly followed with nitrate of silver, and the daily use of the galvanic current.

Living at a long distance from my office, and actively occupied with the details of his business, the patient was quite inclined to neglect his treatment. He, however, fitted up a galvanic apparatus at home, which he employed with considerable skill. By this means he thought that his pain was somewhat relieved. He could not think of abandon-

[1] Medico-Chirurgical Transactions, vol. 37, 1854, p. 179.

ing his work, which was then yielding him a large income, and I soon became convinced that his ataxic symptoms were increasing.

After an absence of several weeks, he one day called upon me, to relate his experience in New York, where he had been obliged to spend some time in connection with his business. While there, he had consulted Professor E. C. Seguin, and was for several days under the eye of Dr. Geo. M. Beard. These gentlemen both concurred in the diagnosis of locomotor ataxia, and warned him against a marriage, for which he was making preparations, an opinion with which I heartily agreed.

During the month of February, 1880, my patient was quite tractable, and underwent a course of energetic treatment with the galvanic current, applied long enough over the back every day to produce great redness of the surface. He also continued the use of nitrate of silver. After taking about a drachm of the silver salt, iodide of potassium and bichloride of mercury were substituted in its place, but without any apparent effect.

As the spring and summer of 1880 progressed there was some relief of the painful symptoms. My patient ceased calling at my office, undertook a journey to California, and again visited New York, so that I did not hear from him again until the last of September, or some time in October, 1880, when he informed me that he had determined to run the risks of matrimony. The marriage took place about the middle of October, and the unfortunate bridegroom was so much exhausted by the event that he was obliged to keep his bed the greater part of the time without the slightest attempt or desire to consummate the union. From this time I lost sight of the case.

A few weeks ago I was much surprised by the information that my former patient had been completely cured by the use of Junod's boot in the hands of a non-medical empiric. I at once took measures to ascertain the residence of Mr. D——, and opened communication with him again. From him I learned the following continuation of his history.

Almost simultaneously with the occurrence of his marriage the mercantile house with which he was connected became suddenly and unexpectedly bankrupt. By this failure he found himself thrown out of employment at a time when he was perfectly helpless. His physical condition became rapidly worse. Eyesight began to fail; ataxia increased, and the muscles of the lower extremities began to dwindle, lightning pains were frequent and agonizing. The rectum became anæsthetic and uncertain in its retention of fæces. The feet were cold and numb. When sitting erect the gluteal muscles would seem to roll outward with a sensation as if the tuberosities of the ischia had suddenly slipped down over the edges of the muscles. Walking was becoming very difficult, and was quite impossible in a dark room.

While in this pitiable condition, some one advised him to consult an empiric who was treating rheumatism with Junod's boot. The interview did not produce a favorable impression, but inasmuch as the remedy was offered gratuitously if no benefit should accrue, Mr. D—— concluded to make the experiment January 8, 1881. At first there was no apparent benefit, though the apparatus was applied twice every day. After about a month the pains began to diminish, and the circulation began to improve in the extremities. Thus encouraged Mr. D—— procured a set of the cups, etc., and his devoted wife conducted the treatment at home. The cups were applied along the spine, and the limbs were treated with the boot. Gradually improvement took place, and during the summer of 1881 the pains were entirely relieved and have never returned. The muscles also resumed their former volume; the rectum recovered its sensibility, and the sphincter renewed its appropriate function. Eyesight improved until now he is able to read without the slightest discomfort. Appetite returned; digestion was restored; the power of locomotion increased; and at the end of a year after the commencement of treatment, erections began once more to occur.

On examining Mr. D—— I found everything as he represented it. There is still some degree of ataxia manifest in the movement of the feet, especially when excited or weary. The upper extremities are perfectly manageable. Anæsthesia has disappeared from the regions where it was formerly manifested, but the tendinous reflexes are still absent. The patient walks easily and rapidly without a cane, turning sharply around without difficulty, but he is unsteady on his feet with his eyes shut, and is unwilling to trust himself in the dark. The eyeballs move perfectly, but the pupils are contracted and do not respond readily to changes of light, though they move somewhat in accommodation. There is considerable atrophy of the optic disk. Difficulty is apparent in recalling proper names, but otherwise the intellectual processes are intact. Appetite, digestion, and sleep are perfectly natural. The patient no longer feels that excessive sensibility to changes of temperature which formerly troubled him. Erections take place as often and as completely as ever. Amatory feelings have revived, and sexual intercourse has been performed several times without much subsequent lassitude, but for prudential reasons has been discontinued. The patient feels competent to resume business, but is wise enough to see that his disease is not cured, and that discretion is still the better part of valor. He still continues the use of the cupping apparatus every other day, and is positive in his conviction that his improvement, though gradual, is progressive. It is certainly true that his condition is vastly superior to what it was when I previously saw him at the time of his marriage—an improvement which is due in part to his long vacation from business, and in no inconsiderable part to the powerful counter-irritation and derivation effected by the use of the cupping apparatus. If this had produced no better result than the mere relief of pain, it would still be invaluable in his estimation. Its effect upon the general health and nutrition gives it the right, in this case at least, to rank with hydrotherapy, massage, and the Swedish movement cure as a method of treatment which deserves trial as a means of retarding the progress and relieving the anguish of one of the most intractable of diseases.

September 8, 1882.

EDISON'S ANÆSTHETIC.—Thomas Alva Edison has invented (?) a new anæsthetic compound of a mixture of chloroform, ether, alcohol, and camphor, which he has protected by letters patent in England and Germany. He probably wishes to use the new compound on the stockholders until the electric light is in successful operation.—*Chicago Medical Review.*

Progress of Medical Science.

TRANSITORY BLINDNESS FOLLOWING CHILD-BIRTH.—The following case is related by Dr. Adolf Szili in the *Centralblatt für Practische Augenheilkunde* for June, 1882: A lady, about thirty-five years of age, on the fourth day after delivery became suddenly blind. There had been no hemorrhage nor eclampsia; the urine contained no albumen. Full light had been let into the lying-in chamber for the first time that morning. No inconvenience was experienced during the period of illumination, but when the room was again darkened, the sight was suddenly lost. When examined a few hours later, there was no sensibility of the cornea; the pupils were moderately dilated and did not respond to light. The fundus was somewhat pale, but there was no especial pallor of the optic nerve nor contraction of the retinal vessels. The patient saw always through a bluish mist which did not change in varying degrees of light, nor was it broken by photopsia on pressure. Nothing else was complained of. The pulse was rather slow; temperature normal. The room was kept perfectly dark. No change occurred for forty-eight hours, when there was a temporary restoration of vision upon the lighting of a candle in a corner of the room, but as soon as it began to burn brightly the sight disappeared again. On the third day such trials were followed by a longer duration of vision. Not until the end of a week was a faint glimmer of light permitted to enter the chamber from one side, and this was gradually increased. At the end of a month the patient could read Jaeger 1 in a half-light, but only 7 or 6 in full light, and that with difficulty. A complete cure was obtained in six weeks. Two years have since passed without any recurrence of the trouble. Dr. Szili defines the condition as a hyperæsthesia of the retina, caused by the dazzling light, aided by the lowered tone of the patient consequent upon delivery.

RECTAL POLYPI IN CHILDREN.—Professor N. J. Bystroff bases the following conclusions upon the notes of thirty-one cases of polypus of the rectum in children, observed by him in the last seven years: The chief symptom of this condition, in some cases the only one, is the presence of blood in the stools, in quantity varying from a few drops to an ounce. The bowels may be regular, or there may be either constipation or diarrhœa. Pain is seldom complained of, but there is nearly always tenesmus. The pathognomonic sign is the protrusion of the tumor, though sometimes, from its situation high up in the rectum, this does not occur. The color of these tumors is darker than that of the rectal mucous membrane. The size varies from that of a pea to a plum, or even larger. The shape is round or egg-shaped, seldom pyriform. In consistence the tumors are soft; the surface is usually smooth, though sometimes rough and uneven. The polypi were located in two-thirds of Bystroff's cases on the anterior wall of the rectum, in one-third on the posterior, and for the most part between the internal and external sphincters. Multiple polypi were not observed. The general health was somewhat impaired through the repeated losses of blood. The youngest of his patients was two years and eight months old, the oldest thirteen years, the average age being, in boys, 6.8 years; in girls, 7.4 years. The sex seemed to have no influence. A polypus is most often mistaken for prolapse of the rectum, but the absence of a round opening in the centre of the tumor and of increase in size when straining will serve to exclude the latter. Polypi are more rare than prolapsus; the latter occurs in young children, the former is seldom observed in children under three years of age. In two cases a diagnosis of hemorrhoids had been made—a very rare disease in young children. A change of size under varying conditions, the presence of other varicosities, and the absence of a pedicle will suffice to distinguish piles. From dysentery polypus is to be differentiated by the absence of fever, presence of a tumor, and passages which are streaked, not mixed, with blood. An irritating enema suffices usually to bring the polypi to view, or they may be detected by digital examination or through a fenestrated speculum. Spontaneous separation of the polypus can occur. Its surgical removal is accomplished, after previous ligation of the pedicle, by the knife or scissors. Bystroff does not favor the use of the cautery in these cases.—*Deutsche Medicinal Zeitung*, June 29, 1882.

STATISTICS OF ONE HUNDRED AND THIRTY-ONE CASES OF CARCINOMA OF THE BREAST IN VOLKMANN'S CLINIC.—Dr. O. Sprengel has carefully analyzed 131 cases of mammary carcinoma operated upon in Volkmann's Clinic, from 1874-78. 112 (eighty-four per cent.) of the patients were married, 8 of whom, however, had never borne children. Of 98 cases in which the fact was noted, 21 had had mastitis once, 4 more than once, and in 4 both mammæ had been inflamed. In 44 cases traumatism was alleged as a cause. In regard to heredity 109 gave exact statements; 13 denied any hereditary taint. The seat of the tumors was in 56 cases in the right breast, in the left in 75. The tumors which appeared in immediate connection with pregnancy or lactation ran an especially malignant course. As regards the involvement of the neighboring tissues the skin was earlier attacked than the muscles. In but 2 cases, in which very small nodules were removed, was the rule for the total ablation of the mamma departed from. The results in the 131 cases, with 200 operations (including the secondary operations), were 10 deaths—1 from shock, 2 embolism of the lungs, 1 hæmatemesis, 1 gangrene, 1 erysipelas, 4 septicæmia. If the disease returned at all it was usually within the first six months after the operation. 15 are reported as cured, of which number 13 remain perfectly free from the disease after a lapse of more than three years after the operation, 1 had cancer in the opposite breast, and 1 died of a tumor, entirely distinct from the original trouble, more than three years after the removal of the breast. The cases operated upon in 1878 are not included in these figures. Of these 6 remain well, 1 for twenty-seven months and 5 for over thirty months. Of 29 cases in which there was no glandular involvement, 6 were cured, but only 9 recovered of the 102 in whom the axillary glands were already affected.—*Centralblatt für Chirurgie*, July 15, 1882.

SNAKE-BITE: RAPID CURE BY PHENIC ACID.—Dr. Sereins relates a case of snake-bite treated successfully by hypodermic injections of phenic acid. The patient, a charwoman, forty years of age, was bitten by a venomous snake on the left foot, just below the external malleolus. Half an hour afterward she experienced an intense smarting at the point of injury, and a sensation of constriction in the abdomen and epigastric region. Soon she began to throw off

quantities of glairy mucus and bile. The vomiting was almost incessant, and each attack was preceded by a painful aura starting from the wound, passing up the limb and radiating toward the stomach. A tourniquet was applied to the limb and the wound covered with a compress dipped in a solution of ammonia. Dr. Sereins arrived two hours after the woman had been bitten, and found her vomiting and suffering from a sense of impending suffocation. The skin was cold and covered with perspiration, the pulse small, feeble, and beating 110 in the minute. On the external surface of the foot, just below the malleolus, were two little red points, and above them a small blister caused by the ammonia. The lower part of the leg was enormously swollen, the skin marbled, with here and there yellowish spots and points of ecchymosis surrounded by small vesicles. The patient complained bitterly of cold. Four hypodermics of a solution of phenic acid in glycerine (2 in 15) were given, one in the neighborhood of the bite and three at the upper edge of the œdematous part of the leg. The wound was also bathed with the same solution. In one hour there was a very appreciable reduction of the swelling, the vomiting became less persistent and ceased entirely in four hours. The next day the constricting ligature was removed from the leg. On the second day the patient had entirely recovered, there was but slight swelling of the leg, and the yellow spots and ecchymosis had disappeared. The case seems remarkable in the rapidity of the cure effected. Few accidents of this kind are ever recovered from (if at all) short of a fortnight. Then the woman was not seen until two hours had elapsed after the wound was inflicted. The nervous centres were profoundly affected, as evidenced by the symptoms. Thus the phenic acid not only destroyed the venom at the point of introduction, but even neutralized its effects in the general system.—*L'Union Médicale*, June 29, 1882.

Pulmonary Tuberculosis of Traumatic Origin.—Dr. Potain, in *L'Abeille Médicale* of July 3, 1882, relates a case of pulmonary tuberculosis of traumatic origin, which may be of interest as tending to disprove the universal applicability of Koch's theory. The patient was admitted to hospital, giving the following history: Four months previously he had received a kick from a horse on the left side of the chest, the accident being at once followed by spitting of blood. Two months later he began to suffer from a frequent cough, with profuse expectoration. When nearly well from this attack he was seized anew with cough, had fever, pain in the left side of the chest, and frequent hemoptyses. Physical examination of the chest at this time revealed an impaired resonance on the left side, weak respirating sounds and numerous râles. There was also a flattening of the chest-wall, the circumference of the left side being nearly one inch less than that of the other side. The man lived but a short time after admission to hospital. At the autopsy the left lung was found to be the seat of extensive tubercular infiltration, with a cavity near the apex. There was no history of tuberculosis in the family. The parents had been long-lived, and none of the brothers or sisters had ever suffered from any pulmonary affection. The origin of this patient's disease was undoubtedly a pneumonia induced by the kick of a horse. The author states that he has observed a similar case in which a severe injury to the chest-walls was followed by a cough with bloody expectoration, the patient finally succumbing to pulmonary tubercular disease. The autopsy in this case revealed a cavity corresponding in location to the seat of the original injury. Dr. Potain, however, inclines to the belief that in some cases, at least, the traumatism may be merely the exciting cause of a previously latent tuberculosis.

Three Hundred Ovariotomies in Italy.—Dr. Domenico Penizzi has published in *Raccoglitore Medico*, July 20, 1882, a paper containing statistics of Italian ovariotomies, of which the following is a brief extract: Nineteen years elapsed after the first operation for the removal of an ovarian tumor was performed in Italy until the hundredth case was recorded. The second hundred was announced two and one-half years later, and the third series of one hundred ovariotomies was completed in twenty-three months. In the first hundred operations 63 deaths were recorded; in the second the mortality was reduced to 36; of the third hundred operations but 26 resulted fatally. Though these statistics compare very unfavorably with those of some other countries, they yet show a gratifying progress in Italy itself. The causes of death in the last hundred were: peritonitis in 10, shock in 6, septicæmia in 5, cardiac thrombosis in 3, hemorrhage and intestinal occlusion in 1 each. One patient, not included in the statistical tables, died of chloroform narcosis. The hundred ovariotomies were performed by 46 operators. In 5 of the cases both ovaries were removed, and all of these recovered.

Punctate Cauterizations in the Treatment of Pulmonary Diseases.—Dr. Vidal writes, in *L'Union Médicale* of July 20, 1882, advocating numerous light cauterizations in the treatment of diseases of the respiratory organs. He employs a Paquelin cautery, with a very fine point kept just at white heat. The point is held in the hand like a pen, and the operator, by a rapid movement of the wrist, makes a number of exceedingly fine lines about fifteen millimetres apart, just grazing the epidermis, but never going deep enough to destroy any of the deeper cutaneous tissues. The efficacy of the procedure depends rather upon the multiplicity of the cauterizations than upon their depth or superficial area. A sitting should be held once in two or three days, care being taken in the repeated operations to avoid the points on the skin previously touched by the cautery. The pain caused by the operation is very trifling, and no disfiguring cicatrices are ever left. The effects produced by this punctate cauterization are of three kinds. The first is in the action on the skin. There is always an intense hyperæmia of the skin following the operation, together with an elevation of local temperature, amounting in some cases to more than 1° C. The impression produced upon the nervous centres is shown by the horripilation of the skin, which is pretty constantly observed over the cauterized area.

The effects produced upon the lungs and pleura are observed in a reduction of the number of pleural friction sounds, together with the gradual subsidence of all the evidences of pulmonary congestion. The dulness diminishes, the lung becomes more permeable to air, and in some instances Dr. Vidal even claims to have succeeded in arresting hemorrhages of some gravity. At the same time there is an evident improvement in the cough and expectoration. The effects upon the general system are equally noticeable. The fever diminishes, the evening exacerbations lose their regularity, sometimes

even disappearing entirely, the sleep becomes refreshing, and it is seldom necessary to continue the use of atropine to control the night-sweats; the appetite improves, the diarrhœa is checked, and in women the suspended menstrual functions are restored.

The author gives the results in forty-four cases of phthisis treated by him on this plan during the winter of 1881–82. Two of his patients discontinued the treatment, three died, two remained stationary, and in one case the disease steadily progressed; the remaining thirty-six were benefited, some markedly so. Eighteen of his patients had previously had hemoptysis; in ten of these there was no return during the winter, and in the other eight each recurrence of hemorrhage was promptly checked by the employment of the punctate cauterization for a short sitting.

While Vidal's claims are to be received with caution, his method certainly deserves a trial, and may yet prove a valuable adjuvant to other plans of treatment.

Cirrhosis of the Liver, with Adenoma.—The following case was reported by Dr. A. Sevestre to the Société Médicale des Hôpitaux: The patient, a man forty-four years of age, had always enjoyed excellent health up to within two months of the time of coming under observation. There was no history of hereditary disease. He had, however, for a long time indulged freely in wine and brandy. The first symptoms were those of digestive disturbance—nausea and vomiting of mucus and bile following each excess in drinking. The appetite failed and was finally lost completely. At this time the patient began to emaciate rapidly, losing twenty-five pounds in four weeks. Two weeks before admission to hospital he experienced a sensation of heat and weight in the epigastric region, and the abdomen increased rapidly in size. On admission to hospital the abdomen was greatly distended, the skin tense and marked with a network of distended veins. The liver could not be discovered on palpation, owing to the abundant ascites. There was no œdema, even of the lower extremities. The forehead, cheeks, and nose were the seat of a confluent eruption of acne rosacea. The skin was of an earthy hue. The urine was scanty, reddish in color, and threw down a brick-dust deposit. It contained no albumen, but nitric acid revealed the presence of biliary coloring matter. Physical examination of the chest revealed nothing of importance. A diagnosis was made of acute cirrhosis of the liver. The abdomen was tapped and a large amount of serous fluid withdrawn, but the patient continued to emaciate and died in a few days. At the autopsy the abdominal cavity was found to contain a moderate amount of fluid. The liver was enlarged, weighing a little over five pounds. Its general form was preserved, but the surface presented the appearance of a cirrhotic liver, with nodules varying in size from a millet-seed to a large pea. In addition there were here and there larger projections, paler than the rest of the organ and resembling cancerous nodules. At certain points, particularly on the under surface of the organ, were seen pale streaks, evidently distended veins. On cutting across these, a thick fluid of a yellowish white color escaped. The portal vein was occluded with what was taken to be a decolorized coagulum. Its intestinal position, however, was patent. The spleen was normal. The stomach gave evidence of gastritis. The histological examination was conducted by M. Sabourin. He reported that the cirrhosis was general and entirely distinct from the tumors disseminated through the organ. The latter were simple and round or irregular in shape, and divided into lobes and lobules. All were encysted or in process of becoming so. These tumors approach the type denominated adenoma of the liver. They take their origin in the hypertrophy of a group of lobules through hyperplasia of the hepatic cells. As soon as one of these adenomatous nodules is in process of formation, it tends to become encysted through atrophy of the neighboring lobules. The portal vein and its branches were filled with colloid material and detached epithelium, and not, as was at first supposed, with a decolorized blood-clot. This case presented in nearly all its symptoms a clinical picture of ordinary cirrhosis—digestive troubles, ascites, enlargement of the superficial abdominal veins, brick-dust deposit in the urine, earthy complexion, etc. But there were other symptoms which are a little unusual. The speedy progress of the disease, the marked emaciation, the rapid development of ascites, and establishment of the collateral circulation. In the etiology alcohol would seem to have played an important part.—*L'Union Médicale*, July 27, 1882.

Hydroa of the Mouth.—Hydroa, when it occurs in the mouth, may give rise to certain erroneous diagnoses—syphilis, for example—leading to energetic treatment which, at best, is useless. Dr. Quinquad (*Annales de Dermatologie*) has recently given a description of this affection, which may be of service in differential diagnosis. The affection is essentially superficial, and varies according to the region which it attacks. On the lips it begins by an intense redness on the median line or on either side of this line. It hardly ever has its place in the commissures which distinguishes it from the syphilides. The erythema is at first circumscribed, sometimes occupying the mucous membrane alone, sometimes the mucous membrane and the skin. The redness is like that of the cherry. Within the first thirty-six hours it manifests an opalescence similar to that of the syphilides; ulceration follows upon the ingestion of irritating viands, and gives rise to a slightly sanguinolent discharge. At this time the lips are covered with disseminated crusts, presenting here and there fissures. These brownish concretions circumscribe whitish, opalescent, humid spaces, which give place to vesicles. The same lesions may be met with on the inside of the lips, on the gums, where it resembles an ulcero-membranous stomatitis; on the tongue, where it simulates thrush, and on the palate. The eruption has three phases of evolution—an erythematous phase, which is very short; an erythemato-phlyctenoid phase, during which are produced the exudations; a phase of ulceration, which simulates the mucous patches of syphilis, and is followed by a period of repair. During all these stages pain is present. As a rule the eruption affects the mouth only when very intense and widespread. To this, however, there are some exceptions. The treatment consists chiefly in mild and astringent gargles.—*Chicago Med. Review*, August 1, 1882.

An Exhibition of Rational Dress is to be held in London under the auspices of the Rational Dress Society. A prize of $150 will be given for the most rational dress.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, September 30, 1882.

SCARCITY OF ORIGINAL WORKERS.

It has often been said by foreign physicians that the American medical man is not much inclined toward original work. While this is not so true as formerly, the charge still holds good in a great measure. But we must consider, comparing the profession in this country with that of Europe, that there are not a few good reasons for this. Taking the American medical profession in the aggregate, its standard of acquirements is much below that of medical men abroad. It goes without the saying that the so-called education of medical men here is cultivated more as a business than a science. Consequently, in order to gain patronage, the struggle with the majority of educators appears to be in the direction of affording the easiest possible entrance into a profession for a given outlay of money. It is not surprising, then, that a goodly majority of the hundreds of yearly accessions to our ranks have a comparatively low standard of qualifications, which scarcely fits them for the every-day duties of the ordinary practitioner, much less for progressive work in the profession. With the average graduate in medicine there is on this account a constant struggle against heavy odds during most of his career.

What inclination he may have for extra study must be in the direction of making good his lost opportunities, of filling in the gaps of what should have been a solid foundation from the beginning. Whatever may be said of the advantage of natural genius in surmounting great obstacles, they never amount to much in professional training, compared with patient, systematic, long-continued, plodding work. It is easy to see under what disadvantages the average medical graduate labors. While we are inclined to pity his miscalculation, we are hardly ready to excuse his shortcomings. He does as well as he can, it is true, but under the circumstances this is his only excuse for trying to do at all.

But even among our well-educated medical men there are serious obstacles to progressive work which do not obtain to an equal extent in other countries. We may refer to them in passing, by way of explaining more than of excusing their natural results, for on general principles it is expected of the ambitious struggler that he shall overcome difficulties. Still, this is not always possible, as we can easily see. For instance, the bread-and-butter question is constantly before the most ambitious and best qualified medical man. He is forced to turn his knowledge to practical account in getting money to support his family and keep on the right side of his expenses. Be his practice large or small, it must under the circumstances absorb his greatest attention, and call forth his best working energy. When he comes to this, he generally does his best in keeping up his knowledge to the actual requirements of his every-day duties. Too often, indeed, it becomes with him the exception rather than the rule that he can study at all.

While this may be difficult enough when the necessities of the hour press themselves upon the busy practitioner, how much more so must it be when he is inclined to strike out in some new or original departure, requiring extra time, engrossing thought, hard study, and untiring industry. We must be understood in all this as attempting to give the reason why he does not do original work, rather than why he should not do it. It may, at least, be said that the difficulties in the way of his climbing, although not insurmountable, are great indeed compared with what they are in other countries, where competition is not so active, and where good doctors are not so plentiful.

But besides this, in the large medical centres of Europe, there is a goodly number of well-educated men, whose living is assured by salaried positions under the government and in the universities, and whose time and opportunities for study are everything which the most ambitious investigator could wish for. Indeed, there is a premium placed upon such original work as tends to the advancement of science, pure and simple. Hence the professors of pathology, physiology, anatomy, and chemistry have larger salaries attached to their chairs than do the professors in the clinical departments, as the latter can necessarily add to their incomes by practice. But underlying all the real good work is a guarantee to them that the living shall be secured, and the question of the supply of actual wants shall be kept decently in the background. Place the average ambitious, well-educated American medical man on such a footing, and he will make equal progress.

We have seen what can be done under govern-

ment patronage, even to the limited extent to which its advantages are extended in this country. Take, for instance, what has been done in the office of the Surgeon-General of the Army during the past fifteen years, the writing of the medical and surgical history of the war of the rebellion, a work unrivalled anywhere, the army medical library, a collection for extent and variety unequalled in this country or abroad, the wonderful microscopical studies in the laboratory of the Army Medical Museum, and last, but not least, the founding and arrangement of the museum itself, comprising thousands of specimens illustrating many of the rarest and most wonderful pathological lesions. Again, the more recent investigations into the origin and causes of yellow fever, cholera, and diphtheria, are not to be omitted in the enumeration of the grand achievements which have been made possible under the auspices named. Unless the proper facilities as to means, opportunity, and livelihood were afforded to the gentlemen engaged in these undertakings, such gratifying results would have been utterly unattainable. The approach to this condition is in the medical men who have assured incomes aside from their practice, or whose business is large enough to allow them the time for studies of their choice. Although much is done by the actual bread-winners in our profession, by men who stop at nothing in the way of an ambition to do and dare, the greater part of the original thinking is accomplished by such as are afforded ample time and opportunity for so doing. The young man of wealth has decidedly the best start in a good education and means to perfect it. He can attend the best schools, can spend his time in our larger hospitals, can enjoy the advantages of special courses here and abroad, and while waiting for practice and studying his cases, he is not worried about his board bill or office rent. From such men, having the right sort of ambition, our best expectations are to be realized. Unfortunately they are as yet too few in number in this country to give the American profession its share of substantial and progressive workers.

In the other category of advancing men are to be found the successful practitioner, whose time can be made his own, whose living is easily earned in his morning office hours, whose consulting-room is always well patronized, and whose hours for study in his library, laboratory, or in the hospital ward can always be secured from his busiest days. Such men make up the bulk of our medical authors, the majority of our original investigators, the winners of our medical prizes, and, best of all, our most accomplished practitioners. Happily, we have many of these; not in a necessary proportion, perhaps, but the number is constantly increasing, and there are proportionately good hopes for the future. We would fain believe that we are approaching the time when endowed professorial chairs will be a demonstrated fact, when higher medical education will be a reality, when government patronage shall be still more extended, and when, by the profession itself, still more incentives for original investigation may be offered in the shape of larger and more substantial prizes.

It is only by such means, and with the increased opportunities for work, that the profession of this country can take its proper position as an advancing scientific body. There are enough men capable of doing the best kind of original work, if reasonable facilities for its accomplishment were within their reach.

COTTAGE HOSPITALS.

We are glad to learn from several parts of the country that the suggestions in the recent article on the establishment of cottage hospitals have been so favorably received. It is quite evident that prominent members of the profession in many of the larger towns of this and adjoining States are in favor of organizing such charities. As such can be done on a comparatively inexpensive scale, there need not be many difficulties in the way.

A good commencement can be made by renting a cottage on the outskirts of a town and fitting it with a small number of beds. When once the utility of the measure can be demonstrated to the local authorities and the men of wealth in the vicinity, there will not be much trouble in obtaining the necessary amount of funds for the erection of a cheap and suitable hospital building.

According to the estimates made to the State Board of Health for similar buildings, the expense of construction need not exceed six thousand dollars for an institution containing from ten to fifteen beds. Where land is low priced and lumber plenty the expense will be proportionately less. In the interesting and exhaustive work of Mr. Henry C. Burdett,[1] of London, on "Cottage Hospitals," will be found descriptions of such institutions of even larger capacity which can be built at even less cost. For instance, the outlay for construction of the Petersfield Cottage Hospital, a model of its sort, capable of accommodating sixteen patients, was but $5,500. In fact, he mentions numerous examples of the relative cheapness and utility of such structures. The number of cottage hospitals in successful operation in England is sufficiently large to leave no doubt that a similar experience can be had in this country, where magnificent distances between centres are the rule and where accidents of every variety are very common.

[1] Cottage Hospitals, General, Free, and Convalescent. Their progress, management, and work, with plans, illustrations, etc. By Henry C. Burdett, Member of the Council and Fellow of the Sanitary Institute of Great Britain, etc. Second edition, rewritten and enlarged. London: J. & A. Churchill, 1880.

In some large manufacturing districts an approach is made to the cottage hospital system by levying an individual tax upon the operatives, and in consideration for the same providing them with medical attendance during sickness. In some instances special buildings are appropriated for the purpose. These are, however, private enterprises, only tending to prove at how small a cost the sick can be cared for. Cottage hospitals as such should belong to the towns and be more or less under the control of the health authorities, by whom the medical staff may be appointed.

BACTERIA AND THE PATHOLOGY OF SYPHILIS.

The idea of living organisms being the cause of syphilis was expressed in a rude form as early as the seventeenth century. It has been reserved for the last decade, however, to defend this view with any facts or arguments deserving attention. In 1872 Lostorfer created a sensation by announcing the discovery, in the blood of syphilitics, of microscopic bodies, pathognomonic, as he claimed, of the disease. The bodies in question were soon found to exist in other diseases, however, and were shown to originate from the white blood corpuscles.

Not long after this, Klebs announced the discovery of micrococci in the initial lesions of syphilis. He did not, however, find them in the secondary lesions. At a meeting of the New York Pathological Society, November 11, 1880, Dr. Berman, of Baltimore, showed what was claimed to be these same organisms. But no positive evidence was given that they had a specific character.

Disappointment has not dampened the ardor of pathologists, however. Aufrecht, following Klebs, found micrococci in the juice from condylomata; and now Birch-Hirschfeld, of Berlin, announces that similar micro-organisms are constantly present in gummatous ulcers and the gummata of internal organs. They were found chiefly in zoogleia or colonies in the outer parts of the syphilomata. In some cases, however, they could be seen within the round, oval, and spindle-shaped elements of the granulation-tissue.

Under high powers these organisms were seen to be very small, rod-shaped bodies, not more than one twenty-five thousandth of an inch in length. In some cases they appeared spherical, but this was, no doubt, owing to their position.

The zoogleia masses were demonstrated in the following way: The specimens were hardened in alcohol; sections were then soaked in vinegar and mounted in glycerine, when they could be seen without further manipulation. Staining with fuchsin, in the ordinary method, brought them out more distinctly.

Birch-Hirschfeld found the above-described organisms in twelve gummata taken from different viscera in seven cases. He also found them in the initial and secondary lesions of three cases. One of the gummata examined was from the lungs of a case of congenital syphilis.

Hirschfeld's alleged discoveries have excited much attention. It seems hardly necessary to make any comment upon them, however. We would call attention simply to two points: The alleged specific micrococci were found in a case of congenital syphilis. It is very difficult to frame an explanation of how the baneful organisms were transmitted to the child from the diseased parent. Again, the organisms were found in the tertiary lesions of syphilis, which lesions are not auto-inoculable, and probably not contagious in any way. The micrococci, therefore, found in them have either lost their specific characters, or they never had any, which, we confess, seems more probable in the light of our present knowledge.

To prove that there is a specific organism for syphilis, this organism must be shown to be present in all contagious lesions, and absent in the non-contagious. It must be isolated and cultivated; and the cultivations must be proved to have specific properties.

At present by far the most satisfactory theory of the pathology of syphilis, if one must have a theory, is that the disease, as urged by Otis, is due to an (speaking provisionally) unorganized, though not inorganic, poison; in other words, to a pathological ferment which impresses morbid activities upon the cells to which it is brought.

THE DOCTOR'S CLOTHES.

It is related of the late Professor Skoda that he was invited to dinner at court one day, and went directly from lectures in his ordinary dress, which was not overclean. Upon being reminded that his costume was not what etiquette expected, he answered that he would go home, if they wished, and send his frock-coat to dine. This anecdote has been much quoted as showing great wit and independence of spirit on the part of the late professor.

It may be looked at, however, from quite another point of view. Society very quickly classes persons who do such acts as boors, and justly finds as much vanity as independence in their parade of slovenliness. Skoda's example was a bad one.

The doctor has two rules which should guide him in his dress. It should be neat and unobtrusive. He should neither flaunt himself in unconventional garments, nor aim at being the glass of fashion.

Uncleanliness and slovenliness are crimes in a sick-room.

The day has long passed when the physician attempts anything like a professional cut to his clothes. In the last century, the physicians were men of learning, and posed themselves as such.

The wig and the gold-headed cane proclaimed the doctor a man of medical skill perhaps, of medical erudition certainly. Now the doctor is a man of the world. He studies human nature and his patients rather more than his authorities. In his dress, therefore, he should ally himself with those whom he meets. Eccentricities are not tolerated now, except among the aged who have won the right to do as they choose, and still claim respect.

To the items of neatness and unobtrusiveness in dress some would now add certain qualifications of a sanitary character. Our dress, says a "Country Practitioner" in the *California Medical Journal*, is quite irrational. The neck and extremities are exposed, the back and hips are swathed in many layers.

No doubt there are some improvements possible, and perhaps, in the future, when every town has a Board of Health, a model suit of sanitary clothes may become the fashion. For the present, most of us can get along very well with the judicious use of flannels. We shall always oppose the idea that one of the physician's duties is to live up to a sanitary ideal—for the benefit of ungrateful humanity.

THE VALUE OF EUCALYPTUS OIL.

Dr. G. v. Schleinitz, of Arnsberg, gives the results of his experiments with eucalyptus oil. He has used the drug quite extensively, giving it in doses of ℥x. to ʒj., dissolved generally in diluted alcohol. A slowing of the pulse was generally observed after large doses, and there was always a very perceptible odor of the oil in the breath, showing that it is excreted by the lungs very largely.

Externally the oil was used in dressing wounds. The results obtained were good, and agreed with those of other observers. No remarkable advantage can be claimed, however.

The oil is somewhat irritating, and it was generally applied by soaking gauze in a five per cent. solution. Eucalyptus is not a powerful aseptic or antiseptic, however. According to Koch's experiments, a solution must be at least of the strength of seven per cent. to destroy germs, although a one per cent. solution will prevent their growth.

In diseases of the skin, eucalyptus oil gave unsatisfactory results. It was tried in eczema prurigo, psoriasis, etc. It seems to be too irritating, and to have no specific effect.

In diseases of the vagina (inflammation) and uterus the oil was employed, but also with unsatisfactory results.

Internally, eucalyptus was given for chronic intestinal catarrh, dysentery, and summer diarrhœa, but without success. Its use in four cases of typhoid fever was equally ineffective. It was not tried for vesical or urethral troubles. Although other observers have claimed something for it here.

The most satisfactory results were obtained in bronchitis, phthisis, and whooping-cough. The oil was given by inhalation. Its action seemed to be somewhat like that of turpentine, but more agreeable.

Schleinitz's experience, as regards respiratory diseases, resembles that of Gunbert, Carlotti, Schultz, and others. His method of giving it by a special inhaler or respirator (Hausmann's) may be an advance. A number of clinical histories are given.

According to the present evidence, eucalyptus oil, although useful in various ways, has no specially good medicinal value, unless it be in diseases of the respiratory organs.

Reports of Societies.

AMERICAN GYNECOLOGICAL SOCIETY.

Seventh Annual Meeting, held in Boston, Mass., September 20, 21, and 22, 1882.

WEDNESDAY, SEPTEMBER 20TH—FIRST DAY—MORNING SESSION.

The Society was called to order at 10 A.M. by the President, Dr. T. Addis Emmet, of New York.

The Secretary, Dr. Jas. R. Chadwick, then called the roll, and the following members responded: Drs. Lyman, Bixby, Reynolds, and Richardson, of Boston; Mundé, F. P. Foster, and Barker, of New York; W. T. Howard, and H. P. C. Wilson, of Baltimore; Joseph Taber Johnson, of Washington; Van de Warker, of Syracuse; Engelmann, of St. Louis; Trask, of Astoria, N. Y.; Jackson, of Chicago; Kimball, of Lowell; Drysdale, of Philadelphia. Subsequently there were present: Drs. Thomas, C. C. Lee and Garrigues, of New York; Skene and Byrne, of Brooklyn; A. H. Smith and Goodell, of Philadelphia; Campbell, of Georgia; and Busey, of Washington.

The following were made

MEMBERS BY INVITATION

during the meeting:

Mr. J. Knowsley Thornton, of London, England; Drs. Abbot, Arnold, Baker, Blake, Boardman, Brown, Curtis, Doe, Draper, Edson, Fifield, Forster, Hodgdon, Homans, Hosmer, Ingalls, Minot, Sinclair, C. E. and J. Stedman, Swan, Wellington, and B. E. Cotting, of the Boston Obstetrical Society; Drs. E. C. Gehrung, of St. Louis; M. D. Mann, of Buffalo; P. H. Ingalls, of Hartford; S. Cooper, of Westfield, N. J.; F. E. Stewart, of Philadelphia; Robert T. Wilson, of Baltimore; Drs. S. A. Green, Mayor, H. J. Bigelow, H. I. Bowditch, C. Ellis, R. H. Fitz, R. M. Hodges, H. C. Haven, J. Homans, F. J. Knight, G. C. Shattuck, G. B. Shattuck, J. C. Warren, J. C. White, C. J. Blake, H. W. Williams, O. W. Holmes. B. Cushing, and C. Withington, of Boston; J. T. Whittaker, of Cincinnati; W. Symerington Brown, of Stoneham; W. E. Moseley, of Baltimore; H. Marion Sims, of New York; L. Wheeler and Geo. E. Francis, of Worcester; L. S. Fox and W. T. Carolin, of Lowell; F. H. Hooper, A. N. Pierce, and Dr. Jewett, of New Bedford; and E. H. Grandin, of New York.

THE ADDRESS OF WELCOME

was made by Dr. G. H. Lyman, of Boston, First Vice-President, upon whom the duty devolved, owing to the illness of Dr. Storer.

The first paper was read by Dr. Joseph Taber Johnson, of Washington, D. C., on

THE PROPER USE OF ERGOT IN OBSTETRICS.

The author had nothing new to offer, but hoped to bring the knowledge already possessed into such shape as to show the powers of the drug for good and for harm, and to formulate a few safe rules for guidance in its administration to women in labor. With its other uses he did not deal. The author then referred to the different teachings concerning the use of the drug. With reference to its physiological action there was an agreement that it produced in a uterus already in labor a persistent tonic contraction which finally became tetanic in character, and that this kind of contraction was diametrically opposed to the intermittent rhythmical contractions of the normal parturient uterus. The danger of long-continued pressure of the head of the child upon the soft parts of the mother was then referred to, and also the liability of producing still-births by the use of the drug to overcome uterine inertia. He did not believe in its efficacy in cases of retained portions of the membranes, and thought that the labor of their extraction was very much increased by its use. He believed that the human race would be better off without than with ergot in the management of labor; certainly it should never be given to a primipara.

The paper was discussed by Drs. J. P. Reynolds, of Boston; Fordyce Barker, of New York; W. T. Howard, of Baltimore; J. D. Trask, of Astoria, N. Y.; G. J. Engelmann, of St. Louis, and the discussion closed by Dr. Johnson.

The Secretary, Dr. Chadwick, then read a paper by Dr. R. S. Sutton, of Pittsburg, Pa., and entitled

SOME REMARKS ON THE TREATMENT OF THE PEDICLE IN OVARIOTOMY.

The paper was largely historical in character, and contained a careful résumé of the different methods of treating the pedicle in ovariotomy, with the dates of their introduction. That Robert Houston, of Glasgow, did attack a cystic tumor of the ovary in 1701, there seemed to be no doubt, and the woman lived thirteen years after the operation. The first systematic ovariotomy was performed by McDowell, of Kentucky, in 1809, and the operation was nearly as perfect as performed to-day. The paper closed with a consideration of the various conditions which influence success and failure, such as climate, avoidance of the operation in public hospitals, avoidance of septic diseases by the operator and his assistants, maintenance of strict cleanliness, etc.

The paper was discussed by Mr. J. Knowsley Thornton, of London, England, and Drs. H. P. C. Wilson, of Baltimore; G. H. Lyman, of Boston, and G. Kimball, of Lowell, Mass. Drs. H. P. C. Wilson, of Baltimore, and J. D. Trask, of Astoria, were appointed Auditing Committee, after which the Society adjourned to meet at 3 P.M.

Wednesday—First Day—Afternoon Session.

The Society was called to order by the President, and

Dr. Theophilus Parvin, of Indianapolis, read a paper on

THE CARE OF THE PERINEUM IN THE SECOND STAGE OF LABOR.

It had been shown by Duncan and Schroeder that in primiparæ some tearing of the vulvo-vaginal orifice was inevitable; only thirty-nine per cent. of women in their first labor, according to the latter, escaping rupture of the fourchette. Concerning the frequency of rupture, the statement that several hundred cases of labor had been attended without the occurrence of that accident could never be accepted, unless the person making it could also state that he had carefully examined the perineum in every case immediately after labor. The statistics of many obstetricians were then given, after which the author passed to the consideration of the causes, such as those relating to the pelvis, condition of the soft parts, etc. In order to reduce the accident to the minimum or prevent it, it was the duty of the accoucheur to hinder the abrupt expulsion of the head of the fœtus, and permit gradual dilatation of the passages which it traverses. The various methods recommended for accomplishing this were then considered. When rupture was otherwise inevitable, it had been proposed to prevent the accident by incision or incisions, but episiotomy should not be resorted to unless it was indispensable. Dr. Parvin advocated immediate closure of the rupture, should it occur, and the use of horse-hair sutures, which certainly were readily obtained, and probably were quite as good as any other material that could be used.

The paper was discussed by Drs. A. H. Smith, of Philadelphia; James R. Chadwick, of Boston; W. T. Howard, of Baltimore; Paul F. Mundé, of New York; and closed by Dr. Parvin.

The next paper was read by Dr. Fordyce Barker, of New York, on

LEUCORRHŒA: ITS CONSTITUTIONAL CAUSES AND THERAPEUTICS.

It seemed to the author of the paper that the fact that leucorrhœa was not a distinct disease, but a symptom of many different and even opposite pathological conditions, had led to a neglect of its study, and practically to a forgetfulness of the fact that it not rarely originates from constitutional causes, and that when long continued it becomes itself a cause of local and important pathological changes. No writer during the last quarter of a century had considered it, except incidentally, as a symptom of some local disease, with the exception of Comty Stoltz and Robert Barnes, who had called attention to some of its constitutional causes. This was equally true of American, English, French, and German gynecologists.

For many years he was an entire disbeliever in the opinion of Tyler Smith that leucorrhœa was in many cases the primary cause of morbid states of the os and cervix, and while now he was not at all disposed to accept the statement that this is the fact in the majority of cases, in the few last years he had been convinced that it was true in some. While all accept the statement that local and constitutional causes continue to develop leucorrhœa, yet he thought it might be questioned whether the latter be not too often disregarded in the present day, both in the diagnosis and treatment of this disorder.

Many of these constitutional causes, such as atmospheric changes, which induced general catarrhal affections, plethora in some, anæmia in others, all forms of defective nutrition and debility, etc., were well understood. The influence of nerve disturbance, as a consequence of defective nutrition, was, perhaps, not so generally appreciated, although most practitioners knew the fact that in some of their patients strong mental emotion was sure to bring on a troublesome leucorrhœa. Dr. Barker

then considered the bearing which certain anatomical facts, pointed out by Mayrhofer, had upon this disorder, namely, changes in the blood-vessels of the uterus produced by pregnancy. Leucorrhœa and its attendant symptoms was not at all rare in young unmarried ladies, and every year he was consulted concerning it, chiefly by those who came to the city "to finish their education," as it is termed. The moral depression from home-sickness and exhaustion of nerve-power, exercised in accustomed directions, seemed to him to be the most common of the constitutional causes of these cases. He suspected the most frequent error in the treatment of these cases was found in a disregard of the necessity of such remedial agents as would secure a healthy performance of all the organic functions, a neglect of the *morals*, and a routine prescription of some preparation of iron, which, under these circumstances, was sure to destroy the appetite and produce headache, etc.

Leucorrhœa, in consequence of parturition, and in women who had passed the climacteric period, was then considered, after which the paper was discussed by Drs. G. H. Lyman, of Boston; H. P. C. Wilson, of Baltimore; A. Reeves Jackson, of Chicago; Joseph Taber Johnson, of Washington, D. C.; A. H. Smith, of Philadelphia, and the President, and closed by Dr. Barker.

The Society then adjourned to meet on Thursday at 10 A.M.

THURSDAY, SEPTEMBER 21ST—SECOND DAY—MORNING SESSION.

The Society was called to order by the President, and the first paper was read by MR. J. KNOWSLEY THORNTON, of London, England, and entitled

THE RELATIVE VALUE OF HYSTERECTOMY AND OF THE COMPLETE REMOVAL OF THE UTERINE APPENDAGES FOR THE CURE OF UTERINE FIBROIDS.

Under the term "Hysterectomy" he included all cases in which the uterine cavity is laid open, more or less of its wall removed along with the fibroid. Whether one or both ovaries is removed is a matter of no consequence. He reserved the term "complete supravaginal hysterectomy" for cases in which the uterine appendages and vagina are removed, and it is therefore a combination of the two operations, which we consider as rivals to-day.

It was well known that yearly a very large number of women died from the direct or indirect effect produced by fibroid enlargement of the uterus. There were many also whose lives were constantly endangered, and many more whose lives were rendered so useless and their suffering made so severe that they were justified in taking the risks of having the operation performed.

The author of the paper considered solely those cases which could be best treated by abdominal section, if treated at all. The conclusion reached, after the presentation of statistics of different operations, was, that surgical aid was justifiable, even necessary in a certain number of cases, and yet there was the grievous mortality of somewhere between thirty and forty per cent. after abdominal section, and a still higher rate of mortality when the uterine cavity was cut into, or the supravaginal portion of the uterus was removed. Notwithstanding all the improvements, the operations of hysterectomy and complete supravaginal hysterectomy remained very formidable. But thanks to American surgery, the brilliant conception of Blundell, in 1823, was made a recognized surgical procedure by Battey in 1874, and from the labors of others he was able to present a perfected operation, which would render hysterectomy still less formidable than it had been.

The complete removal of the uterine appendages, when efficiently performed, cured fibroid of the uterus with a rapidity and certainty that Blundell in his most sanguine moments never dreamed of. Mr. Thornton then gave statistics of the operation, so far as he had been able to collect them, and showed that removal of the uterine appendages was attended by less immediate danger of life than other operations for the removal of uterine fibroids. The reasons for performing the operation were made apparent in the brief histories of eight successful cases which were given, and the condition of the ovaries was also mentioned. The remaining portion of the paper was devoted to the consideration of the selection of cases, and the method of performing the operation, which must be done thoroughly; mere removal of the ovaries being useless, still less useful the removal of a portion of them, thorough strangulation of the tubes and overies at their bases, antiseptic precautions, etc.

The paper was discussed by Drs. Goodell, of Philadelphia; Thomas, of New York; Kimball, of Lowell; Engelmann, of St. Louis; and closed by Mr. Thornton.

ANNUAL ADDRESS BY THE PRESIDENT.

The President, DR. THOMAS ADDIS EMMET, of New York, then delivered his address, in which, after making fitting reference to the death of Dr. James P. White, of Buffalo, one of the founders of the society, he proceeded to speak on a special subject, namely,

A NEW METHOD OF EXPLORATION, WITH THE PATHOLOGY AND TREATMENT OF CERTAIN LESIONS OF THE FEMALE URETHRA.

The general practitioner has yet gained but little knowledge pertaining to diseases of the female urethra. In fact, it might be held that the subject had remained to this day in as much obscurity for the profession at large as existed regarding uterine disease some forty years ago, before the introduction of Sims's speculum. Individuals doubtless had attained dexterity in the use of certain instruments, and had been fairly successful in the treatment, but the existence of a profound degree of ignorance had been the rule, and consequently much damage had resulted from the frequent confusion of cause and effect. We could scarcely credit the fact that the female bladder had been treated heroically for diseases, when the cause of the irritation was due to a fissure in ano. He had known of several instances where, with a pertinacity worthy of a better cause, the bladder had been injected with solutions of nitrate of silver, week after week, until at length cystitis became established. Many, with himself, had treated without success a supposed diseased condition of the bladder or urethra, when the seat of irritation existed in an unsuspected inflammation about the folds of the utero-sacral ligaments. He had opened the bladder, for supposed disease, by making a vesico-vaginal fistula, and subjected the patient to months of inconvenience from escape of urine, closed it, and reopened it, because of return of the symptoms, and finally found that the disease was urethral polypus, which the use of the endoscope,

in the hands of an expert, had failed to discover. Regarding the various means which had been heretofore proposed for examining the female urethral track as possessing but very little practical value, even in the hands of those most accustomed to their use, Dr. Emmet at once passed to the description of the new method of exploration, which formed the basis of his address.

It was some six years since he devised the plan of making a buttonhole-like opening in the female urethra for the purpose of making a diagnosis and also for facilitating any operative procedure. In the second edition of his book he had entered into the subject at considerable length, but during the last two years he had given it very careful study. The method described he regarded as the only one within our knowledge which fulfilled every indication, was safe, simple, and within the scope of any one possessing the least degree of surgical dexterity. It was as follows: administer an anæsthetic, place the patient upon the left side, and use a moderate sized Sims' speculum for bringing into full view the vaginal surface covering the urethral tract.

He had devised an instrument with which to make the opening into the urethra, but it had not been yet perfected to his satisfaction. It operated much on the plan of the ordinary scissors used for cutting buttonholes. The operation could be readily performed by means of tenaculum, knife, and straight-pointed scissors with a block-tin sound, of size sufficient to place the tissues upon a moderate stretch, within the urethra. The opening should be made in the median line, forward to within one-fourth of an inch of the meatus, and backward nearly to the neck of the bladder. The neck of the bladder should never be involved in the incision. The line along the vaginal surface should be nearly one-third longer than the one through the urethral mucous membrane, and it was important that the chief difference should be at the end of the line from the neck of the bladder. If the opening was simply for exploration, it might be closed without delay, as in vesico-vaginal fistula. The advantages claimed for the method were that the whole of the canal could be fully exposed; that it was safe, and could be applied by any one possessing ordinary surgical dexterity; that, if properly performed, control over the urine will not in the slightest be impaired; that no difficulty has been experienced in closing the urethral opening afterward; and that no difference has been appreciated in the passage of the urine after the operation. It is not intended to supercede the formation of a vesico-vaginal fistula for the treatment of cystitis or removal of stone.

The paper was discussed by Dr. Barker, of New York, who referred to cases in which Dr. Lusk, of New York, had performed this operation with the most gratifying results.

Dr. A. J. C. Skene, of Brooklyn, was unable to accept the President's unqualified condemnation of all other methods of exploring the female urethra, and took issue with several statements, believing that there was no disease which could be diagnosticated with more certainty than cystitis and diseases of the urethra, with one exception, and that was polypus or any neoplasm. Other than that our means of diagnosticating urethral diseases were as accurate as those we now had for recognizing lacerations or inflammation, or fissures, as explained by Dr. Emmet.

After some further remarks and discussion, the Society adjourned to meet at 3 P.M.

Second Day—Afternoon Session.

The Society was called to order at 3 o'clock, Dr. G. H. Lyman, of Boston, first Vice-President, in the Chair.

The first paper was read by Dr. T. G. Thomas, of New York, and entitled

NOTES OF TWENTY-ONE CASES OF EXTRA-UTERINE PREGNANCY.

Until the last decade very little special attention had been paid to the clinical study of extra-uterine pregnancy. During the last ten years this has been changed chiefly through the labors of Bandl, Barnes, Hecker, Schroeder, Spiegelberg, and Hennig, in Europe, and Parry, Allen, Goodell, Reeve, Wilson, and Lusk, in this country. But despite all this advance, our knowledge of the subject is still very elementary, our means of diagnosis still uncertain, and our methods of treatment unsettled.

The paper was based upon twenty-one cases which he had been called upon to treat within the last fourteen years.

As to the treatment, no one at present could speak dogmatically, and he simply gave the rules which his experience induced him to adopt.

First.—If the diagnosis be well settled before the fourth month of gestation, he would destroy the life of the fœtus by electricity in preference to all other methods.

Second.—Should the fourth month of gestation have passed and surgical interference be called for, laparotomy or, with the tumor low down in the pelvis, elytrotomy should be preferred to electricity.

Third.—Should the pregnancy be abdominal, the practitioner might watch and wait until full term, and deliver by laparotomy or by elytrotomy and the forceps, or manual delivery.

Fourth.—Should the full term be passed and the fœtus be dead, wait and watch and aid nature when she demonstrates the outlet by which she desires extrusion to be effected. If bad symptoms under these circumstances at any time develop, perform laparotomy under strict antiseptic precautions.

Fifth.—Should rupture of the fetal nest have occurred before diagnosis have been fully made, wait and see whether nature is powerful enough to overcome shock, to control hemorrhage, and further, if the patient is going to escape the dangers of peritonitis and septicæmia. If these favorable results do not occur, if hemorrhage is about to destroy the patient immediately, or if septicæmia attacks her later, laparotomy, followed by antiseptic cleansing, should be promptly adopted.

Dr. H. J. Garrigues, of New York, then read a paper on

ELECTRICITY IN EXTRA-UTERINE PREGNANCY.

The paper was prepared with special reference to one point, namely—treatment. The author first gave the history of the case which had come under his care. The treatment was by the use of electricity, a single-celled French apparatus being used. The applications were made daily, and continued ten minutes at each sitting. Ten applications were made.

With reference to diagnosis he thought the difficulty was no greater than in normal pregnancy.

As to treatment, so far as killing the child was concerned, five methods were at our command, which could be conveniently grouped under two heads:

First.—Sharp instruments introduced through the vaginal wall or through the roof of the vagina; in the second way no external part of the body is wounded; the first comprises puncture, injection, elytrotomy, and laparotomy.

Second.—Dilatation and electricity. The author gave a careful discussion of the advantages and disadvantages of these methods, and reached the following conclusions:

First.—Experience has proved electricity to be an efficacious and safe agent to arrest extra-uterine pregnancy during the first three months, and perhaps after the pregnancy in some cases has advanced more or less into the fourth month.

Second.—It seems likely that the same agent may be profitably used at any period of fetal life.

These papers were discussed by Drs. H. F. Campbell, of Augusta, Ga.; Wilson, of Baltimore; Goodell, of Philadelphia, who gave a brief history of thirteen cases which had come under his observation; A. H. Smith, of Philadelphia; Lyman, of Boston; Howard, of Baltimore, and Mr. Thornton, of London.

The Society then adjourned to meet on Friday at 10 A.M.

FRIDAY, SEPTEMBER 22D—THIRD DAY—MORNING SESSION.

The Society was called to order by the President.

DR. THOMAS, of New York, was elected to prepare a memoir of the late Dr. James P. White.

DR. A. H. SMITH offered resolutions complimentary to the services of the late Secretary, Dr. Jas. R. Chadwick, which were unanimously adopted.

The first paper was read by DR. SAMUEL C. BUSEY, of Washington, D. C., and entitled

THE INFLUENCE OF HIGH-HEELED FRENCH SHOES UPON THE FEMALE FORM AND UPON THE RELATIONS OF THE PELVIC ORGANS.

The first part of the paper was historical. This style was introduced under the regency. Under Louis XIV. the heel was high and circular, but not oblique. During the reign of Louis XVI. this objectionable style began to disappear, but has been again revived and is, perhaps, more general now than at any previous time.

Age, pregnancy, and maternity were manifest and admitted agencies in the causation of deviation of the female form. Stature and the habits of posture and carriage were perhaps equally potential. Asymmetry, either connate or acquired, was the most common of physical defects. Paget has supplied the following description of a perfect female foot: "Great breadth and fulness of instep, a well-marked toe, a long second toe, projecting a little beyond the great toe, and a very small or, in some cases, almost suppressed little toe." From this point the author entered into a minute description, with illustrations, of the mechanical construction of the normal human foot, and then placed in comparison the malformed foot as produced by wearing improperly shaped shoes.

The physical well-being of the feet is a necessary and important part of the general sanitation of health. Pedestrian exercise is the great promoter and conservator of functional activity and constitutional vigor. To enjoy it, and to realize the benefit to the fullest extent, the feet must be healthy and the foot tackle free and easy. Sore, contracted, and crippled feet, strained and stiffened joints, altered and displaced articulating surfaces, restrained mobility, and alteration of the line of gravitation (any one or all of which results may find their cause in too early and too constant use of high-heeled shoes) impede and augment the fatigue of locomotion, and make walking exercise painful. *Per contra*, they conduce to the acquirement of ungainly habits of carriage; to disproportion of the component parts of the body; and to a sedentary life, with its manifold disturbances of the animal economy. The injuries, however, are not confined to the feet.

Dr. Busey then demonstrated the normal position of the uterus in the pelvis, and answered the question, "How are these relations of the natural conformation influenced by the excessive and constant elevation of the heels by the use of high-heeled shoes?" The answer involved the study of the natural curvatures of the body and the deflections consequent upon the primary deflection of the line of gravitation taking place at the base. It was easy to comprehend how the general health might be influenced by such functional and local disturbances, and when such conditions existed in women, where the nervous systems were always waiting for an opportunity to be troublesome, the pathological consequences might be serious.

The paper was discussed by Drs. Barker and Thomas, of New York, who had been unable to trace any serious results upon the pelvic organs of the female arising from wearing high-heeled shoes.

Dr. Busey exhibited photographs illustrating the position of the limbs and trunk with and without high-heeled shoes, and maintained that the axis of the pelvis was changed by elevation of the heel and inferred that the position of the uterus and other organs was changed in like manner.

AMENDMENT TO THE CONSTITUTION AND BY-LAWS.

THE PRESIDENT introduced amendments to the fourth clause of the fourth section of the By-Laws, and the third clause of the fourth section of the Constitution, so that it will read: "Candidates shall be proposed to the council one month before the first day of the meeting by two fellows, and shall be balloted for at the following annual meeting, a list having been sent to each fellow, with a notification of the time of the meeting."

DR. T. M. DRYSDALE, of Philadelphia, then read a paper on

THE OVARIAN CORPUSCLE: ITS ORIGIN AND CHARACTERISTICS.

It was in reply to a paper read by Dr. H. J. Garrigues, of New York, at the last annual meeting.

Dr. Drysdale's views are that the cell called the "ovarian granular cell" is almost invariably found in the fluid of ovarian cysts; that it is distinguished from other cells by its appearance and by its behavior with acetic acid; that it has been so named to distinguish it from all other cells found in abdominal dropsical fluids, not meaning to assert that it may not be found in cysts in other parts of the body; that when found in this locality it is pathognomonic of ovarian disease; that it differs from any other known granular cell found in this abdominal cavity, and by means of reagents can be readily recognized.

On the other hand, Dr. Garrigues claims that the bodies found in ovarian fluids and known as Drysdale's corpuscles are not cells, but are only nuclei; that in appearance they are entirely like the pyoid bodies of Lebert, described as early as 1846, and can be found in various parts of the body; that in

ovarian fluids these bodies were first described by John Hughes Bennett, in 1852; that they are not pathognomonic of ovarian nor any other cysts that may be found in various parts of the body. All these points were discussed at length.

The discussion was opened by MR. THORNTON, of London, who thought there was not at present any basis to stand upon concerning the origin of the ovarian cell, because of the very great difference of opinion among expert observers as to what a cell is and how it grows. Although he had not devoted special attention to the subject for some time, he long ago reached the conclusion that the nucleus perhaps was the first and not the last element, and that the cell was developed afterward. Of course that view struck at the basis of much that Dr. Drysdale had said with regard to the origin of the cell in question. Whether it was called a cell or not, he had, long before Dr. Garrigues read his paper, concluded that it was a nucleus of a rapidly degenerating cell of the cyst membrane. With reference to the question of the action of reagents, upon which Dr. Drysdale relies so much, it seemed to him that the reaction, or rather the want of reaction, in his cell was in favor of the view that it is a degenerating cell, and not, as he (Dr. Drysdale) seemed to think, an immature cell; because in immature, rapidly growing cell-substances protoplasms of embryonic character, there existed a special proneness to take on the action of staining and other agents. Concerning the question of diagnosis, he had some time ago reached the conclusion that the cell had no practical value—at least for himself.

DR. ENGELMANN, of St. Louis, thought that the ovarian corpuscle was not unlike the syphilitic corpuscle in practical value and destination.

The discussion was closed by DR. DRYSDALE, who said that he had quoted from the latest observations made by Carpenter, Max Schultze, and others, as to what constitutes a cell. As to regarding the body as a nucleus, he would have done so twenty years ago, but continued study had convinced him that it was a cell—an aborted, epithelial cell. The fact that other gentlemen had not seen it was no fault of his, and he himself had made serious mistakes concerning it when he had not given fluids a sufficiently careful examination.

The Society then adjourned to meet at 3 P.M.

THIRD DAY—AFTERNOON SESSION.

The Society was called to order by the President, and DR. E. VAN DE WARKER, of Syracuse, read a paper on

THE MECHANICAL THERAPEUTICS OF VERSIONS AND FLEXIONS OF THE UTERUS.

The author united the historical part of the subject with a consideration of certain fixed principles which govern the constructive application, mechanically speaking, of instruments designed to correct versions and flexions of the uterus. The mechanical therapeutics of uterine displacements was yet unsettled. No department of gynecology was more interesting, and no department in general surgery had stimulated greater inventive activity. It was doubtful if, in the entire range of gynecology, a subject could be brought up which would elicit such hostile criticism upon one side, and such hearty approval on the other, and for this there must be some reason. It was possible that this difference of opinion came from over-confidence in methods and instruments, as pessaries could no more be blindly relied upon than could a mere splint for a fractured limb. The instrument, in common with all others, required to be used with watchfulness, and such changes made in it as adapted it to the conditions which first demanded it and subsequently appeared in the course of its use.

Do pessaries accomplish what they are designed for? was the question Dr. Van de Warker asked, and its consideration from a purely mechanical standpoint constituted the basis of his paper. His opinion was that the uncertainty in the results obtained by the use of pessaries came (1) from expecting too much of the instrument, and (2) from selecting an imperfect agent for want of more clear ideas of the absolute limitations imposed upon the action of pessaries, and which must govern the mechanical results to be expected. Two things must be clearly defined: 1, the limits imposed by the uterus and its appendages upon the mechanical agencies acting upon it, and, 2, the action of the mechanical forces under these limitations. These limits, both in their mechanical and uterine relations, were fixed and absolute, and were not to be evaded by skill or ingenuity, and ought to be clearly understood. One was, however, reluctantly forced to conclude that the majority of pessaries were invented either in ignorance or defiance of these limits, and as if the only restriction upon their action was that of gravity.

The paper was illustrated by tracings made with the mercurial manometer, showing the movements of the uterus in respiration, forced respiration, coughing, speaking, walking, etc., and was also extensively illustrated with woodcuts. It was discussed by Drs. Campbell, of Augusta, Ga.; Wilson, of Baltimore; Mundé, of New York; Lyman, of Boston, and the discussion was closed by Dr. Van de Warker.

On motion by Dr. Wilson, of Baltimore, the sympathy of the Society was extended to Dr. Humphrey Storer in his sickness, with an expression of hope that he might be restored to health.

The retiring President then made a few appropriate remarks, after which he introduced the President-elect, Dr. Gilman Kimball, of Lowell, Mass., who thanked the Society for the unexpected honor it had so generously conferred upon him.

After votes of thanks to the retiring officers and to the gentlemen who had so cordially entertained the members and invited guests, the Society was declared adjourned, to meet in Philadelphia on the third Tuesday in September, 1883.

The following officers were elected for the ensuing year: *President*—Dr. Gilman Kimball, of Lowell, Mass. *Vice-Presidents*—Dr. A. H. Smith, of Philadelphia, and Dr. Theophilus Parvin, of Indianapolis. *Council*—Drs. Byrne, of Brooklyn; Howard, of Baltimore; Jackson, of Chicago, and Campbell, of Augusta, Ga. *Secretary*—Dr. Frank P. Foster, of New York. *Treasurer*—Dr. Paul F. Mundé, of New York. *Active Members*—Dr. Matthew D. Mann, of Buffalo, N. Y., and Dr. W. H. Baker, of Boston. *Honorary Members*—Mr. Lawson Tait and Mr. J. Knowsley Thornton, of England.

The following papers were read by title: "A New Operation for Ruptured Perineum," by Dr. J. C. Warren, of Boston; "Measurements of the Uterine Cavity in Childbed," by Dr. W. L. Richardson, of Boston.

PROFESSOR ERB, of Leipzig, has been called to the late Professor Friedreich's chair at Heidelberg.

Correspondence.

PERCENTAGE OF COLLEGE-BRED MEN AMONG MEDICAL STUDENTS.

To the Editor of The Medical Record.

Sir: The editorial article entitled "The American Medical Student," published in your issue of February 11th, could not fail to attract the attention of all interested in medical education. There was, however, an error in the statement as to the proportion of medical students who were college graduates, resulting from the mode in which the result was arrived at in consulting the Report of the Commission of Education for 1879. Thus it is stated in the editorial "that the per cent. of college-bred men in the Harvard Medical School is nearly fifty. That in the Kentucky schools it is zero. Among Missouri's seven hundred graduates two had received a classical education. New York's per cent. is about seventeen; that of Illinois sixteen; that of Pennsylvania eight, and that of Ohio six, these being only approximate figures." I was much struck by the small percentage of Pennsylvania, put down at eight, knowing that in the medical department of the University of Pennsylvania for that year the proportion of students who possessed college degrees was twenty-two per cent.

Desiring to make some use of the facts in an address I was then preparing, I wrote to General John Eaton, the Commissioner of Education, for further information. With his usual promptness he wrote me immediately as follows: "It is hardly correct to say that my report for 1879 gives this proportion (for Pennsylvania) as eight per cent. The summary of statistics of regular medical schools shows that there were one thousand and thirty-one students reported by the institutions of this class in Pennsylvania, and that but eighty-two of these were reported as being college graduates. By a reference to Table XIII., page 590, of the same report, it will be seen that only one of the institutions called regular, namely the medical department of the University of Pennsylvania, reported the number of students who had received such degrees. Doubtless there were many graduates in medical colleges which did not report the item, so that the percentage of students of medicine in Pennsylvania in that year who had received such degrees would be much larger than eight per cent."

In like manner, in the State of New York, the same tables show the total number of students to be 1,976, and of those who possessed degrees in arts or sciences 310, or about sixteen per cent. But of the New York medical colleges, only the medical department of the University of Buffalo, the College of Physicians and Surgeons, the medical department of the University of the City of New York, the Woman's Medical College, and the College of Medicine of Syracuse University report the number of students possessing collegiate degrees, while Bellevue Hospital Medical College, the Albany Medical College, and the Long Island Hospital College do not report.

I have not taken the trouble to examine farther, but it is likely that the same omission to report has operated to affect the ratio in other States.

There is no doubt but that most important results will accrue in the course of time from the accumulation of such statistics as Mr. Eaton is annually collating. While it is certain, also, that their value will be much less if institutions are not willing to take the trouble to make the returns now rendered so easy by the blanks annually distributed by the Bureau of Education at Washington.

James Tyson.

Philadelphia, September 1, 1882.

RELATIVE MORTALITY OF CITY AND COTTAGE HOSPITALS.

To the Editor of The Medical Record.

Sir: My attention has been called to an article in the Medical Record of the 16th instant with the above title, which is based upon a paper of mine read recently before the Statistical Society in London, England. I notice that by a printer's error my name is given as Burnett instead of Burdett. I further desire to point out that the writer has fallen into an error, probably due to the fact that the whole of my paper and statistics were not reproduced in the *Medical Press and Circular*, in supposing that my figures relate to a period prior to ten years ago. The figures given are brought down to the end of 1879 in some cases, and to 1880 in others. I further proved by statistics that if the latest German figures are to be accepted, as I believe they may safely be, that the Listerian system of treating open wounds and cases of operation has practically settled the vexed question of the relative mortality after amputation in city and cottage hospitals, because the size of the building has ceased to be an all-important feature in the controversy. This is proved by the statistics given in my paper, which show that a mortality after operations of 41.6 per cent. in England; of 58.8 per cent. in Paris; of 43.3 per cent. in Edinburgh; and of 34.1 per cent. in Glasgow fell in Professor Erichson's case at University College Hospital to 25.7 per cent.; in the return of all the cases of which a detailed history could be obtained up to the end of 1879 in cottage hospital practice to 18.6 per cent., and at the leading German hospitals under the aseptic of Listerian system, according to Schröde, whose figures are brought down to the end of 1880 to less than 5 per cent.

I am paying a short visit to America, and so I cannot send you a copy of my paper, but this I will take care to do on my return home.

I am, etc.,

Henry C. Burdett.

New York, September 25, 1882.

The Summer Corps of Physicians.—Assistant Sanitary Superintendent Janes has presented to the Board of Health the final report of the entire work performed by the summer corps of physicians during the five weeks ending September 4th. From this report the following is taken: Number of houses visited, 26,883; families visited, 153,983; patients treated, 3,671; patients revisited, 662; circulars distributed, 23,111; excursion tickets, 4,802. Of the cases treated 2,186 were diarrhœal, 472 were pulmonary or bronchial, 238 were contagious, and the remainder were miscellaneous. The free excursion on the Floating Hospital of St. John's Guild have, it is believed, proved an important auxiliary to the efforts of this department toward promoting and preserving the health of the tenement-house children.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending September 23, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Sept. 16, 1882.	0	26	18	4	4	26	0	0
Sept. 23, 1882.	1	26	29	5	7	28	1	0

THE WONDERFUL DISCOVERIES OF MICROSCOPISTS in the field of pathology and food adulteration are wittily commented upon in the *New York Times*. The author describes a dinner given to a number of microscopist experts:

"When the microscopists sat down to dinner, each one produced his compound oscillating microscope and carefully examined every article of food. Excited shouts went up as new discoveries of metallic, vegetable, and sausage substances were discovered in the soup. An examination made of the water resulted in the discovery of such an enormous quantity of infusoria, mammalia, and pachydermata that the microscopists unanimously refused to drink it. During the progress of the meal, much enthusiasm was aroused by the announcement of Prof. White that he had discovered a trace of hairpin in the beefsteak, thus upsetting the theory that the beefsteak of American hotels is a chemically pure carburet of sole-leather, and, at a later hour, Prof. Black's assertion—based on a thorough microscopic examination—that he had discovered whortleberries in the whortleberry pudding, and wine in the wine sauce, led to a heated discussion, in the course of which thirty-eight microscopists declared that Prof. Black was an ignorant and unprincipled pretender, and eleven others maintained that the Professor was acting in good faith, and that his discoveries could be accounted for on the theory that the waiter had given him by mistake a piece of whortleberry pudding made expressly for the landlord's private table."

HOMŒOPATHY IN THE COOK COUNTY HOSPITAL, CHICAGO.—Under recent rules, one-fourth of all patients on the medical side, and one-fifth of the surgical cases are placed under the care of the homœopathic internes. No consultations allowed.

THE COMPOSITION OF PREPARED FOODS AND FLOURS, as given by Dr. E. Cutter, seems to have received a too hasty endorsement in some quarters. Professor Albert R. Leeds, Public Analyst and Professor in the Stevens Institute, denies the correctness of many of Dr. Cutter's statements. We quote a few of his criticisms:

"Fine granulated wheat: said by Dr. Cutter to 'contain no gluten.' Analysis shows it to contain 13.62 per cent. of albuminoids, chiefly gluten. Franklin flour: Highly extolled by Dr. Cutter. 'A blessing to mankind.' It contains 8.55 per cent. of albuminoids, chiefly gluten, together with a very large proportion of cellulose or finely ground bran. It is greatly lacking in nutritive elements. Cold blast flour: said by Dr. Cutter to 'contain no gluten.' It contains 16.74 per cent. of albuminoids, chiefly gluten, and is very rich in nutritive elements. Arlington wheat meal: said by Dr. Cutter to be 'rich in gluten and all the elements of entire wheat.' I have found no wheat flour as poor in albuminoids as this."

Will not Prof. Leeds now give us his analyses?

THERAPEUTICAL NOTES.—A pomade of muriated tincture of iron (1 to 15) is useful in psoriasis and eczema of the scalp.

Pyrogallic acid pomade (1 to 10) has similar uses.

Iodoform is a new treatment for infantile convulsions.

Phenate of soda, 25 parts, glycerine 100, cologne 75, water 300, makes a good lotion for prurigo.

The pulse plant *lathyrus sativus*, from its known power of producing rigidity of the limbs when mixed with wheat flour in bread, is suggested as of probable benefit in paralysis.

Ext. of ergot. fluid, ℥ 40; acid carbolic, ℥j.; aqua, ʒjss., may be used as a throat spray every half-hour in tonsillitis.

Acid salicylic 3 parts, starch 10, powdered talc 87, is used as a foot-powder in the Russian army; it prevents perspiration and sore feet. A strip of sticking-plaster worn for a few days will cure a patch of foot-soreness.

Alstonia constricta (the Australian fever tree) is reported as combining the effects of quinine and nux vomica as a cerebro-spinal stimulant and tonic in typhoid and puerperal fevers and nervous depression.

A French practitioner describes a new febrifuge, borate of quinoidine. It is one-tenth cheaper than quinine, but of only half its therapeutic power, requiring twice the dose of the latter.—*Australian Med. Journal.*

CONTAGIOUSNESS OF PHTHISIS.—Dr. Vincent Edwards, for seventeen years resident medical officer at Brompton Hospital for Consumptives, gives the following facts telling against the asserted contagiousness of consumption: Of fifty-nine resident medical assistants who lived in the hospital an average of six months each, only two are dead, and these not from phthisis. Three of the living are said to have phthisis. The chaplain and the matron had each lived there for over sixteen years. Very many nurses had been in residence for periods varying from months to several years. The head nurses, says the writer, sleep each in a room containing fifty patients. Two head nurses only are known to have died; one from apoplexy; the other head nurse was here seven months, was unhappily married, and some time afterward died of phthisis. Of the nurses now in residence, one has been here twenty-four years, two twelve years, one eight years, one seven years, one six and a half years, and one five years. No under nurse, as far as I am aware, has died of phthisis. All the physicians who have attended the in and out patients, during the past seventeen years, are living, except two, who did not die from phthisis.

MR. HENRY C. BURDETT, the author of "Cottage Hospitals and the Pay Hospitals of the World," is on a short visit to this country, for the purpose of studying the management of several of our larger medical charities. We bespeak for him a hearty welcome, especially from such as are interested in the work which he has so long and so satisfactorily pursued.

Poisonous Colors in Food Articles.—The German Government has just laid before the Reichstag a decree prohibiting the use of poisonous colors for the coloring of certain alimentary substances and food articles. The following articles are prohibited: antimony (oxide of antimony), arsenic, barium (except the sulphate), lead, chromium (except chromic oxide), cadmium, copper, mercury (excepting annabar), zinc, tin, gamboge, picric acid.

Revulsives.—During my recent trip through portions of Mexico, some peculiar practice was observed. Being ever ready to absorb any new crumbs of science, prompted me to travel through that strange country with eyes wide open. The natives have a very successful mode of allaying or mitigating pain—the old theory of "revulsion" put into thorough practice. Several severe headaches were quickly relieved by rapidly chafing or scratching some remote part of the body. Stomach-cramp was apparently thoroughly relieved by rapidly scratching the arm of the patient, and a child, suffering with extremely painful ophthalmia, was quickly lulled to sleep by rubbing the feet and limbs with a soft silk handkerchief.—*Chicago Medical Times.*

Midwifery in the Sandwich Islands.—The brother (non-medical) of one of the members of the British Medical Association resident in Honolulu gives the following description of the *modus operandi* of the Hawaiian midwife: "The midwives here are for the most part men—usually old men. When the woman's time draws near and labor commences, she is placed, sitting, on a man's knees with her back to him. He then clinches his hands over her abdomen, and with all his strength hugs the woman to him, until the child is actually forced into the world, falling to the floor between the operator's feet. The umbilical cord is then cut, and always left very long. Then the woman is placed upon her feet, and the midwife takes her tongue and draws it steadily until she gulps, or retches, this action causing the prompt ejectment of the after-birth. After this she goes and flounders about in the sea, and returns to land, ready for such domestic duties as may fall to her lot or inclination. Native children are—as may be inferred from the way in which they are introduced to existence—very easily born; but should the baby stick at all, or make any bother about being born, then the mother knows it is going to be half white, as this latter kind of baby is so much bigger in the forehead. It is a wise child that knows its own father in this country. So well recognized is this fact that natives never ask, 'Who is your father?' but only, 'Who is your mother?' when they desire any acquaintance with one another's genealogy."—*British Medical Journal.*

What Church is It?—Mr. Geo. C. Booth recently said that "the wealthiest and most prominent church corporation in New York City has scores of tenement houses which are in a most foul condition, and that the church corporation exacted last May ten and fifteen per cent. increase of rent under pain of eviction, instead of spending some thousands out of its millions in remedying such monstrous evils."—*Medical News.*

Tuberculous Diseases from Tuberculous Nurses.—"Inquirer" writes: "Your editorial of September 9th on 'Literature of Tubercle' leads me to ask if it is not overlooked that we have right around us millions who have been nursed by tuberculous mothers, and that (as I see the question) this is a source for the most reliable and most easily reached statistics upon the main question of the effect of ingestion; and I have no doubt a multitude could be found, not inheriting tubercules, but having had nurses who were tuberculous. It seems to me that, so far as ingestion affects the matter, every phase of it can be shown by statistics taken in this manner most easily."

A Hitherto Unpublished Work on the Brain, by Swedenborg, has been translated into English by Professor Tafel.

Dr. Wm. B. Carpenter, of London, is visiting this country. He was present at the Unitarian Conference in Saratoga, and on September 20th delivered a speech on "The Influence of Science upon the Progress of Religious Thought."

American Academy of Medicine.—At a recent meeting of the Council the annual meeting of the Academy was postponed until Thursday, October 26th, when it will take place at Philadelphia, at the time of the Bicentennial Celebration in that city.

Prince Leopold, who has long been an invalid, is said to suffer from a liability to hemorrhages—hæmatophilia.

American Doctors.—Mr. W. H. Rideing, in an article on Medical Education in New York, in *Harper's Monthly*, for October, says: "It would be difficult and hazardous to state the precise condition of medical science in America contrasted with the science abroad, but it may be said with entire veracity that no occupation in the United States stands higher numerically, socially, or financially, than the medical profession. It may be added also that the facilities presented in New York for a medical education are such that a student finds no urgent necessity to cross the Atlantic in search of professional knowledge, and that the most successful members of American faculties are the graduates of American colleges." The above is very true; only we fear that Mr. Rideing overrates the difficulty of stating the comparative condition of medical science in America and Europe.

Therapeutic Memoranda.—When arsenious acid is kept in solution it is liable to oxidize to arsenic acid, which is less potent.

Dr. Magilot considers that an osteo-periostitis of the alveolar border of the jaw is a constant, early, and pathognomonic sign of diabetes.

Extract kava kava fluid, in twenty-drop doses three or four times a day, is recommended in gonorrhœa.

Dr. Weir Mitchell is an advocate of the skim milk treatment in Bright's disease. He gives eight to ten pints daily and nothing else.

Galattofore is reported to be a new and effective galactagogue. Two tablespoonfuls in a pint of water in divided doses during the day.

A French practitioner claims capsicum as an emmenagogue, and as of similar properties to ergot. The tincture is given in small doses every two hours. It is also useful in pulmonary hemorrhage.—*Australian Med. Journal.*

Enteric Fever and Dysentery in Egypt.—Several deaths have occurred among sailors and marines at Alexandria from enteric fever, and Captain Baines, of the 75th Regiment, has fallen a victim to dysentery.

The Most Recent Instance of Cremation is that performed by Dr. Gaetano Pini, of Milan, on the body of M. St. Cyr Jullien, a deceased French gen-

tleman, whose brother is a consul in England. The cremating process in the Milan furnace took two hours, and double that time was necessary for cooling the ashes. Among them could still be observed the teeth, and fragments of bone also. The cost of the cremating process came to $50.

During the past few years 5,000 persons have joined the cremation societies, which have been formed in twenty-two of the principal cities of Italy, including Rome, Venice, Turin, Genoa, Milan, and Bologna. Of the number who have been actually cremated, the annual increase in Milan alone has been as follows: In 1876 there were 2; in 1877, 9; in 1878, 14; in 1879, 25; in 1880, 40; in 1881, 70; and thus far in 1882, that is to June, there have been 36, making a total of 196, of whom 123 were men and 73 women.

A National Examining Board.—Navis, Medical Inspector, U. S. Navy, writes:

"Sir: Had your hypercritical correspondent of the navy *carefully* read my letter he would have found that the 'reflections' of 'Hesperus' and others had *not* been 'coolly appropriated by Navis.' The necessity for national medical examinations had long been canvassed in the leading medical journals, and the subject was so familiar to the profession, that I merely expressed my opinion that there appeared to be 'no good reason why a national medical examining board should not be immediately organized.' I am not egotistical enough to believe, with your correspondent, that 'this scheme of forming general examining boards from the army and navy is the *only* one that promises the least hope of success,' though I commended the selection of members from the medical corps of the army and navy. I agree with the *Lancet* that "we are not quite clear that army and navy surgeons would have the necessary knowledge of detail to make good examiners," and for this reason I suggested that 'the American Medical Association—representing the profession in the United States—be empowered to select or elect medical men of known ability to serve as civilian members of such examining board.' This would form a representative and impartial body of government officers and civilians, which might be divided for convenience into smaller boards, so that yearly examinations could be held about the same time in the North, South, East, and West."

A Fortunate Hospital.—The Philadelphia Hospital had a considerable tract of land in Pennsylvania devised to it many years ago. It had been considered, however, of little value, and had furnished it no income. Recently, report states that oil has been found, and that the property is worth thousands of dollars.

Discountenancing Samaritan Societies.—The Berlin physicians have, so to speak, sat upon Professor Esmarch, on account of that gentleman's activity in the matter of Samaritan, or First Aid to the Injured Societies. A resolution has been adopted by the central committee of the Berlin Society of Physicians, to the effect, that in their opinion, Samaritan societies, although theoretically beautiful, practically are a useless and mistaken form of philanthropy. A letter has also been written in answer to Esmarch's.

Tabes Dorsalis Produced Artificially by Ergot.—Dr. Franz Tuczek had an opportunity, in 1879, to study an epidemic of ergotism, the cases being brought to the clinic at Marburg. In many there were mental disturbances with epileptic seizures. These cases all showed plainly symptoms of ataxia: inco-ordination, parasthesia, pains, complete absence of tendon-reflex. In four, upon whom post-mortems were made, there were no brain-lesions, but the posterior root-zones showed sclerosis; the posterior roots were also affected, but not the columns of Goll. Attempts were made to produce tabes by feeding animals with ergot. Mice and hens rapidly died with fatty degeneration of the internal organs; rabbits thrived upon it even in large doses; cats and dogs emaciated rapidly, and showed signs of inco-ordination, but on post-mortem no lesion of the nervous centres was found. Ergot in man seems to be "homœopathic" to tabes. We hope our homœopathic friends will not come out now and say that they knew it long ago, and have been curing tabes right and left with ℥ x. and think nothing of it.

A Society for the Erection of Sea-side Hospitals for Children has been organized, and has already one hospital built.

A Clinic for Nervous and Mental Diseases has been organized at the University of Leipzig.

Bright's Disease.—An old lady, who lives in Massachusetts, heard that Mr. John Bright was going to visit this country. "Well," said she, "I hope he won't bring his disease with him."

Medical Registration in Oregon.—The Oregon State Medical Society at its recent meeting adopted the draft of a law providing for the proper licensing and registration of physicians. It is to be recommended to the next Legislature.

The Indiana Medical Journal is the title of a new semi-monthly journal of medicine and surgery, edited by Dr. F. C. Ferguson, and published in Indianapolis. It starts with a good prospect of success.

To Abort Styes.—Dr. J. P. McGee recommends small doses of belladonna and calcium sulphide every hour. This method will abort them in three cases out of five, if began early.—*Philadelphia Reporter.*

New Marine Hospitals.—Commissioners have been appointed by the Acting Secretary of the Treasury to select sites for marine hospitals at Baltimore, Cincinnati, and Cairo.

A Prior Claim for the Discovery of the Bacillus of Tubercle.—Dr. J. M. Blaisdell, of Bangor, Me., writes us that on April 4, 1878, he published in the *Macomb* (Ill.) *Journal* a description of the bacilli of tubercle, and claimed then that they were the cause of phthisis. In this article he says:

"Thus it seems to us, that pulmonary consumption has its origin in the little vegetable germs or spores, with which our atmosphere is constantly impregnated; so inconceivably minute indeed as to be only 1-4000th part of an inch in diameter, yet capable of producing the most alarming and serious results."

Klebs did not publish his discovery until the following year, hence, Dr. Blaisdell claims a priority.

The only objection to Dr. Blaisdell's claim is that when his article was published he did not say how he discovered his bacilli, nor did he figure them or in any way prove that they were not ordinary bacteria. Such, at least, is the opinion we draw from the extracts which he sends us.

AN ANCIENT GYNECOLOGIST.—Archigenes, a distinguished Greek gynecologist, who lived about A.D. 50, used and described the vaginal speculum and also sponge-tents. He operated for atresia vaginæ, and recognized and treated pelvic abscesses. He treated procidentia uteri by posture and astringent tampons, used a reed catheter for the bladder, and performed embryotomy, using the scalpel, volsella, tractors, and bone forceps.

So says Dr. Maughs, of St. Louis, who quotes from a Latin translation of the works of Oribasius of the fourth century, and Ætius of the sixth.

NATIONAL MEDICAL AND SANITARY EXHIBITION.—The meeting of the American Public Health Association at Indianapolis, next October, is to be made the occasion for considering the holding of a National Medical and Sanitary Exhibition in 1883. A call has been issued to secretaries of State Boards of Health, requesting them to appoint commissioners to meet at Indianapolis to discuss this subject. It is signed by many prominent medical men.

ARMY AND NAVY HOSPITAL AT HOT SPRINGS, ARK.—At its last session Congress appropriated $100,000 for the erection of an Army and Navy Hospital at Hot Springs, Ark., to be built in accordance with plans and specifications to be prepared by the Surgeon-General of the Army and Navy. Surgeon J. S. Billings has been ordered to go to Hot Springs, and, in company with a medical officer of the Navy, to be detailed for that purpose, to select a site for this hospital.

DEATH IN A DENTIST'S CHAIR FROM CHLOROFORM.—A lady living in Dunnville, Ontario, died in a dentist's chair on September 11th, while under the influence of chloroform, which had been administered by her physician for the purpose of having some teeth extracted.

HYDROCEPHALUS FOLLOWING FORCEPS DELIVERY.—Dr. A. M. Leonard sends us the history of a case of hydrocephalus in a child aged four months. The circumference of the head at its largest part, measured horizontally, was thirty-nine inches. Over each parietal bone was an ulcer. At birth the child appeared perfectly normal, excepting a cut that nearly severed the ear, and bruises upon the mastoid processes and frontal bone, caused probably by locking the forceps (the case was not in Dr. Leonard's practice). Soon after birth a swelling was noticed at the point of injury to the os frontis, which continued to enlarge until death. It was a head presentation, with forehead coming under the arch of the pubis (fourth position).

THE POISONOUS PROPERTIES OF ANILINE DYES is the title of a work recently published by M. Grondhomme, superintendent of one of the largest laboratories in France. These dyes are now extensively used in the manufacture of socks, stockings, and other fabrics worn in contact with the cutaneous surface. Such dyes are especially used in the fancy fabrics sold for the wear of children from four to ten years of age, and in the blues and various red shades of gentlemen's socks. M. Grondhomme declares that the cases of poisoning recorded by medical men as due to these dyes are really traceable to the arsenious acid used in the preparation of the colors, not to the coloring matter itself. The fumes of a few of the dyes arising from the manipulation of petroleum produce difficulty of respiration when persistently inhaled. This is true of naphtholin, for example. Others are perfectly neutral and inert in their effects, and possess no toxic potency whatever, and to this category belongs aniline and its immediate relatives. M. Grondhomme pleads the cause of aniline dyes very strongly. There is no doubt, however, that some of them are poisonous, and quite actively so when taken internally.

ANTISEPTIC COLOGNE.—The following is commended as a preparation combining antiseptic properties with a perfume:

Eau de Cologne	8 fl. oz.
Chloral hydrate	2 drachms.
Quinine (alkaloid)	10 grains.
Carbolic acid (pure)	30 "
Oil of lavender	20 drops.

This may be used on the handkerchief, the doctor holding it gently to the mouth while in the sick room. Warranted to keep out bacillus tuberculosis; also b. termo, b. elephantiasis A., and b. gonococci.

DISINFECTION BY HOT AIR.—Koch and Wolfhügel, in experiments made to determine the disinfecting power of hot air, were led to the following conclusions: 1. Bacteria are destroyed by being exposed to a temperature of a little over 100° C. for an hour and a half. 2. Spores of brewer's mould require for their destruction an exposure for the same time at 110°–115° C. 3. Bacilli are killed only by three hours' exposure at 140° C. 4. The heat of hot air penetrates articles so slowly that in three or four hours' heating at 140° C. of small objects, such as a bundle of clothes, etc., disinfection was not secured. 5. Five hours' heating at 140° C., necessary to certain disinfection, does serious injury to most articles.

WHOOPING-COUGH.—Dr. Aymerick, in the *Medical Press and Circular*, recommends, in the treatment of whooping-cough, the employment of phenic acid with bromide of potassium; bromide of potassium, one drachm; phenic acid, three to four grains; syrup lemons, q. s.; vehicle, six ounces. A large or a small spoonful, according to the age of the patient, every two hours. He has never seen any accident to follow the antiseptic method.

ATROPIA FOR EAR-ACHE.—The most effectual treatment, and the one which has stood the test of years, says Dr. A. D. Williams in the *Chemists' and Druggists' Bulletin*, is the local application of a solution of the sulphate of atropia. Not a single case but has yielded at once. The solution is to be simply dropped into the painful ear and allowed to remain there from ten to fifteen minutes. Then it is made to run out by turning the head over, then being wiped with a dry rag. The solution may be warmed to prevent shock. From three to five drops should be used at a time. The strength of the solution must vary according to the age of the child. Under three years, one grain to the ounce, and over ten years, four grains to the ounce of water. In grown persons almost any strength may be used. All ages will bear a stronger solution in the ear than in the eye. The application should be repeated as often as may be necessary. Usually a few applications will stop the pain. In acute suppurative inflammation of the middle ear, and acute inflammation of the external meatus, atropia will only slightly palliate the suffering, but in the recurring nocturnal ear-aches of children it is practically a specific.

THE DAISY, called by botanists *bellis*, is dragged from its high æsthetic heights by the eclectics and

made into tinctures and infusions. Its properties resemble those of arnica and hamamelis. It is a useful application for bruises, sprains, etc., and it is a reputed antisuppurative.

The red clover (*trifolium prætense*) is also much commended as a remedy in spasmodic coughs (pertussis, etc.). Teaspoonful doses of the infusion are given.

CHIARI, THE PATHOLOGIST, has just been made Professor at Prague and will leave us in September. He is a man thirty years old, who has already made over 8,000 post-mortem examinations. A better teacher of pathology one could not wish for, while to see him make a post-mortem is a wonder. At a recent supper given in his honor one of the speakers said he could not wish for greater happiness than that of being post-mortemed—if I may use the expression—by his friend Chiari.—*Vienna Correspondent of Maryland Medical Journal.*

A FAVORITE SEAT FOR THE BACILLUS OF TUBERCLE, according to Chiari, to lie dormant in obscure cases, is the suprarenal capsule; from this point frequently the acute disease starts, leaving no organ in the body untouched.

THE VENEREAL WARDS OF THE VIENNA HOSPITAL.—It makes a strange impression on an American to go for the first time through the syphilis wards with the professor. Arranged in long rows on their backs in bed, with nothing covering them from their knees to their navels, lie the men ready for examination. Standing around, with various implements and dressings, are five or six active women awaiting orders from their lord and master, the professor. The men are not allowed to touch themselves, so with their hands under their heads they lie there with anxious faces awaiting the next development in the treatment. Truly, it is a comical sight this mixture of the sexes under the circumstances.—*Correspondent Maryland Medical Journal.*

THE AMERICAN PHARMACEUTICAL ASSOCIATION.—The thirtieth annual meeting of the American Pharmaceutical Association began its sessions at Niagara Falls on Tuesday, September 12, 1882, in the parlors of the Cataract House. The attendance was large, probably exceeding four hundred on the first day, and five hundred on later days. Various papers having a pharmaceutical interest were read.

THE MEDICAL SCHOOLS OF NEW YORK begin their regular terms next week. Already a large number of students are in the city, and there is every promise of full classes.

AN EPIDEMIC OF DYSENTERY is reported to exist in Malmö, Scotland. Five hundred cases are reported weekly, of which one-half died. The disease is spreading.

PAUL VOGT has been called to the Chair of Surgery at Greifswold, in place of the late Hueter.

CHANGES IN THE LOUISVILLE MEDICAL SCHOOLS.—In the University of Louisville, Prof. L. P. Yandell has been transferred to the Chair of Medicine, and Prof. Parvin to that of Obstetrics. Prof. Holland has been given the Chair of Pathology, Clinical Medicine, and Nervous Diseases.—The Jefferson School of Medicine, a new summer-course institution, seems likely to cease its not obtrusively useful existence.—Dr. C. W. Kelly has been made Professor of Anatomy and Clinical Medicine in the Kentucky School of Medicine, Dr. Holloway has been chosen to the Chair of Surgery, Dr. T. Anderson to the Chair of Medicine. There seems to be an admirable versatility on the part of our Louisville brethren, which enables each one to teach all things equally well.

PROFESSOR ERB goes to Heidelberg as successor of Friedreich.

CULTIVATING THE BACILLUS OF SYPHILIS.—M. Martineau reports to the Academie de Medicine that he has cultivated the bacillus of syphilitic chancre after the method of Pasteur and has inoculated a pig with the cultivated germs. There resulted a sore and swelled glands with bacilli temporarily in the blood. The animal recovered in two months. Fluid from its sore did not affect two other pigs inoculated.

THE GERMAN SCIENTIFIC ASSOCIATION met at Eisenach, September 18th to 23d. The antiseptic system was among the subjects discussed.

PROFESSOR E. S. WOOD, M.D., of Harvard College, and Professor B. F. Davenport, M.D., of the Massachusetts College of Pharmacy, have been appointed the analysts under the act relating to the adulteration of food and drugs in Massachusetts.

THE YELLOW FEVER EPIDEMIC.—The yellow fever is decreasing in Brownsville, Texas. It has, however, been creeping up along the Rio Grande, and the sanitary cordon has been changed from Corpus Christi and Laredo to Arroyo and Laredo. The cases and deaths in Brownsville for the week ending September 23d, as reported by the Surgeon-General of the Marine Hospital Service, are as follows:

	Cases.	*Deaths.*		*Cases.*	*Deaths.*
September 17	27	1	September 21	8	1

PIDOUX, the eminent collaborator of the late Trousseau, died at Paris, September 4th. He took his first degree in 1835, and had been a member of the Academy of Medicine since 1864. He was also a member of the Legion of Honor.

HYPEREMESIS AS A CAUSE FOR PRODUCING ABORTION.—Professor C. Braun, of Vienna, thinks that hyperemesis is not a proper cause for the production of artificial abortion. He has never seen a case of death from vomiting, and believes that it can be kept within safe limits by proper means. In a case reported he afforded relief by the application to the cervix uteri of a ten per cent. solution of nitrate of silver. In France, where the operation is frequently done for this purpose, the vomiting is relieved by the abortion in only about forty per cent. of the cases, while ten per cent. of the cases are fatal.

Original Lectures.

ON THE TREATMENT OF DIPHTHERIA.[1]

By PROFESSOR DUGARDIN BEAUMETZ,

PARIS, FRANCE.

Part I.

Gentlemen:—Diphtheria has made frightful ravages in our population these late years. Cast your eye over the careful statistics of our colleague, Ernest Besnier, and you will observe that the mortality from diphtheria these past ten years has exceeded by considerable the mortality from typhoid fever and that of the three eruptive fevers—small-pox, measles, and scarlet fever—combined. Thus the total number of deaths from diphtheria were 16,290; those from typhoid fever, 10,304; while those from the eruptive fevers mentioned amounted to 11,180. Diphtheria, then, is a disease which you will often be called to treat, and which, with all your therapeutic resources, you will continually fail to treat successfully. But if there is really no medication which is curative for these affections, there are certain modes of treatment which are dangerous and which you must avoid. Moreover (and this is an important point), the varying constitution of the malady profoundly modifies the results of treatment, and explains why a host of remedies have been prescribed for diphtheria, which have, in certain epidemics, given good results, and which have signally failed in others.

In fact, the disease presents different types of malignity. Some epidemics, like that which prevails at the present time in Paris, are rebellious to almost every kind of treatment. We have seen in our hospitals this very year a mortality of sixty-six per cent.; *i.e.*, out of 1,255 cases there were 829 deaths. In other localities the mortality has been almost nil. How, then, can you draw serious and satisfactory conclusions from statistics applied to the therapeutics of a disease whose morbidity is so variable? We see almost every day physicians practising in localities more or less distant from Paris, who affirm with the utmost good faith that this or that medication has enabled them to save all their diphtheritic patients; we try the remedy in our hospitals and meet with complete failure. We have then to make account of differences in type and malignity, in accordance with seasons, climate, location, and other circumstances, and have need of caution in the application of statistics to the results of therapeutics.

The subject of the present lecture is not so much diphtheria in general, which is a constitutional disease, contagious and epidemic, with marked local manifestations, as that particular form or species known as diphtheritic sore throat, or membranous angina; and if I have placed the treatment of this disease in the therapeutics of affections of the larynx and pharynx, it is because this is a convenient place to speak of a malady which logical exactness would consign to the department of general diseases.

The German school has in these late years disturbed somewhat those precise notions, so generally held by us as a nation, of the unity of diphtheria. You well know that we are indebted to Bretonneau for the general view that all the pseudo-membranous affections, croup, membranous angina, cutaneous diphtheria, etc., have a common origin, and are expressions of a general disease which he called diphtheria. According to the German school, on the contrary, every false membrane, whatever may be its origin, is a croupal affection, and they have established two sorts of pseudo-membranous affections—the one without infection and local, the other depending on a general poisoning of the organism. They have even dignified with the name of croupal the false membrane which follows the application of certain caustics, as nitrate of silver, to the mucous membrane, and they apply the same name to the false membrane which diphtheria produces, basing their description, not on the general symptoms, but on the pathological anatomy of pseudo membranes. From a histological standpoint, it is very difficult to distinguish between these pseudo-membranous exudations due to caustics and those which characterize diphtheria.

One reason for the want of prevalence of clear ideas on this subject is the existence of mild forms of diphtheria, the local and benign membranous anginas. The diphtheritic intoxication presents different degrees of intensity. In certain cases the general toxic symptoms predominate, and the false membrane has only a secondary part. In others the general symptoms are little marked, but the local manifestations are well defined. Hence the morbid unity has been lost sight of, and the different phases of the same disease have been classed as different affections. The convincing evidence of this unity is the epidemicity and contagiousness of all these diphtheritic affections, and just as we see manifested in epidemics of the eruptive fevers forms varying widely from the type as well as typical forms, so you will meet in the same house and in the same family all the forms of diphtheria, from the most benign to the most malignant. To-day, then, the idea of Bretonneau, supported by Trousseau, seems to have triumphed over all its adversaries, and even in England, where the doctrine of duality had been for some time maintained, the opinion is becoming prevalent (as expressed by West and Jenner) that angina membranacea and diphtheria have a common origin.

Excuse me for having so long dwelt on this particular point, which belongs rather to clinical medicine than to clinical therapeutics, but it has an important bearing on the discussion on which I am now to enter.

If it is to-day demonstrated that membranous angina is truly the local manifestation of a general affection, you readily perceive that all the topical applications at your disposal play but a secondary part in the treatment, and that to cure the diphtheritic affection you must not merely direct your treatment to the pharynx, but above all to the general malady of which the local disease is the expression.

You must recognize the fact that we are ignorant of the nature of diphtheria. We have advanced no farther than certain hypotheses. The most probable is surely that which considers diphtheria as a disease produced by microbes, and the ideas of Pasteur have given a progressive impetus to all these questions of contagious diseases, in calling attention not only to the influence of inferior organisms on the production of morbid phenomena, but also in showing us how we may in certain cases, by preventive inoculations, obtain protection from such

[1] Delivered in the Hôpital St. Antoine. Translated (by permission) from advanced sheets for The Medical Record by E. P. Hurd, M.D., Newburyport, Mass.

affections. But to the present time we are ignorant of the mitigated "vaccine" which shall give us immunity from this terrible malady.

Being unable to reach the supposed parasitic causes of diphtheria, we are restricted to the treatment of the manifestations, and it is this which at at once explains our therapeutic impotence in such cases. Nevertheless, it must not be supposed that the labors of Pasteur have not in a certain measure modified the treatment, general and prophylactic, of diphtheria, and you will see that antiseptics, and in particular parasiticides, have here a considerable part. We shall have here to study, from the standpoint of membranous angina, three kinds of treatment: the local treatment, the general treatment, and the prophylactic treatment.

In order well to understand the conditions which the local treatment of diphtheritic angina should fulfil, you must know how the local manifestations of this constitutional affection develop, and I cannot do better than refer you to the researches of Laboulbène, Letzerich, Klebs, Tommais, Hueter, Homolle, Duchamp, Eberth, Cohn, Zahn, Talamon, etc., and to the more recent researches still of Leloir, of Thomas, and of Cornil. Constituted by fibrinous deposits, enclosing in their meshes leucocytes and epithelial fragments, the false membranes are of variable thickness and consistence. Below them the epidermis is destroyed and the derm presents alterations more or less profound; often it is affected with sphacelus, and then is observed that diphtheria of gangrenous form which you will see described by all the authors. In other cases there is a marked hemorrhagic tendency, and it is only necessary to brush away the false membrane to determine an oozing of blood, more or less active, from the derm thus denuded.

These false membranes sometimes remain stationary and are reproduced very slowly. Sometimes, on the contrary, they invade the surrounding tissues very rapidly and are reproduced with extreme facility. But there is a fact of the utmost importance which it would be well for you to remember—these false membranes have a tendency to invade and to occupy all parts of the mucous membrane and of the skin that are deprived of their epithelium.

But before discussing the conditions which a local treatment of diphtheria ought to fulfil, we should first prove the utility of that treatment. Since it is a recognized fact that the false membrane is but the local manifestation of diphtheria, one may ask himself, Why direct therapeutic endeavors to this manifestation, since we cannot prevent its reproduction?

To reply to this question we must venture upon one of the points the most mooted in the study of diphtheria; I refer to the possible inoculation of diphtheria by the false membranes, or of what has been described under the name of auto-infection. It has, in fact, been maintained that the contagious principle of diphtheria resides in the false membrane, and that it is sufficient to place portions of this product on certain parts of the skin or mucous membrane to see diphtheria develop, when the conditions are favorable. It has even been maintained that the presence of these false membranes is a constant source of infection in the same individual.

Although there is not unanimous agreement on all these questions, it none the less remains a fact—as a result of such views as are above stated—that there is everywhere a real and dominant interest in causing the false membranes to disappear by a local treatment. Let us now examine what conditions this local treatment ought to fulfil: it should dissolve the false membranes on the one hand, and oppose, as far as possible, their reproduction on the other.

The number of means devised to attain this object is considerable. For the sake of order I will consider them under four distinct groups. The first act mechanically, the second attack the false membrane and aim at its solution, the third modify, more or less deeply, the structure of the derm (caustics), the fourth have an action quite different, being medicaments which, administered internally, are eliminated on the surface of the mucous membrane. Let us examine each of these groups.

The mechanical measures are the most numerous. They consist of brushes, swabs, and pencils, with which attempts are made to detach the false membranes. My own preference is for little bits of sponge attached firmly to a whalebone. The elasticity of the latter prevents serious injury to the pharynx, and the sponge is in no danger of leaving hairs or portions of lint in the throat to provoke cough, as are the swabs and camel's-hair pencils in common use. Irrigations with cold water and the topical use of ice are of great use in the treatment of diphtheria. The spray or jet of water is far superior to the brush as a means of detaching the false membrane. Its action is as thorough without being as harsh. Whenever the patient will allow it, you may with a syringe throw into the back of the throat a jet of water with sufficient force to gradually separate the false membranes. In the absence of a syringe you can make use of a seltzer siphon bottle, like that which the soda-water dealers furnish, and you will have, by reason of the pressure of the carbonic acid gas, a powerful jet which will thoroughly wash out the fauces and pharynx. Blache has even proposed, in order to make these irrigations, a tongue depressor, furnished near its median part with a canula, to which he adapted the extremity of an irrigator or of a syringe, which enables him, in the case of little children, to open the mouth, depress the tongue, and irrigate the throat.

Ice is one of the best of the mechanical means for clearing the throat of false membranes, and without admitting with Grand-Boulogne, Baudon, Lebert, and especially with Bleynie, that diphtheria may with certainty be cured by this means, I am nevertheless convinced that it renders real service. Ice calms the irritation of the throat, diminishes the congestion of the mucous membrane, and clears the parts of false membranes. Fortunately, ice can always be obtained in our large cities, and the most refractory children accept very readily the little bits of ice which you give them. By the side of injections of water we may place pulverizations, made with steam atomizers and spray-producers. Prosser James, Oertel, and Mackenzie have demonstrated the benefit which can be derived from the vapor of water in diphtheria. The steam atomizer is of undoubted utility in this disease. It enables us to keep our patients in an atmosphere of moisture, which favors the separation of false membranes, and the atomized medicine (inhaled with the air of respiration) can be conveyed some distance into the upper air-passages.

Next to the steam atomizer, I am partial to the apparatus known as the spray-producer. Those in common use have a single bulb, with nickel-plated tube of sufficient length to permit of being applied directly to the faucial region. These atomizers

throw a spray which may be medicated with any antiseptic or solvent, and the atomizing canula can be made to convey the pulverized liquid into any part of the throat or nares.

The solvents of false membranes have another end—that of dissolving these products as fast as they are produced. The experiments of Bricheteau and Lebaigne show that by strong acids one hardens rather than dissolves these false membranes, while a solvent action is obtained by the less energetic acids, and particularly lactic acid. The best solvent action (singularly enough) is obtained from lime-water. Kuchenmeister and Bierner, of Berne, have proved this.[1]

Other substances act by digesting the false membranes. Hale White (*vide Lancet*, 1881) has employed, in grave cases of diphtheria of the throat and larynx, pulverizations of a combination of glycerine and pepsin, and Bouchut has recommended local applications of papaïne as a useful solvent of diphtheritic exudations[2] (*Bulletin de Ther.*, T. ci., p. 128).

It is customary to employ the mechanical measures above mentioned and the solvents conjointly. You make with a sponge probang local applications of lime-water or injections into the pharynx of different solutions. Solutions of citric acid, lactic acid, the juice of limes, etc., have obtained a certain reputation as solvents of false membranes.

The modifiers of the mucous membrane are much more numerous. One class has for result to cauterize the mucous; another to modify the secretion; another still is addressed to the parasitic element of the disease. Commence, then, with the caustics. Energetic cauterizations of the throat in diphtheria have long had a great repute, and even to-day we hear practitioners affirm that by this means they have arrested on the spot the development of diphtheria. The most violent acids have been employed locally; chlorhydric, nitric, and even inhalations of fluorhydric, concentrated solutions of caustic alkalies, and nitrate of silver, in crayons or in solution. It is the custom of a great many physicians to practice these cauterizations with the lunar caustic as soon as they see the false membranes appear in the isthmus of the fauces. Gentlemen, I cannot too strongly protest against this treatment, which is not only useless but painful and dangerous—useless, because caustics do not in any manner dissolve the false membranes or prevent their reproduction; painful, as any one can testify who has made these caustic applications. After you have done it *once* you can seldom get the consent of your young patient to allow you to repeat the cauterization, or even examine the throat, and you are sure to provoke such a degree of inflammation of the mucous membrane of the throat that your patients (and especially children) take nourishment with great difficulty. Dangerous, for this reason especially, that these cauterizations deprive the mucous membrane of its protective epithelium, and thus present a wider extent of surface to be invaded by the false membranes.

I would advise, then, that you should avoid cauterizations altogether, for they place your patients in most unfavorable conditions, in that they prevent the due administration of food and hinder any further treatment. Moreover, they have no effect whatever on the constitutional affection, and they certainly have this deplorable result, that they favor the extension of the diphtheritic exudation.

Let us examine now the modifiers of the secretion of the mucous membranes. Among those which have great repute we must assign the first place to perchloride of iron[1] and to tannin.

Perchloride of iron has given good results. In solutions more or less dilute, it modifies the surface of the mucous membrane, acts as an antiseptic, and opposes the hemorrhagic tendencies which we observe in certain cases; I am of opinion, then, that it is well to continue the use of this medicinal agent in very dilute solutions. If you use it in too concentrated a form, you must expect all the inconveniences and dangers which attend caustic applications.

Great expectations have been based on the use of tannin. It was maintained some twenty years ago that insufflations of this medicament would cure not only diphtheria, but also croup. Dr. Loiseau, of Montmartre, gave to this treatment a certain notoriety. Loiseau had been the subject of a curious mistake, which resulted from the artificial production of false membranes by the tannin, which had been conveyed into the pharynx by a powder-blower. Tannin coagulates the albumen of mucus, and after the application of this medicament to the throat by insufflation, the patient frequently coughed up pseudo-membranous flakes which were the result of the coagulating action of which I have spoken. This treatment is at the present day abandoned. The same may virtually be said of the treatment by iodine and bromine. The second of these remedies has considerable testimony in its favor. Peyraud, of Libourne, was one of the first to call attention to the caustic and alterative action of local applications of bromide of potassium;—the pseudo-membranous patches being literally dusted over with the bromide in fine powder, and afterward sprayed or gargled with a tolerably strong solution of the same medicament. Although he claimed astonishing results (twenty-seven out of twenty-nine

[1] Kuchenmeister was the first to remark the solvent action of lime-water in diphtheritic exudations, and, in 1864, Bierner, of Berne, verified the observation. The following mixture, containing saccharate of lime, is much used as a gargle. It may also be taken internally in dessert-spoonful doses, every two hours:

℞. Lime (or lemon) juice..... ℥ x.
Chloride of sodium ..... ʒ ijss.
Sulphate of sodium..... ʒ ijss.
Honey..... ℥ ss.
Saccharate of lime..... ʒ j.
Acid carbolic (or phenate of soda) ..... gtt. xx.
M.

The free use of lime-juice, internally and locally, has been recommended by Revilloud, Chatard, and Soulé.

[2] Bouchet's experiments show that papaïne will dissolve false membranes. The application must be repeated often (every second hour). The diphtheritic membrane slowly thins out, breaks up, and disappears under the treatment, three or four days generally sufficing. Thirty-two cases were treated by papaïne. Of these there were only four deaths.

[1] Vaunted especially by Aubrun in 1860, and by his son in 1867, the perchloride of iron has been considered a powerful antiseptic in diphtheria. This is Aubrun's way of giving it: Four to seven grammes [1 to 2 drams] are administered daily, given in fractional doses of twenty drops in a little sweetened water; every few minutes the patient takes a swallow of this solution till the quantity prepared is all taken. Immediately afterward a little pure milk is given. Wine and a tonic regimen is prescribed.

Isnard and Courty have employed the same preparation with success. Heslop and Houghton advise the following solution:

℞. Tinct. fer. perchloride. ..... ʒ iij.
Acid hydrochloric dil. ..... ʒ ij.
Aquæ..... ℥ viij.
M. Signa: Two tablespoonfuls every three hours.

Clar, of Germany, combines the perchloride of iron with glycerine, as in the following preparation:

℞. Glycerine..... ℥ ij.
Liquor ferri perchloride..... gtt. xx.
M. Signa: A teaspoonful every half hour.

[In this country we are much in the habit of combining the tincture of perchloride of iron with glycerine and chlorate of potash, as in the following formula for a child five years old.

℞. Tinct. fer. perchloride..... ʒ jss.
Chlorate potas..... ʒ j.
Glycerine ..... ℥ i.
Aquæ flor. aurantii..... ℥ i.
M. Signa: A teaspoonful every half hour or hour.

There is much testimony in favor of chlorate of potas. as an antiseptic agent of great power.—*Translator.*]

cases), other experimenters in other epidemics have not met with the same success. Cadet de Gassicourt, who experimented with this mode of treatment in the Hôpital des Enfants Malades, lost all of his patients, eight in number; the epidemic was very fatal that season.

Along with these substances we must reckon alum and borax, which act as topical alteratives, but which are to-day abandoned.

It is not so with the parasiticides, which are held in high favor. Influenced by the important discoveries of Pasteur, physicians have maintained that the parasitic element is the one most imperatively demanding attention. Undergoing development in the false membrane, and thus at first of local origin, the parasitic germ penetrates forthwith into the economy, where it oppresses and paralyzes all the vital functions. Let us then, say they, kill the parasite on the spot before it gets into the blood and infects the entire organism. Hence local parasiticide gargles, pulverizations, injections, have been recommended; solutions of carbolic acid, chloral, creosote, coal-tar, thymic acid, carbolated camphor, etc. I have myself used resorcine. All these means modify, sometimes happily, the pharyngeal mucous membrane, but one cannot base upon this treatment any positive medication.[1]

These solutions are sometimes applied directly by means of a brush or swab, sometimes they are atomized, the steam apparatus or spray-producer being used. The latter method is the best, and although I do not believe in the certain efficacy of these local applications, I yet see the great advantage of making our diphtheritic patients (and young children especially) live in an antiseptic atmosphere. By this means you can not only medicate the fauces and pharynx thoroughly, but you can, to a certain extent, prevent contagion. The reservations which I have made *à propos* of antiseptic solutions, I also make *à propos* of benzoate of soda, which has been vaunted of late, and especially in Germany. I have often employed the benzoate of soda in my service in the children's hospital, and I have not obtained better results than by other methods.[2]

I have finished what I was going to say about the local modifiers of the faucial mucous membrane, and I now take up the fourth group of medicaments, those which modify favorably the mucous membrane by their elective elimination on its surface.

(To be continued.)

[1] The phenated camphor, employed with success by Soulez and Pératé, is applied locally to the diphtheritic exudations. It is prepared by dissolving twenty-five grammes of powdered camphor in a solution of phenic acid (nine grammes in nine grammes of alcohol). Lemoine advocates continuous injection of coal-tar, which acts mechanically as disinfectant and parasiticide (Th. de Paris, p. 369, August 4, 1879).

[2] Graham Brown has studied the action of antiseptic liquids on the diphtheritic virus, and he concludes from his experiments, made with hares, that quinine, salicylate of soda, and benzoate of soda, when they are mingled with the diphtheritic virus, destroy the virulent properties of the latter. The most active of these substances is the benzoate of soda; even in hypodermic injections the benzoate of soda retards the development of the diphtheritic poison. Letzerich, concluding from experiments of his own, has employed the benzoate of soda in the case of infants affected with diphtheritic laryngitis, losing but one out of twenty-seven. To a child above a year old he prescribes the following potion:

℞. Benzoate of soda..... gr. 0.75
Distilled water.....
Peppermint water.....āā ʒj. and ʒ ijss.
Syrup aurantii ..... ʒ ijss.

M.—Dose, half a teaspoonful every hour.

The dose of benzoate of soda increases in proportion to the age: From one to three years old, from ʒ jss. to ʒ ij. daily. From three to seven years old, from ʒ ij. to ʒ iij. After seven years, from ʒ ijss. to ʒ ss. Adults may take from ʒ ss to ʒ vi. daily. No untoward results have ever followed its use. The diphtheritic patches in the throat are treated by insufflations of the benzoate.

Original Communications.

THE PRODROMIC STAGES OF DIFFUSED KIDNEY AFFECTIONS.

A CONTRIBUTION TO THE PATHOLOGY OF THE SAME, WITH SOME REMARKS ON DIAGNOSIS AND TREATMENT.

BY HUGO ENGEL, A.M., M.D.,
PHILADELPHIA, PA.
FELLOW OF THE AMERICAN ACADEMY OF MEDICINE, ETC.

WE have for a long time been familiar with the fact, that under certain circumstances a transient albuminuria may happen in a person of normal physical health, and the idea has gained ground that such an albuminuria may be a physiological occurrence. But a more thorough study of this subject and a large number of observations have convinced me that the following conclusions are correct:

First.—In a perfectly healthy individual the presence of albumen in the urine is one of the rarest occurrences and only happens under conditions which by themselves have an influence on the temporary health of the individual, *i.e.*, at the time of such an occurrence the person whose urine contains albumen is not in perfect health.

Second.—If without any other symptom or sign denoting the presence of any disease, albumen appears in the urine of an apparently healthy person *occasionally*, and not very *rarely* only, then this fact alone indicates further mischief, and predicts that such an individual, sooner or later, will fall a victim to a diffused kidney-disease.

Third.—A person in whose family diffused kidney-affections seem to be hereditary, and who is apparently in perfect health, but whose urine does occasionally contain, no matter how little, albumen, will surely be affected by the same disease if medical skill is not able to prevent it.

Fourth.—If a person, apparently in perfect health, and whose urine occasionally gives evidence of containing albumen, suffers from dyspeptic symptoms at times, and if, on examination, the second sound of the heart, especially over the seat of the aortic valve, is found accentuated, louder than normal, such person is already in the first or prodromic stage of a diffused kidney-lesion, the character of which depends upon many different conditions existing in the individual itself.

In the following I will endeavor to prove these hypotheses, and to contribute some not unimportant facts to the pathology of these dangerous morbid processes. My observations were continued for about twelve years. At that time, *i.e.*, twelve years ago, a patient, F. J. M——, aged twenty-three years, who had been suffering from an attack of indigestion, due to too great an indulgence in champagne at a marriage feast, but who usually took very good care of his health, asked me amongst other questions, how it came that his urine so often assumed a different color? I explained to him how the different substances we eat and drink, the amount of fluid imbibed, and the state of the perspiration, had all their influence on the composition, and, therefore, on the appearance of the urine. He insisted, however, that in him it all seemed to depend upon the quantity of a meal, rather than upon quality. Avoiding a useless discussion, I asked him to show me, occasionally, specimens of his urine. He should

always micturate before a dinner and then bring me some of the urine passed five or six hours after such meal. The young man was often invited to dinners, when he used to more than satisfy his appetite, while when he took his meals at a restaurant, he contented himself with the plainest dishes. He gave as cause, that it was the company, the interesting table-talk, which made him eat more when invited, besides he wished to counterbalance his frequent rich dinners by plain meals at other times. I did not take the trouble of a thorough chemical analysis, for which I had neither the time, the necessary preparations, nor the stimulating desire, intending rather to satisfy the curiosity of the patient, than to make scientific or clinical observations. I mention this in such length to show what small causes may often lead to important results.

What, then, was my astonishment, when I found that the urine of this young man always contained albumen and a surplus of urea whenever he had indulged in a hearty meal, especially after having eaten much meat and rich dishes composed of the same, as croquettes, etc., while, at other times, the urine was free from albumen. I now questioned him further, and heard that his father and an uncle had died of Bright's disease, and that he had been told that his grandfather and several other members of his family had suffered from the same malady.

This fact set me thinking, and thence dated my observations. There never were, at the time, any tube-casts in the urine of this patient, of whom I later shall speak again.

Being myself then in the best possible physical health, I next made experiments on myself. I purposely ate sometimes very little for breakfast, to be able to eat the more at dinner, but, notwithstanding, I succeeded often in eating a meal, which, mainly consisting of meat or other rich albuminous dishes, would have been enough for two hearty sailors, only twice in the course of three months was I able to detect a small amount of albumen in my urine, and both times I had not felt quite well after the meal, and had concluded from the long-continued pressure and the feeling of weight I experienced in the epigastric region, as well as from some belching, want of appetite for a day, and a slightly coated tongue, that the heavy dinner had each time disturbed my digestion.

I then endeavored to persuade some of my friends and some patients, who were suffering from minor, mere external ailments, which could not possibly have had any influence on the composition of the urine, to give themselves up to these experiments. The result of the latter, which were made in the years 1871–73 inclusive, was as follows:

Wm. M. J——, aged twenty-six years, healthy, parents the same. Number of observations, fourteen; time, four months. Results: only twice found albumen; had in both cases eaten too much, and complained of indigestion. The last time the albumen was present his appetite left him for several days and he gave up the experiments in disgust.

Chas. K——, aged twenty-two years, healthy. Father died of pneumonia; mother living and in good health. Number of observations, five; time, six weeks. Results: none.

Fr. B——, aged thirty-three, healthy, parents the same. Number of observations, nine; time, two months. Result: albumen once only; here also the last time, and the symptoms of indigestion caused by the meat induced B—— also to drop the experiments.

J. F. C——, aged twenty-four, healthy, parents the same. Number of observations, sixty-three; time, five months. Result; albumen found twice. C—— was anyhow a heavy eater, but after the first time albumen had been met with, he could tell me of its presence beforehand the second time, from the same dyspeptic symptoms he had experienced in the first successful trial.

A. S——, aged twenty-nine years, healthy, but parents dead. Father died of cancer, mother of typhoid fever. Number of observations, eleven; time, two months. Result: none.

Besides, I requested twenty-eight other men to send me some of the urine they would pass about six hours after what they might consider an unusually heavy meal, consisting of beef, eggs, and oysters mainly; fourteen did so, but I never detected any albumen.

Though perhaps not conclusive, these observations prove that it is rather difficult to cause in a healthy person, even after a heavy, abundantly albuminous meal, the presence of albumen in the urine, that such will happen very rarely only, and that in case it does occur, the person is not in a *perfect* state of health at the time; the digestion seems to have to be interfered with to produce, even under the circumstances mentioned, the appearance of albumen in the urine.

But now come three cases of a different character. I had frequently noted before, that in persons who had been drinking large quantities of undiluted alcohol, the urine would contain albumen for some time, but considered these cases as not properly belonging to the present category; the influence of alcohol in this respect being well known. After beer I had, notwithstanding numerous experiments, never been able to find albumen in the urine, under ordinary circumstances.

P. McL——, aged twenty-six, a young Irishman of healthy descent, and himself a splendid specimen of ruddy health, was attended by me April, 1873, for subacute bronchitis. On examining the urine I found albumen in it. His urine I analyzed daily, and during the six weeks he was under my care he had albumen in his urine every Sunday morning. He never drank any alcoholic liquor during the week, but every Saturday evening he treated himself to a rich supper and imbibed freely in beer, though not enough to cause intoxication, but the next morning he did not feel, for an hour or so, quite so well as usually, and the urine then passed contained albumen, which gradually disappeared again, as I convinced myself once, before evening the same day. I persuaded him one time to omit his Saturday evening libation; the next day there was no albumen in the urine, but as he missed his beer too much and made up for what he had lost the same evening, the urine on Monday told me by the presence of albumen what he had done the night before.

W. C——, aged twenty-four, a young negro, of a very decent and healthy colored family, came under my observation March 4, 1873. He was the picture of health, and only requested the removal of a small tumor from his right ear. The appendix looked to me first like a keloid, but the successful result of the operation, the non-recurrence of the growth, and its microscopical appearance, proved it to be a simple hypertrophy. C—— told me that he had always enjoyed very good health, complaining only occasionally of back-ache, which he dated from a cold taken a year before. The pain was of the character of lumbago, and yielded to electricity, the faradic

current being applied to the small of the back in moderate strength. When I examined his urine I found albumen in it, but no tube-casts. Repeated examinations convinced me that whenever he had a feeling of weight in the stomach after a meal, this sensation was sure to be followed by albumen in the urine. During the three weeks I then treated him, a specimen of his urine, passed five to six hours after dinner, was daily analyzed, and found, from two to three times a week, to contain albumen.

Chr. F——, aged nineteen, shot, on July 4, 1873, with a revolver, a piece of the small finger of the left hand off. He came to me for surgical treatment. To my surprise I found albumen in his urine. F—— was very small in stature, being only a little over five feet in height, but well built and enjoying very good health, as his parents did also. Whenever he would get excited and angry, which happened rather frequently—according to the saying, that little men get their temper easily up, just as is the case with small dogs, those barking the most that can bite the least—he would lose his appetite for the next meal, and his urine contain albumen. During my treatment of him at that time—nearly a month—I also examined daily his urine, and found it to contain every few days a small quantity of albumen, but no tube-casts.

I will now mention the case of a cousin of F. J. M——, viz., of Louis M——, aged thirty-one. Louis came under my charge a year later than F. J. M——. He also was a strong and healthy man. His father, too, had died of morbus Brightii, and Louis showed the same tendency to albumen in his urine as his cousin, but still more strongly developed. He needed only to eat very rapidly and the urine would contain albumen. He suffered besides, most of the time, from mild dyspeptic symptoms.

I had the opportunity of watching the further progress of the cases of F. J. M—— and L. M——, Chr. F——, P. McL——, and W. C——. With some of them I should have lost this chance, perhaps, if I had not offered them my professional services free of charge, on the condition that they would always appear with a specimen of their urine when wanted. They are all now in about the same condition as another case, N. S——, was when he, three years ago, came first to me, and who was destined to die, before his expected time, a violent death.

N. S—— was a young painter, and, when I saw him first, in February, 1879, then twenty-six years of age. His father had died of dropsy, caused, if I may judge from the description given me, by diffused kidney disease. S—— had enjoyed good health till his twenty-second year, when he commenced to have a sensation of weight and pressure after meals, suffered a great deal from flatulency, and had some eructations. He had never been afflicted with lead colic, lead-poisoning being anyhow a far rarer occurrence in fresco painters than in common painters. S—— had been attended for a time by a very conscientious, skilful, and old physician, who had benefited him greatly, and who told him also that he should be careful and never expose himself to cold and inclement weather, as his urine contained albumen, and this might possibly lead to Bright's disease. The physician died, and N. S——, beginning again to suffer from dyspepsia, called on me. On examination, I detected albumen in the urine, but no tube-casts. Auscultating the heart, I found the second sound of the organ accentuated, and this was especially clear over the aortic valve.

This observation had the more interest for me, as I had noted the same fact for over three years already on F. J. M——, Chr. F——, P. McL——, and W. C——, while in Louis M—— the disease had progressed still further. There were occasionally epithelial casts in the urine of the latter. Beside, Louis M—— complained of palpitation, and though by percussion hypertrophy could not as yet be demonstrated, the heaving impulse and the also stronger first sound of the heart indicated only too well the approaching danger.

I attended N. S—— for about a year. But while his dyspeptic symptoms had undoubtedly improved, the urine still continued to contain albumen regularly, and the heart-sounds became louder. The want of greater improvement was partly due to the fact that S——, whenever his dyspeptic symptoms were milder, would be satisfied, and take neither his medicine regularly nor follow other directions given him, as he should have done. I saw him the last time alive May 8, 1880. His urine then contained epithelial tube-casts, beside albumen. The next day he fell from a scaffold, broke his skull and died. At the post-mortem I found a proof for the correctness of my diagnosis. Both kidneys were large and presented the initial state of an interstitial nephritis, exactly the same picture which Dr. O. Israel[1] has so well described. The endothelium of the aorta was softened and slightly thickened, the condition of the tissue under the microscope exhibited an exudation due to chronic endoäortitis. The muscularis in the small arteries was hypertrophied, and the lumen of the aorta without doubt decidedly enlarged. This was especially apparent in the ascending arch of the vessel. In fact the same condition was present as that which is artificially produced in animals after having been fed largely on nitrogenous substances (urea, nitrate of sodium, etc.). If there is a surplus of material which enters into the composition of the urine, especially urea in the blood, the heart as well as the aorta has a greater amount of work to do for the purpose of driving the blood as fast as possible to the kidneys, so that they may carry the obnoxious substances out of the circulation and the system.

If, now, in an individual there is the slightest, perhaps inherited, tendency to weakness in the arterial system, the consequences are clear. First, if large quantities of rich nitrogenous food are eaten, they alone, in a healthy person, and while no other disturbance anywhere exists in the system, will be tolerated in the blood and carried to the kidneys, there to be excreted. But if the quantity has been too large, or other circumstances are not favorable, so that the stomach and the small intestines become overburdened and digestion interfered with, then the blood pressure is altered and a transient congestion of the kidneys ensues. If the latter occurs oftener, or if a new element adds another factor, as, for instance, chilling of the surface of the body by cold, then a similar process commences as in a person with an hereditary weakness. The muscular coat of the smaller arteries becomes hypertrophied, an alteration of the blood pressure follows naturally, the lumen of the aorta is widened, the kidneys enlarge, and at last the endothelium of the arteries suffers, in consequence of the irritating character of the urine-forming compounds, and especially of the abundant urea. It is then that the interstitial nephritis begins and hypertrophy of the heart, followed often by dilated hypertrophy, commences. The murmurs heard occasionally over the heart in such cases are

[1] Virchow's Archiv., lxxxvi., p. 229.

as much due to the altered composition of the blood as to the changes going on in the endocardium and in the muscle of the heart and in the coats of the aorta.

In connection with this, and to endeavor to explain how, in certain cases, an augmentation of urea, the primary source of the evil, may take place, it is well to consider the experiments of C. Peyrani,[1] whose observations on animals justified him in the following conclusions:

The stronger an electrical current is, sent through the uninjured sympathicus, the greater is the quantity of the urine and the urea excreted by the kidneys, the induced current being, in this respect, more effective than the constant. If the sympathicus is divided and not irritated, the quantity of urine and urea sinks to its minimum, and the arterial blood of the kidneys assumes a black color. On irritating the peripheral end of the divided nerve, the quantity of urine and urea increases with the strength of the induced current, but the total quantity is smaller than on irritation of the undivided nerve.

For the purpose of finding the urea, which, after division of the sympathetic nerve in the neck is not excreted by the kidneys, Peyrani examined the blood of dogs, rabbits, and guinea-pigs, six to eight hours after division of the nerve, for urea, and comparing it with blood which, a week before the division, had been abstracted from the left femoral vein, he noted that, while before in dogs 1,000 grammes of blood contained 0.152 gramme of urea, this latter quantity increased to 0.164 gramme in the blood abstracted after division, and that a proportionate increase took place in the blood of other animals.

Hereditary influences are generally most apparent in the nervous system. When this peculiar tendency to irritability exists in the vaso-motor nerve, and is set in action by stimulation arising probably from the peripheral branches of the nerve in the stomach, and there due to heavy and not well digested meals, overloading of the organ with especially albuminous matters, a temporary surplus of urea and urine would first be the consequence, causing in its turn a transient congestion of the kidneys, indicated by the presence of albumen in the urine. The original cause then continuing to act, on the principle of acquired habit, and as "a point *minoris resistentiæ*, we can well perceive how this condition of affairs becomes stationary at last, how the endoaortitis, the enlargement of the lumen of the aorta, and all the other morbid lesions of the initiatory stages of diffused kidney affections are brought about—one producing the other till the chain is complete—and how disturbances of the stomach, if, under such circumstances, too frequently repeated, may, especially with the addition of another factor (dyspepsia, chilling of the skin, etc.), at last induce the same pathological changes in a person not predisposed to them, and how the whole morbid process may permanently develop itself in the manner above described.

As a consequence of the first transient congestion of the kidneys albumen appears in the urine, and this symptom is necessarily almost always accompanied by mild dyspeptic symptoms. Before the beginning of the interstitial nephritis the alterations in the blood-pressure become apparent already by the accentuation of the second sound and by the circulation being in general more active. With the appearance of tube-casts in the urine the actual commencement of the interstitial nephritis is indicated, hand in hand go the excitement of the circulation and the beginning changes in the heart, as evinced by the heaving impulse, louder first sound, and later by hypertrophy of the organ.

The further progress of the disease depends upon peculiarities in the constitution of the individual and upon other conditions favoring one issue more than another. The inflammation may continue its simple chronic inflammatory process or cause atrophy of the kidneys—recognizable by the albumen, tube-casts, rapid deterioration of the general health, great emaciation and absence of dropsy in uncomplicated cases, while fatty degeneration or a granular kidney may also be the result of the same initial pathological changes.

Concerning the diagnosis, we must remember, that, so far, by most physicians the beginning of Bright's disease was dated synchronously with the appearance of tube-casts in the urine, while a few spoke of prodromic stages, in which circulatory disturbances and changes in the coats of vessels were mentioned, but not recognized in the living body. But in the light of the foregoing observations we are able to go still a little farther back.

We recognize the first initial stage of therefore most chronic diffused kidney-affections, especially those which, without apparent cause, seem to grow gradually upon the individual, by the occasional presence of albumen in the urine in a person otherwise healthy, by dyspeptic symptoms recurring with the appearance of the albumen, or rather the first preceding the latter; and the second initial stage by the more continued presence of albumen accompanied by circulatory disturbances and accentuation of the first sound. These two prodromic stages are then followed by the initial symptoms and signs of interstitial nephritis—albumen and tube-casts in the urine, excitement of the circulation, as evinced by a heaving impulse and increase of heart-sounds, later hypertrophy, etc. We may mention here what we forgot to say above, that in all the prodromic stages the quantity of urine and of urea excreted is in the first initiatory stage increased *at times*, in the second *more permanently*. This increase of from four to twelve ounces per diem is occasionally noticed by the patient himself; more frequently it becomes first apparent by actual measurement.

From the foregoing the conclusions may be drawn that the examination of the urine in every case that comes under medical attendance is of the utmost importance, that a conscientious physician should make these examinations frequently, and that the latter are especially necessary in persons belonging to a family, in which morbus Brightii seems to arise from a constitutional taint, and lastly, that in applications for life-insurance careful and repeated examinations of the urine should be insisted upon.

Concerning treatment we may achieve a great deal of good, if we only have the morbid process continuously before our eyes. Such a patient should be placed on a mild diet, and nitrogenous substances less abundantly given. No overloading of the stomach is to be permitted, the digestion has to be looked after, and, if need be, assisted by artificial means, and existing disturbances corrected. The secretions must be kept open and the skin carefully protected against the vicissitudes of the weather. All remedies containing salts to be excreted by the

[1] La Sardegna Med., 1870; Biol. Centbl., 19, 1881; Senator's comment in the Centbl. f. d. Med. Wissenschft., No. 16, p. 229, 1882.

kidneys should be omitted and small doses of pilocarpia, digitalis, and similar drugs form the only diuretics. Cups should immediately relieve any transient congestion of the kidneys. The albuminate of tannic acid has so far achieved the best results in checking the drain of the system caused by the continuous loss of albumen, the main nutritive element of the blood.

In F. J. M——'s case I observed the first time, eight months ago, the presence of epithelial casts and the continuous presence of albumen in the urine. We know, especially from the investigations of Baumann and C. Preusse,[1] that benzyl bromide (C_6H_5Br.) causes in the urine, besides products of oxidation of benzyl bromide, the presence of substances which are the balance of the benzyl bromide in union with organic sulphurous and nitrogenous compounds. The latter are intermediate products of tissue-change, protected by their union with benzyl bromide from further alterations. This benzyl bromide seemed to me to be just the remedy for such cases. I gave it in doses of ten grains every four hours, and the result has so far been excellent. Not alone that the casts in F. J. M——'s case have not reappeared, but albumen has also ceased to be present. I gradually decreased the dose to three grains *ter die*, and the effect continued the same. In all the other cases I have not been so lucky, though also there the good influence of the benzyl bromide in diminishing the frequency of the casts and the quantity of the albumen, which, under the influence of this remedy, becomes again irregular in its appearance, was very apparent. But not a single one of the other cases will see the necessity of adhering to a limited diet. Some are willing enough to swallow medicine, but they do not think it worth while to abstain from good meals, rich in albuminous food. I have come to the conclusion, therefore, that if, in such cases, any fresh supply of nitrogenous substances is limited as much as possible, benzyl bromide by its peculiar effect upon the urates, etc., making them less irritating in character or promoting the formation of other unirritating compounds, will decrease permanently the amount of urea in the blood, so that the morbid processes may have a chance for their retrogade formation.

Under favorable hygienic conditions, at least, and if the morbid changes have not proceeded too far, a regeneration of the altered tissues may be possible by removing their original cause, the surplus of urea and of urine, forming irritating compounds in the blood. This once achieved, the dreaded organic lesion of the kidneys may be, perhaps, avoided or postponed, at least for a long period of time, life, therefore, prolonged, if not actually saved.

But while the science of medicine has of late made immense progress, and while we learn every day more and more how to prevent dangerous morbid processes, even if we are not able to cure always the once established lesions, persons who have the means and who wish to reach a good old age, free as much as possible from disease, should alter their relation somewhat to their physician. And here I may be permitted to make a few suggestions. As it takes a physician always some time to study the constitution and individual peculiarities of a person, the latter should be careful in selecting a skilful physician, but *keep him*, if once their choice is made. They then should either visit their physician at stated intervals, say once or twice a week, or have their physician visit them. He can then best teach them the way they should live, what diet is best for them, and guard them against many of the ills human flesh is heir to, or nip these in the bud, as it were, or at least postpone the fatal end often wonderfully long. Those who know the value of an hour in some diseases, and who are aware of the progress medicine has made of late, will see the truth of these remarks. Certainly such arrangements can only be made by the well-to-do, as a physician's time and his knowledge form his capital, from the interest of which he must live; but by the establishment of really effective Boards of Health, much may be done also for the general population.

CHINOIDINE AND CAPSICUM IN INTERMITTENT FEVER.

By R. C. M. PAGE, M.D.,

new york.

Case I.—J. C——, iceman; born in Ireland; aged twenty-two, and single; has resided in New York City during the past fifteen years. Had a chill for the first time September 24, 1880. It came on about 10 A.M. and lasted an hour. It was well marked and was followed by the usual symptoms of headache, fever, vomiting, and sweat. The chill returned on the 26th and 28th, in the forenoon.

I saw him for the first time September 29, 1880. He had received no antiperiodic treatment, but had taken some "opening medicine" the day before, and his bowels had moved three times. General health good. Never drank to excess, but was in the habit of taking a glass of whiskey occasionally.

Treatment.—Ordered three powders, each containing ten grains of powdered chinoidine and three grains of capsicum. To take one powder at bedtime, one at 6 A.M., and one at 12 M. next day. In order to make sure of his taking the whole powder, he was directed to shake it on his tongue from the paper, and to take a swallow of water afterward.

October 1st.—Chill has not returned. Ordered tr. ferri chloridi, in ten-drop doses well diluted, four times daily, and to continue the same for two weeks. I saw him three months afterward, and he stated that there had been no return of the chills.

Case II.—J. M——, laborer; born in Ireland; aged fifty-four, and married; has resided in New York City most of the time since 1849. About the middle of May, 1880, he went over to Hunter's Point, L. I., and remained there five weeks. During the last ten days of his stay there he had chills and fever for the first time in his life. I first saw him June 20th, following, and treated him with powdered chinoidine and capsicum. He was cured for the time, but was quite anæmic, and left off treatment too soon. As a consequence the chills returned.

September 27, 1880.—Patient applied to me again. Has had chills and fever off and on ever since I last saw him. During the past week he has had a chill every day. Bowels regular, but he is very anæmic.

Treatment.—Ordered six powders, same as in Case I. To take one powder before breakfast and at noon every day.

September 30th.—No return of chills. Ordered tr. ferri chloridi as in Case I. After two days the powders were repeated once and the tr. ferri chlo-

ridi pushed for a month. There had been no return of the chills when last seen six months ago.

Case III.—K. M——, aged fifteen; born in the United States; resides in New York City. Had a chill for the first time August 20, 1880. She had them every other day for about ten days when she took a bottle of "fever and ague cure" and got well, as she thought. I first saw her October 15, 1880. Had been having chills and fever off and on ever since the first attack. During the past week she had one every other day. Bowels constipated, and she is anæmic.

Treatment.—Ordered pil. aloes et ferri, to take one or two at bedtime as required to regulate her bowels, and powders of chinoidine and capsicum (gr. x. to j.).

October 18, 1880.—No chill since I last saw her. Ordered three more powders, to take one every day before breakfast, and to take tr. ferri chloridi as above described, and to continue it for a month.

There was no return of the chills up to February, 1882, when she was last seen.

The foregoing three cases are average descriptions of 140 cases of intermittent fever that have been treated by me during the past two years, of which I have any notes. Of these, 10 were treated with tinct. iodine without any appreciable benefit. The remaining 130 were treated with powdered chinoidine combined with capsicum, the dose of the former being always 10 grains, and the latter 1 to 3 grains, according to the age, sex, and habits of the patient. Women and young people (not children) were given, as a general rule, only 1 grain of powdered capsicum. Men were given 3 grains, and beer-drinkers, of both sexes, were given 3 to 5 grains of powdered capsicum at each dose.

In only one case was vomiting produced by the powders. In large doses, however, and especially with children, chinoidine not unfrequently causes vomiting.

Of the 130 cases treated with chinoidine and capsicum the chills soon recurred in 9, evidently because the patients left off treatment too soon. Five were benefited, though not cured, that is to say, the chills returned from time to time. This was doubtless due to their locality, occupation, etc., and nothing short of a change would effect a cure. Twenty-two cases were only seen once, but I believe that they were cured, or else they would have returned, since the majority of them were dispensary patients, having applied for treatment at the North-Western Dispensary in this city.

Of 20 cases of intermittent fever recently treated by Dr. J. C. Mackenzie, of this city, in a similar manner, in only one case did the chills return within two weeks, and he had only applied once, having failed to return for iron. In one case the chills returned after the expiration of two months, but he had evidently taken the disease over again.

Dr. John H. Ripley recently treated a case of intermittent fever by giving large doses of quinine every day for a week, without success. He then gave 20 grains of chinoidine each day for three days, when the chills ceased to recur.

The powder of chinoidine should not be obtained by pulverizing the resinous mass simply, as the particles would soon coalesce again. But if it be evaporated to dryness and powdered in combination with some inert substance, as althea, it will then retain its form. Thus prepared it is about half the bulk of sulphate of quinine, *and very much resembles in appearance the so-called dextro-quinine.* I have never given any other preparation of chinoidine than the powder, but see no reason why it should not be administered in the form of pills, capsules, etc.

Whatever be the value of chinoidine alone, it appears that in ten-grain doses, when combined with capsicum, it is nearly, if not quite, as good as quinine in breaking up ordinary cases of intermittent fever. Regulating the bowels, and following up the powder with iron in some form, preferably the tr. ferri chloridi, given frequently in moderate doses, and well diluted, appear to be necessary in order to effect a permanent cure.

With regard to chinoidine, Bartholow ("Mat. Med.") says: "When the mother liquor, left after the crystallization of the alkaloids of cinchona bark, is evaporated, a black residue is obtained which is called chinoidine. This contains amorphous quinia and cinchonia, and probably also quinidia and cinchonidia. It is a very efficient anti-periodic, and may be used with advantage as a substitute for quinia in doses about twice as large."

According to Nothnagel and Rossbach ("Handbuch der Arzneimittellehre," Berlin, 1880), chinoidine is "a resinous, dry mass, of a brown color, slightly soluble in water, but readily soluble in alcohol. This very cheap preparation is essentially a mixture of quinine, cinchonine, and resinous matters. The dose is considerably larger than that of quinine."

Prof. Binz, of Bonn, says: "When pure the action of chinoidine approximates that of quinine. The effect appears much more quickly, but passes off more rapidly than in the case of quinine, on account of its being more rapidly excreted" ("Grundzügs der Arzneimittellehre," Berlin, 1879).

In view of the fact that quinine is very much more expensive than chinoidine, and that the latter can be used, when combined with capsicum, in as small doses as quinine, with equally good effect in the cure of most cases of ordinary intermittent fever, it would be a considerable saving of money to the laboring classes, in such cases, to buy chinoidine and capsicum instead of quinine—or even the other alkaloids of cinchona bark.

31 West Thirty-third Street, New York, September 28, 1882.

A SIMPLE MEANS OF CHECKING PULMONARY HEMORRHAGE WITH SHAWL-STRAPS.

By H. HOLBROOK CURTIS, M.D.,

NEW YORK.

A year ago I had occasion to try strapping the extremities in a severe case of pulmonary hemorrhage, where the attacks rapidly followed one another. The free hemorrhages were so quickly controlled by this convenient method of treatment that I should like to record my observations on the subject. The first case upon which the straps were used was as follows:

Mr. B——, aged twenty-one, had lately returned from the Adirondacks, where he had sojourned for two years. His case had been pronounced so much improved that he was permitted to remain at home, where he had been spending the months of April, May, and June. By over-exertion he experienced a severe hemorrhage from one or both lungs, which recurred every few days and sometimes with but a few hours' interval. Ergot and ergotine internally

and by hypodermic injection, gallic acid, turpentine, etc., were each successively tried, but did not control the hemorrhages, until the patient, of a somewhat robust nature, was completely exhausted. Alarmed by the excessive bleeding and also by the frequency of the attacks, I had a pair of ordinary shawl straps punched with holes a quarter of an inch apart, and also braided three strands of drainage-tubing, making two cords of as many feet long. The next hemorrhage being an excessive one, I laid a folded napkin over each femoral vein just below the fold of the groin, and adjusted the straps about the thighs as high up as possible, so that the buckles would be over the napkins. I then proceeded to tighten the straps as much as I conveniently could, intending to stop the venous return without interfering with the arterial supply of the extremities. Having drawn these up tightly, I hastened to bind the arms near the shoulders with the rubber tubing. To my surprise the hemorrhage was checked almost immediately, and in about five minutes I loosened the straps and tubing. This was no sooner accomplished than the patient complained of a great shock to "the sore place," and the bleeding commenced again. The same procedure checked it almost as quickly as before, the sudden decrease in the pulmonary arterial tension following the temporary removal of so much blood from the circulation allowing a coagulum to form. The straps also afforded such relief to his dyspnœa that the patient begged me not to remove them. In about five minutes, the extremities becoming markedly cyanotic, the straps were loosened, a hole at a time, when no hemorrhage recurred.

By this method alone I as successfully checked no less than fourteen hemorrhages, the patient placing such confidence in the straps that he refused to allow their removal, but kept them loosely about his limbs. His shallow and difficult respiration was greatly relieved by keeping an arm and the opposite leg strapped. At the end of five minutes, however, or as soon as the members became mottled and blue, it was advisable to change and strap the opposite limbs. This often diminished the respirations five to ten a minute, my patient becoming very dependent on this means of relieving his dyspnœa. Mr. B —— would frequently remark to me, "Wait until I go back to the woods; I will then show them how to stop a hemorrhage"—referring to the little band of consumptives who gather daily to take their temperature and discuss their symptoms at Saranac Lake. Since this, which I present as a typical case, good fortune has enabled me to observe the effects of this method on four patients, the results being as good or nearly so. My esteemed friend, Dr. W. G. Thompson, of the New York Hospital staff, reported that he had tried my method last winter on a patient in one of his wards, who had resisted all other means employed to stop his hemorrhages, and obtained immediate relief. At the time, I supposed myself to be the initiator of this method of controlling pulmonary hemorrhage, but have since learned that Galen made use of some such means, and more recently Dr. Detmold, of this city, is said to have employed somewhat the same principle in hemorrhage in general, and also to relieve the dyspnœa of pneumonia. Esmarch also suggested tying the extremities in gunshot wounds of the lungs. The tradition among the laity that a string tied around the finger or toe would relieve nose-bleed undoubtedly descended from an ancient practice of so relieving hemorrhage, the string having likewise ascended on the extremity. I neither dispute priority with Galen nor Dr. Detmold. The one claim to originality I advance is the employment of the ever-ready shawl-strap, which simple means I recently had an opportunity to employ successfully on the top of a stage-coach. If this method has been advanced previously, I would like to ascertain why it is not more generally used, and call the attention of practitioners and the laity to a method convenient in its simplicity and efficacious in its application.

251 Madison Avenue, September 26th.

Reports of Hospitals.

BOSTON CITY HOSPITAL, BOSTON, MASS.

Service of W. H. THORNDIKE, M.D., and C. D. HOMANS, M.D.

(Reported by Royal Whitman, M.D., House Surgeon.)

SPONGE-GRAFTING.

Case I.—The patient, a Swede, came to the hospital January 31, 1882. His history was as follows: About seven weeks before entrance, without known cause, commenced to have pain, swelling, and tenderness in each groin. These symptoms rapidly increased, and were accompanied by fever and general prostration. Examination showed several large suppurating buboes in each groin, above and below Poupart's ligament. The patient was weak and emaciated. The abscesses were opened and stimulants and tonics were given. His condition did not improve. Suppuration increased and was accompanied by considerable sloughing of the tissues in the right groin. In a few days the entire extent of Scarpa's triangle was exposed, and the saphenous veins and the sheath of the femoral vessels could be seen at the bottom of the wound. He then began to improve, and on March 13th there was a clean granulating surface, triangular in shape, about three inches long, two and one-half inches wide at its base, and three-fourths of an inch in depth. There was also a small, granulating surface above Poupart's ligament, on the same side, and several small suppurating buboes on the left side, which showed no tendency to heal after incisions. The large, granulating surface having been thoroughly cleansed, two sponges, which had been previously prepared by soaking in dilute nitro-muriatic acid, to remove the lime salts, were accurately adjusted to the surface and pushed under the undermined edges of the wound. The sponges were then covered with oiled silk and a carbolized compress.

On the following day, March 14th, there was no change in the appearance of the sponges. They were thoroughly irrigated with a carbolic solution (1 to 40), and dressed with absorbent cotton and iodoform.

On March 18th there was considerable suppuration about the wound, and a slight odor. The sponges were firmly adherent to the surface. Sponges irrigated twice daily with 1 to 20 solution carbolic acid.

March 26th.—Considerable suppuration, and quite a disagreeable odor.

March 29th.—Less suppuration. There is now a faint reddish tinge about the edges of the sponges. No redness or induration of the surrounding tissues. Patient's general condition much improved.

During the following week there was no particular change. The reddish tint gradually became more marked.

On April 13th the extent of the wound was considerably reduced in size the edges rapidly closing in above the sponges.

April 27th.—Several small projecting portions of the sponge were removed. The entire surface of the sponge was now quite red and bled freely on being cut.

May 4th.—Granulations could now be seen coming up through the openings in the sponge, which was rapidly being absorbed.

May 18th.—The larger portion of the sponge has now been absorbed. The granulations are now level with the surrounding tissues. Extent of the granulating surface is much diminished.

June 8th—only a few shreds of sponge can now be seen on the granulating surface, which is about one inch in diameter. No pain or tenderness. Considerable induration over the grafted area. No puckering of the skin.

June 29th.—Discharged with a small granulating surface, about three-fourths of an inch in diameter. Still a small amount of suppuration from the smaller abscesses in the opposite groin, which had not entirely healed.

There was a peculiar, solid, indurated feeling about the grafted area. There was no pain or tenderness, and no contraction of the surrounding tissues.

Case II.—The patient, a woman, seventy years of age, entered the hospital March 4, 1882. Has had ulcers on the legs for the past fifteen years.

Examination was as follows: On the left leg, just above the external malleolus, was an ulcer, two and one-half to three inches in length, oval in shape and about one and one-half inches in diameter, and one-fourth of an inch in depth. Its edges were thickened and indurated and its base covered with a slough. The integument of the leg was pigmented, showing the scars of former ulcerations. On the right leg, about two inches above the external malleolus, was an ulcer, slightly smaller than the preceding, with indurated, adherent edges, and at the junction of the upper and middle third of the leg, upon the inner surface of the tibia, was a similar ulcer. Both legs were swollen and œdematous. Poultices were applied, and on March 11th the surfaces of the ulcers had nearly cleaned off, and were covered with pale, indolent granulations. The ulcerated surfaces having been thoroughly cleansed, sponges which had been previously prepared with nitro-muriatic acid were accurately adjusted to the surfaces of the ulcers and covered with oiled silk and pads of salicylic cotton.

On the following day the sponges were irrigated with carbolic solution (1 to 40), and dressed as before. Patient says that the dressing is a very comfortable one.

March 17th.—No odor; an increased amount of purulent discharge; slight reddish tinge about sponges, which are now firmly adherent.

March 20th.—Slight odor; reddish tinge more marked; sponge bleeds on being pricked. Dressed with boracic acid and pads of absorbent cotton. This dressing caused her so much pain that it was omitted on the following day and iodoform was substituted.

March 26th.—The area of redness is rapidly increasing and numerous granulations project through the openings in the sponge.

April 10th.—Sponges are now almost uniformly red; there is but slight discharge from them and no odor. Patient discharged.

August 15th.—The patient, immediately after her discharge from the hospital, commenced walking about. Swelling of the legs followed, which she attributed to the presence of the sponges. She tore out as much of the sponge as possible, and is now in about the same condition as upon her entrance to the hospital.

Case III.—The patient, a boy, sixteen years of age, entered the hospital May 5, 1882. His history was as follows: About five weeks before entrance, without apparent cause, commenced to have acute pain in the leg, which was soon followed by swelling, induration and considerable constitutional disturbance.

Examination showed the left thigh to be much swollen, surface slightly erythematous. There was deep fluctuation, especially marked on the inner surface of the leg. The knee was semi-flexed, and the mobility of the hip- and knee-joints was much impaired by muscular spasm.

There was intense pain in the leg, increased by motion. The temperature was high, and the patient was delirious at night.

May 7th.—Incisions were made on the inner aspect of the thigh, and a large amount of pus was evacuated. On May 9th counter-openings were made, and the lower extremity of the femur was found to be extensively necrosed.

During the next few weeks the patient continued in about the same condition. His temperature continued high, and there was a large amount of suppuration.

May 30th.—Fluctuation was discovered in the knee-joint.

On June 30th Dr. Homans amputated the thigh at the junction of the upper and middle fourth. The lower three-fourths of the femur was found to be necrosed, and there was a spontaneous fracture at the junction of the lower and middle fourth. There was also disorganization of the knee-joint. A long sinus was found, running from the extremity of the stump up to the tuberosity of the ischium, and a long horse-hair drain was inserted. The vessels were ligated with silk and catgut, but there was continuous hemorrhage from the femur, which could not be controlled, and which would evidently prevent healing by first intention. A carbolized sponge was then packed tightly into the femur, pressing back the marrow, and then it was cut off, on a level with the bone. This controlled the hemorrhage perfectly. The stump was dressed with iodoform and salicylic cotton. The first dressing was done on the fifth day, and the horse-hair drain and sutures were removed. There was almost complete union by first intention. The patient was up on the fourteenth day, and all dressings were omitted on the twentieth day.

Case IV.—The patient, a woman, thirty-five years of age, entered the hospital June 15, 1882, with a large medullary cancer of the breast, and enlarged glands in the axilla. The breast, with the pectoral muscles, was removed, and the axillary glands, large and small, were also removed. After the operation there was a denuded surface about six inches in diameter. The wound was dressed antiseptically in the usual manner until July 9th, when a sponge which had been previously prepared was inserted into the cavity of the axilla. July 14th it was firmly adherent. Since then it has slowly filled with gran-

ulations, the process of repair in the whole wound having been very slow. Owing to the position of the cavity, and the large size of the sponge, it has been quite difficult to keep it thoroughly cleansed. It has been irrigated with carbolic solution (1 to 40) twice daily, and the wound has been dressed with Lister gauze. There has been but little odor.

Remarks.—Case 1st was undoubtedly benefited by the application of the sponge. The large cavity filled up from the bottom, with no contraction of the tissues, and probably more rapidly than it would have done without the application.

Case 2d would probably have been benefited had she remained longer in the hospital.

Case 3d.—The application of the sponge to the bleeding bone promoted healing by first intention—by controlling the hemorrhage. It would seem, however, that in such cases the application of some substance which would be more easily absorbed than sponge would be preferable, such as shreds of gold-beater's-skin.

Case 4th.—In this case the result has not been successful, and the sponge has probably retarded the closing of the wound somewhat.

These cases comprise all the sponge-grafting that has been done at this hospital. It will be seen that this method of treatment has not been followed by the remarkable results that have been reported in the English journals.

Sponge-grafting seems to be of use in a certain limited class of cases, such as deep, circumscribed ulcers of the leg, which are often followed by adherent cicatrices, which readily break down. In these cases the sponge forms a trellis-work, through which the granulations spring up from the bottom of the wound, thus preventing the contraction from the edges. The sponges used in grafting should be perfectly clean, and thoroughly carbolized. They should then be soaked in dilute acid until they become quite friable, in order that they may be absorbed more rapidly.

EPISCOPAL HOSPITAL, PHILADELPHIA.

SERVICE OF LOUIS STARR, M.D.

(Reported by THOMAS R. NEILSON, M.D., ex-Resident Physician to the Hospital.)

A CASE OF PNEUMONIA OF THE APEX WITH MARKED CEREBRAL SYMPTOMS.

GEORGE McM——, aged forty-five years, a weaver by trade, was admitted to the Episcopal Hospital on the evening of September 27, 1881.

His friends, who accompanied him to the hospital, stated that his habits were intemperate, that he had been on a spree only a day or two before. They knew of no previous illness except an "apoplexy," which occurred "sixteen years ago," and which was followed by paralysis of the right side, from which he slowly, but completely recovered.

No definite history of the onset of this attack could be obtained. In addition to drinking to excess, he had been exposed to the sun the day before he was taken ill. During the day, while at work, he had several times complained of "feeling badly," and in the afternoon he suddenly became "almost speechless." On admission to the hospital there was constant swinging backward and forward of the right arm, as if in the act of feeding a loom; there was almost complete aphasia, the patient being able to utter only three words, "through great misery," which he repeated over and over again, rather indistinctly, in answer to any question; the face was flushed; the right foot was dragged when he attempted to walk; the tongue was coated and moist; physical examination of the abdomen yielded negative results. The temperature was 106°. There was no cough. The patient was placed in bed, and potass. bromid., gr. xxx., ordered to be given at ten o'clock and at six o'clock the following morning.

September 28th.—At 6 A.M. had a convulsion lasting for four or five minutes. 8 A.M.—Breathing stertorously. The right nostril is paralyzed, flapping with each inspiration. The hands and feet are held rigidly flexed. The patient is entirely unconscious. Occasionally he cries out, or sometimes mutters so loudly as to disturb the ward. Urine voided freely in the bed. Temperature, 105°; pulse good in volume, and slow. A simple enema was ordered. Diet, milk, which, however, he could not be made to swallow. No medicine to be given. In the afternoon an ounce and a half of blood was drawn from the nape of the neck by means of an artificial leech. Urine obtained by use of the catheter examined and found to contain a trace of albumen. 6.30 P.M.—Temperature, 103°.

September 29th, 8 A.M. — Still unconscious. There are decided signs of cerebral irritation. The breathing is quite natural. Temperature, 103°; carotid pulse, 72, full and strong. Bowels not moved yet. Urine passed freely. While this note was being written, the patient raised himself up in bed, and suddenly became conscious. He could not speak and was very irritable, actively resisting the nurse's efforts to give him a little milk. He was finally persuaded to take about four ounces of it, which he swallowed without difficulty. Ordered potass. bromid., gr. xxx., thrice daily and as much milk as he would take.

September 30th, 8 A.M.—Conscious, but almost entirely aphasic. The cerebral irritation has entirely disappeared. The skin is cool. The bowels not having been moved yet, magnesii sulph., ℥ ss., was ordered for him. The regular treatment was changed to potass. bromid., gr. xx., with potass. iodid., gr. x., three times daily.

October 1st, 8 A.M.—There is not much change in the general condition since yesterday morning. The mouth is drawn slightly to the left side, and the right arm is tremulous as it lies on the bed. The temperature, 101°. Bowels still confined. Enema ordered, and chloral hydrat., gr. x., three times a day, added to treatment. 6.30 P.M.—Temperature, 98¼°.

October 2d, 8 A.M.—Calls out to imaginary horses, and seems to be startled by objects from which he shrinks. Cannot draw up the right leg as well as he can the left. Temperature, 98°. The bowels were moved by the enema given yesterday. Treatment changed by discontinuing the iodide of potassium, and adding tinct. digitalis. It now stands: potass. bromid., gr. xx., and chloral hydrat., gr. x., every three hours; tinct. digitalis, gtt. xv., three times a day. Beef-tea added to the diet. An enema containing turpentine was ordered, and was answered by a scanty stool. 6.30 P.M.—Temperature, 102°.

October 3d, 8 A.M.—The patient is much more quiet to day. The pulse is a little weak. Temperature, 100°. The chloral was discontinued. 6.30 P.M.—Temperature, 101.5°.

October 4th, 8 A.M.—No change since yesterday, except that he is a little weaker and cannot move

his right leg well. Temperature, 99.5°; pulse, 116. The treatment was ordered to be changed to ammonii carbonat., gr. v., and tinct. digitalis, gtt. xv. every four hours; potass. bromid., gr. x., every three hours. 6.30 P.M.—Temperature, 99°.

October 5th, 8 A.M.—Slept very well last night. Much weaker this morning; very quiet and perfectly himself. The motions of the right leg are no longer impaired. The left pupil is dilated. A large bed-sore has formed over the sacrum. The bowels were freely moved this morning. Temperature, 98.5°; pulse, 112. Dose of carbonate of ammonium ordered to be increased to gr. x. every four hours, and whiskey, f ℥ iv. (in milk-punch) in twenty-four hours. 6.30 P.M.—Temperature, 99°.

October 6th. 8 A.M.—Much better than he was yesterday, though still very weak. The pupils are even. Temperature, 98°; pulse, 112. The bowels were moved three times in the last tweaty-four hours; passages were formed and natural. Bromide ordered to be stopped; quiniæ sulph., gr. iv. (in lactic acid solution), to be given hypodermically in the afternoon. 6.30 P.M.—Temperature, 101°.

October 7th, 8 A.M.—Skin hot and dry; tongue loaded with a heavy white fur, and moist; hands and arms tremulous. There is a slight cough. The temperature is 99.5°; the pulse, 108°. 6.30 P.M.—There is now active talking delirium. Temperature, 103°; pulse 124. Quiniæ sulph., gr. iv., given hypodermically, and potass. bromid., gr. xx., ordered to be given every three hours.

October 8th, 8 A.M.—The patient is much weaker. The delirium has become low and muttering. Temperature, 103°; pulse, 140. Quiniæ sulph., gr. iv., hypodermically, to be given every eight hours. 6.30 P.M.—Temperature, 101.5; pulse, 140.

October 9th, 8 A.M.—General condition about the same as it was yesterday. There is some œdema of the right hand, and hypostatic congestion of both lungs, more marked in the left. The bowels have been moved three times in the last twenty-four hours. Temperature, 101°; pulse, 136. Ordered amount of whiskey to be increased to f ℥ viij. in the twenty-four hours, and the chest to be rubbed with a liniment composed of spt. terebinthinæ and linim. ammoniæ, and a cotton jacket to be placed around it. The patient grew steadily weaker during the day and died at 4.20 P.M.

Post-mortem examination, October 10th, at noon. —*Brain:* Veins of pia mater of left convexity slightly engorged. *Thorax:* Pneumonia of left apex in the third stage, the upper part of the lower lobe of the same lung was in the second stage of the disease. Hypostatic congestion of both lungs.

The other organs were examined and found to be healthy.

Remarks.—This case of cerebral pneumonia is worthy of being recorded for two reasons: first, the comparatively rare occurrence of apex pneumonia in the adult, and secondly, the severe type of the cerebral symptoms which were present. In children, more especially very young children, the apex is perhaps more frequently attacked than the other portions of the lung, and in them, too, cerebral symptoms, delirium, convulsions, coma—not at all rare when any portion of the lung is attacked—are more frequently met with and more prominent when the apex is the seat of the disease. In the adult there is the same tendency to cerebral disturbances when the apex is involved. Heinze, quoted by Juergensen (Ziemssen's "Cyclopedia"), states that in "one hundred and seventeen cases in which" the upper lobes were attacked, either alone or in connection with other lobes, forty-seven presented severe head symptoms (40.2 per cent.); out of two hundred cases, in which the lower lobes were alone affected, there were only fifty-one in which the symptoms in question were present (25.5 per cent.). The cause of cerebral symptoms lies in the character of the fever, which develops suddenly and rises rapidly. Juergensen says: "Experience shows that the most severe cerebral symptoms usually occur in connection with pneumonia of the apex setting in with a rapidly developed fever."

It can easily be understood why children, who are attacked more suddenly and with comparatively greater severity by diseases accompanied by fever than adults, should be more subject to nervous symptoms.

In conclusion, there seems to be no special time in the course of the disease at which head symptoms may show themselves; indeed, they may appear even after defervescence; and, of course, they may vary widely both as to their character and intensity.

Progress of Medical Science.

SURGERY AND THE DOCTRINE OF EVOLUTION.—C. Pittfield Mitchell, M.R.C.S., of Orange, N. J., contributes to the *New York Medical Journal and Obstetrical Review* for September, 1882, an essay, entitled, "An Evolution Aspect of the Healing of Wounds, with Deductions as to Treatment." As the author tells us in a prefatory statement, this is an application of the Spencerian doctrine of evolution to some of the phenomena of reparative action. The essay sets out with a classification of methods of repair from the standpoint adopted. Next, the grounds for this classification are given, and incidentally we are introduced to an important conception—arguing that, since whatever is profitable to an organism, in the way of structural or functional variation, will be taken advantage of by heredity and natural selection, the functional changes naturally involved in recovery from disease will come within the sphere of their operations. With the zymotic diseases, for instance, natural selection may segregate, and heredity may fix both the physiological peculiarity which insures immunity, and the physiological activities which establish the *status quo* when the disease has been contracted. Entering upon the immediate topic of the paper, the phenomena elicited by an incised wound, as the occlusion of arteries, the organization of plastic lymph, the development of granulations, and the physiological adjustment of the tissues to new external conditions, are viewed as non-specific functions of the tissues injured superadded to their specific functions. Deducing the evolution of these phenomena from the known action of physical forces, the shares taken by natural selection and sexual selection as factors are then dwelt upon. Special attention is directed to the protective value of the plastic lymph forming on the surfaces of wounds, and the evolutional steps are described by which this function is acquired. Passing from the structural, the evolution of certain more strictly functional adaptations is next considered. Knowing, in general terms, the atmospheric and other forces to which wounded tissues in the past must

have been exposed, the corresponding accommodations of function are inferred. Thus, the general conclusion is drawn that "the molecular constitution of wounded tissues should fit them, on the average, for contact with a mean atmosphere, and certain moderate deviations from this mean." It is pointed out that, although traumatic injuries are not necessarily accompaniments of life, they are of such frequency among the lower animals and man as to give validity to this conclusion. An absence of organized adjustments of function to the remaining forces commonly incident upon wounds is inferred from the inconstancy, diversity, and nature of these forces. Such deductions are shown to harmonize with experience, and certain principles of treatment for healthy wounds are presented as corollaries. The gist of them is, that, so far as the exigencies of practice will permit, wounds should be shielded from the incidence of any force to which we may know *a priori* there can not exist an organized adaptation. A normal atmosphere should be maintained, and cleanliness should be absolute at every step. Believing that the plasma exuding from the severed tissues is, by "its chemical and mechanical properties, and contact with environing forces during evolutionary time, specially fitted to protect the less stable cells which lie underneath," much importance is attached to the preservation of its integrity. "Wounds should remain open until the surfaces have become glazed, and all interfering applications should be scrupulously withheld." Finally a verification of these inferences is found in the facts disclosed by Dr. McVail, in his paper in the *British Medical Journal* for July 23, 1882, on the results of "Ten Years' Surgery in Kilmarnock Infirmary." The method of dressing employed (dry-dressing) essentially fulfilled the above-mentioned theoretical requirements, and gave, on comparative analysis, the "best general results covering a lengthened period of time that have ever been recorded in the history of British hospital surgery;" and the last group of cases reported—numbering 421, including 90 operations, 23 major amputations, 45 injuries, 52 abscesses, and seven compound fractures—showed not a single fatality from any cause.

Infectious Pneumonia.—Germain Sée, in *L'Union Médicale*, Nos. 76–79, 1882, distinguishes three varieties of infectious pneumonia. 1. Pneumonia caused by malarial infection of the intermittent type. 2. Erysipelatous pneumonia, arising from the extension of facial erysipelas downward through the trachea and bronchi. 3. Typhoid pneumonia. Under the latter he does not include pneumonia with typhoid symptoms, nor hypostatic pneumonia, occurring in the course of a typhoid fever, but an inflammation of the lungs, arising in the first stages of typhoid fever and existing as the chief or only local expression of the typhoid poison. Infectious pneumonia is characterized by its asthenic symptoms. The disease first shows itself by repeated chills and an irregular rise of temperature, and it subsides, as a rule, gradually, seldom by crisis. There is frequently inflammation of other organs—the kidneys, pleura, pericardium, etc. Accompanying it there is enlargement of the spleen, with icterus, marked disturbance of the sensory functions, prostration, etc. Ordinary croupous pneumonia the author considers to be a local, not a general disease.

An Unusual Relation between the Placenta and the Membranes.—In the September number of the *New York Medical Journal and Obstetrical Review*, Dr. Henry J. Garrigues, of New York, describes a very remarkable relation between the membranes and the placenta. The placenta measured twenty centimetres in diameter, the cord sixty-four centimetres in lenth, and both were of nominal thickness. The cord was inserted centrally. The membranes which had contained the child did not adhere to the edge of the placenta, but started from the point of insertion of the cord on this organ. Measured in a flaccid condition, hanging down around the cord, this bag was forty-one centimetres long. It was easily separated into two layers. The inner layer was covered with the epithelium characteristic of the amnion, a single layer of flat polygonal cells, which were in a state of fatty degeneration, as proved by numerous oil-globules found in their interior. The outer layer consisted only of connective tissue, which, in some places, contained a few round or oval cells, and many fat-drops. In other places some loose shreds were found on the outer surface, which showed a greater number of similar cells. At the placental end of the cord the sac was seen to form a kind of triangular mesentery, embracing the first eleven centimetres of the cord, and attached to the sac to a similar extent. The two layers forming this fold were not united, so that the finger could be pushed in between them up to the cord; but at the lower end (*i.e.*, nearer to the fœtus) they grew together, so that a pouch was formed between the "mesentery" and the cord, admitting half the length of the index. At the placental end of the cord there was found in the interior a small clear vesicle of the size of a pea (the umbilical vesicle). The placenta presented a common, shining, smooth fœtal surface, and rough maternal surface. The edge looked ragged, as if something had been torn from it, and in one place even a small, square piece of membrane about two centimetres in either direction was found attached to it. This membrane had no epithelium, and was composed of an inner layer of connective tissue, and an outer layer containing many round and oval cells. From the fœtal surface two membranous layers could be dissected off. The most superficial was exceedingly thin, the deeper one comparatively thick, and bound by isolated fibres to the placental tissue. The fœtal surface had no epithelium. The chief point of interest was that the sac in which the fœtus was placed, and which contained the amniotic fluid, was not attached to the circumference of the placenta, but to its centre, all around the insertion of the cord. Microscopical examination showed that this sac was composed of the amnion and the chorion, but had only scant remnants of decidua attached to it here and there. On the other hand, the portion of membranes found attached to the edge of the placenta was composed of decidua and chorion without amnion, and the fœtal surface of the placenta had no amniotic epithelium. Dr. Garrigues supposes, therefore, that the placenta all around was separated, after the birth of the child, from the decidua, which remained attached to the interior of the womb. Secondly, that the amnion and the chorion together formed a fold from the circumference to the centre of the placenta, which fold on one side was open, and formed the meso-cord described. Such a folding was perhaps brought about by accumulation of fluid between the chorion and the decidua after the formation of the placenta. At first he supposed that the amnion alone partook of the folding; but then we should find, he adds, on the sac surrounding the fœtus, the line where the chorion had been torn,

and there was no trace of anything of the kind. He thinks, therefore, we must conclude that the chorion remained close to the amnion all the way, and was folded with it so as to cover the fœtal surface of the placenta twice, as well as the amnion. This supposition is corroborated by the fact that two layers could be dissected from the fœtal surface of the placenta. The outer one was very thin, and this he took to be the chorion; the inner was thick, and this he explains as being the two layers of amnion grown together by their epithelial surfaces.

Acute Spinal Perimeningitis.—Lemoine and Lannois relate a case in the *Revue de Médecine* for June 10, 1882, in which a slight fall was followed in five days by paraplegia and symptoms suggesting acute ascending paralysis. The only lesion discoverable at the autopsy was a suppuration of the perimeningeal cellular tissue, which had caused, by compression, a rather extensive softening of the cord. The authors could find but one similar case, recorded by Levitsky, of Warsaw.

Stenosis of the Left Ventricle.—Rollet relates the following case in the *Wien. Med. Jahrbücher*, Heft II., 1881: A woman, forty-seven years of age, was admitted to hospital suffering from palpitation, thoracic pain, dyspnœa, and cephalalgia. There was no œdema of the limbs, no stasis of the pulmonary or hepatic circulation, no especial fulness of the jugular veins, nor any of the rational signs of mitral disease. The cardiac rhythm was irregular, the radial pulse small, compressible, uneven, and 104 to the minute. There was an increased area of dulness over the region of the heart, and the apex beat was exaggerated and to the left of normal. On palpation a very distinct thrill was perceptible, but felt only under the lower part of the sternum, to the left of this bone, and at the apex of the heart. On auscultation, a rather prolonged systolic murmur was heard, of maximum intensity, in the fourth intercostal space at the left border of the sternum. The second sound was short and feeble, but without murmurs, audible at the base, and in the carotids, thus showing the integrity of the sigmoid valves. A diagnosis was made of a true stenosis of the left ventricle without valvular lesions, and was confirmed post mortem. The hypertrophy was confined to the left ventricle, the walls of which were pale and presented here and there small spots of sclerosed tissue. The aortic orifice was normal. A fibrous band was found extending from the under surface of the aortic lip of the mitral valve to the interventricular septum and the aortic portion of the ventricle, at a little distance from the sigmoid valves. This new growth narrowed the aortic cone to such an extent that one finger could with difficulty be introduced. The author thinks this was due to an endocarditis of intra-uterine life. The patient had never had rheumatism. A similar lesion of the right ventricle was described by Dittrich in 1849.

Perforation of the Left Ventricle by a Round Ulcer of the Stomach.—The following case is related by Dr. Brenner in the *Wiener Medicinische Wochenschrift*, No. 47, 1881: A woman, fifty-five years of age, was admitted to hospital suffering from repeated hemorrhages of the stomach, from which she finally died. She had had a pleurisy on the left side some six months previously. At the autopsy the left lung was found to be retracted and closely adherent to the diaphragm. The two surfaces of the pericardium along the left border of the heart could not be separated without dissection, and the dilated stomach was also adherent along the lesser curvature to the diaphragm. About two inches from the cardiac orifice, on the lesser curvature, was a round ulcer almost as large as the palm of the hand, at the edges of which were seen the gaping coronary vessels whence the fatal hemorrhage had come. At the bottom of this ulcer was a sinus communicating directly with the cavity of the left ventricle, through an opening in the endocardium, the size of a pea. It is remarkable that, notwithstanding this perforation of the heart, there were no serious cardiac disturbances during life, and the hemorrhage causing death was from the open ends of the coronary vessels of the stomach, and not from the heart.

Treatment of Malignant Tumors by Electrolysis and Iodide of Potassium.—Professor Mariano Semmola, of Naples, presented a paper to the International Congress, in which he advocated the treatment of external malignant tumors by electrolysis. His method is to introduce both needles into the growth at some little distance apart. The applications may be made every day or two or three times a week, according to the size and duration of growth of the tumor. A mild current applied during a long sitting is preferable to a short application of a stronger current. The application causes pain. In conclusion, the author asserts: 1. Tumors of malignant nature can be cured by electrolysis. This result is attained (*a*) by exciting little centres of inflammation, with consequent formation of cicatricial tissue; (*b*) by inducing a fatty degeneration in the mass of the tumor, especially when the latter is already on the way to softening; (*c*) by provoking a suppurative inflammation, with consequent sloughing and disintegration of the tumor. 2. In conjunction with the treatment by electrolysis, it is necessary to administer large doses of iodide of potassium for a considerable time to obtain its alterative effects. The cure is slow but complete if one will but persevere. The author believes that the cure is permanent, but cannot assert it positively, as his cases have not been under observation long enough.—*Le Progrès Médical*, July 15, 1882.

The Treatment of Intussusception.—In the September number of the *New York Medical Journal and Obstetrical Review* Dr. W. R. Gillette, Physician to Bellevue Hospital, relates a case of intussusception in a child nine months old, relieved by injections of water, the administration of chloroform by inhalation, and manipulation of the tumor felt through the abdominal wall. This, he states, is the third case of intussusception in infants which he has seen, and which he has been able to reduce by these means. He thinks that these cases, from the philosophy of their condition, and the necessary measures for relief, are best managed in the way indicated. In two other instances, in which he saw and advised this treatment, reduction was utterly impossible under the other methods tried. The children in each of these cases were held while struggling, and the injections forced into them against all voluntary and involuntary efforts which they could make. He deems the administration of chloroform almost absolutely necessary in these cases. The reason is not difficult to find, inasmuch as, while it gives us such perfect control of the patient, it also eliminates the element of muscular spasm. Moreover, massage is a powerful adjuvant to the hydrostatic pressure of water in these cases. In the first two cases the obstruction was not overcome until massage also was employed.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, October 7, 1882.

POST-GRADUATE STUDIES.

THE establishment in this city of schools for post-graduate instruction is in many respects an evidence of the readiness with which the medical mind takes hold of a new idea and the earnestness with which it attempts to carry it out. It is eminently fitting that New York, the acknowledged medical centre of the country, should be the chosen field for taking the initiative of the movement. In fact, in no other place could any experiment of the sort be more satisfactorily tested. The field which from this point of view opens itself for cultivation is a large and fertile one, and capable of yielding the best fruits to conscientious and earnest workers. The want of just such training as a properly conducted post-graduate school can give, has been keenly felt by thousands of practitioners throughout the country. The evidences of this are in the rapidly increasing numbers who come to the city every winter for the purposes of attending medical lectures, of walking the wards of our hospitals, and of taking special courses.

There is hardly a medical man to be found in active business, outside of the larger cities, who does not look forward to the possibility of coming at some time to New York to make up what he knows to be his deficiencies in knowledge and experience. Many of these can obtain all they desire by attendance upon our medical colleges, going over much of the old ground afresh, and filling in the spare time by visiting our hospitals and dispensaries. But this is hardly calculated to satisfy the majority of post-graduate students. Whether such post-graduate courses as are promised this coming winter will meet their requirements, depends as much upon the particular plan of instruction adopted as upon the reputation and skill of the teachers. Everything in the way of success rests upon a proper appreciation of the real needs of the student practitioner. Generally it is safe to assume that he knows his own weak spots. No man can practise medicine actively for five or more years without gaining such a knowledge of his shortcomings. The latter are almost entirely in the direction of the clinical study of disease, in its wider, more comprehensive sense. His special studies must necessarily narrow themselves to such as tend to perfect him in diagnosis, and to add to his skill in treatment. In other words, the more practical his instruction the better. This, it strikes us, is to be the pivotal point upon which the real utility of any post-graduate course must turn. Didactic instruction must necessarily hold a secondary place to fill in what might otherwise be gaps in a full clinical course. In reality, however, there is more danger of doing too much in the way of formal lecturing than too little. How to avoid the former must be a matter for serious consideration with the instructor, for there can scarcely be any erring on the side of the latter. We believe we speak now in behalf of the men who may come here to make the most of their time and opportunities.

If we are to gain anything from the experience in post-graduate instruction abroad, we must look in the direction of the establishment of a polyclinic in connection with each school. The building up of such a clinic will, of course, take time, labor, and money. In the meantime such of the gentlemen as are connected with the larger hospitals should open their wards to the students and give daily instruction at the bedside to these classes. The larger dispensaries might also be utilized for such purposes, thus making available much material that might otherwise go to waste. In no more direct and more satisfactory way can the requisite amount and variety of clinical material be obtained. The most successful polyclinic will entice the greatest number of students, and will lay the foundation for the most successful post-graduate school. With the patients at hand, and with every member of the faculty an actual clinical teacher, it is then only a matter of detail to systematize instruction on a thoroughly practical basis, to divide the students into classes, and to give them every opportunity for thorough and personal examination of the leading symptoms of every disease brought to their notice. There is one thing in listening to the most graphic description of a heart-murmur and quite another in actually hearing it in the patient's chest; one thing in being told that a fracture exists and quite another in feeling the crepitus; one thing in seeing a blackboard illustration of a microscopical appearance and another thing in actually verifying the same on the field of the microscope itself. It is this kind of instruction that the student practitioner has a right to expect, that he is willing to pay for, and that the post-graduate schools that intend to be successful must give.

TEMPORARY HOSPITALS.

CIRCULAR No. 27, issued by the State Board of Health, is an instructive pamphlet upon the subject of "Temporary Hospitals." When sudden epidemics of small-pox or other acute infectious disease break out in a small town, it is often necessary to provide immediate quarantine, or, if the disease continue, to furnish hospital accommodations. For instruction and help in such emergencies the present circular has been issued. It contains a series of plans and sketches of temporary hospitals and refuge tents.

The first building is a small board hut, ten by twenty feet, with an average elevation of twelve feet. This gives an air-space of 2,640 cubic feet. It can be put up in a day and a night, at a cost of $65. It will accommodate one or two patients while a larger building is being erected. This larger building should be erected close by. It will measure twenty-two by thirty or forty feet, and will accommodate from eight to twelve patients. When finished, the first and small building can be used for convalescents. Plans for accessory structures for attendants are given. These can be put up whenever needed.

It will occur to every one that ordinary tents are better and cheaper than the structures here described. This fact is admitted in the circular, and designs for a refuge hospital tent are also given. In cold or wet weather, however, such an accommodation is quite insufficient, and then the temporary buildings will have to be erected.

It is evident that our State sanitary officers have exercised much care and forethought in the plans which they here offer. Their work will be likely to save much labor and expense on the part of others.

WHAT NEW YORK HAS DONE FOR PUBLIC HEALTH.

THE State Board of Health has sent us a batch of circulars which contain a number of items of interest.

A memorandum is given summarizing the duties of State and local health boards, and giving the latest statutes regarding sanitary matters. As is well known, the law establishing local health boards was at first permissive. It is now obligatory, and its provisions must be complied with everywhere, although penalties cannot be enforced except as the last resort. The local sanitary officers are made responsible for carrying out the provisions of the law. The question of compulsory notification of infectious diseases has, we should judge, been ingeniously evaded. Neither the doctor nor the householder is made specifically responsible for failure to report disease. The local authorities, however, are compelled to report the presence of all infectious diseases. It is to be inferred that a kind of local option is given as to how information regarding these diseases shall be obtained. A most important result from the present compulsory duties of sanitary officials is the securing complete returns of deaths, diseases, births, marriages, etc.

We suspect that the scope of our State sanitary legislation is much broader than is generally supposed. We have now, besides the laws organizing and maintaining boards of health in every city, town, and incorporated village, statutes providing for the compulsory vaccination of all attendants at public schools; also statutes forbidding the adulteration of food and drugs, and requiring the conduct of analytical investigations. The State Board is furthermore authorized to carry into effect the statute forbidding the use of such petroleum products as give off an explosive vapor at a temperature below 100° F. Every kind and mode of adulteration and deception in milk is prohibited. Either local boards or individuals can bring action in court to secure the infliction of penalties for breaking this law. Statutes framed as long ago as 1869, but subsequently modified, provide ways and means for securing public drainage wherever public health and a commission judicially appointed demand such general drainage works.

Our sanitarians are working diligently to do for public health whatever is possible. The way has been well opened, and progress has been made against what is generally the great obstacle, ignorance and indifference on the part of the people.

THE ELECTRICAL BATH.

DR. W. O. STILLMAN, in the *Philadelphia Medical and Surgical Reporter*, has called attention to and aroused some controversy over the subject of electrical baths and their therapeutical value.

It is true, as Dr. Stillman affirms, that ordinary treatises on medical electricity say little or nothing about it, Erb's recent "Handbuch der Elektrotherapie," and Beard and Rockwell's work being about the only exceptions. The subject has, however, been discussed in periodical literature. So long ago as 1874, Dr. Schweig published some interesting articles in THE RECORD upon the uses of galvanic and faradic baths. Chapot-Duvert, C. Paul, Lagrange, Barth, and others have also published clinical reports of their experience. From the testimony given it cannot be doubted that the electrical bath deserves a place in therapeutics, and that it should not be relegated so entirely to charlatans as heretofore. There are a number of prosperous quacks in this city who live in fine style upon the profits of electrical baths alone, using them largely in rheumatic and nervous diseases.

The administration of electricity by baths is not difficult. An ordinary bath-tub has often been used. It is better, however, that the tub be of some non-conducting material like wood. A double-cell faradic

battery will furnish quite enough electricity. The electrodes should be large, made of metal or carbon, and should dip several inches into the water. The patient lies in the tub so that neither electrode touches him. The current is passed generally from one shoulder to the opposite foot. It may, however, be localized. The general effect of the current can be strengthened by adding salt, soda, or an acid to the water. The baths are generally given for from ten to twenty minutes and repeated alternate days.

The claim for the electrical bath is that it is the best way to apply general faradization. It is certain that by the influence of the warm water the skin is made a better conductor. It is well known that the dry skin opposes immense resistance to electrical currents, and that it is largely by virtue of its pores that electricity passes through to a sensible extent. The warm bath moistens the skin, dilates its ducts, stimulating at the same time the cutaneous vessels and glands. The conditions are thus favorable for the so-called catalytic actions of the electrical current.

The objection occasionally made that water is a poor conductor and hence not suitable for electrical action is quite trivial. The resistance of pure water as compared with that of mercury is about 120,000,000 to 1; that of salt water, however, is better by only five or ten millions, and the resistance of salt water is nearly the same as that of the moist tissues. In other words, water is a vastly better conductor than the skin under ordinary conditions.

There is no reason *à priori*, therefore, why the electrical bath should not be useful, and we have referred to the matter at some length because it is quite possible for the general practitioner to prescribe and use it as well as the specialist.

Its real value, however, has of course to be tested by clinical experience. The authors already quoted have used it successfully in mercurial and alcoholic tremor, acute and chronic rheumatism, obstinate sciatica, neurasthenia, etc. Weisflog has used local electrical baths in rheumatism with good results. What is needed, however, is further careful clinical records which shall tell the failures as well as successes from this treatment. The former, we fear, as in electro-therapeutics generally, will not be rare.

THE HUDSON RIVER VALLEY.

The Hudson River Valley, says some sagacious writer in the New York *Times*, has a group of causes operating to depopulate it. The whole southern stretch of the valley, we are informed, from Newburg to Yonkers, is infected with malaria to a serious and dangerous extent.

To this sweeping judgment the *Yonkers Standard* strongly protests, and shows that the Yonkers death-rate at least is the lowest of any section in the State, being only thirteen per thousand. The valley of the Hudson, says this authority, is one of the healthiest in the world. It adds, however, by way of concession:

"We do die. The forms of disease are changing with us, as they are everywhere else. Types of malaria, to which we have been strangers, are in some degree known to us. They have lately penetrated all the New England States, have found lodgment in the Berkshire Hills and on the highest points of the Catskill Mountains, and have also made their appearance in scattered localities here. Its habitat seems to prove that it is no longer entirely climatic in its origin. It once was confined to low, marshy spots, and to unclean places. It now strikes the highest and the purest surroundings."

We conceive that the Yonkers journal is nearer the right in its defence of our valley. Taken as a whole the Hudson River country is healthful and has a low mortality-rate. At the same time, it is the fact that considerable malaria does exist, and may exist also without greatly increasing mortality. In fact, a country may be uncomfortably, though not dangerously, unhealthy. Such a stricture will apply to many parts of the locality in question.

Reviews and Notices of Books.

Diseases of the Rectum and Anus. By Charles B. Kelsey, M.D., Surgeon to St. Paul's Infirmary for Diseases of the Rectum, etc. New York: Wm. Wood & Co. 1882.

Dr. Kelsey's treatise on diseases of the rectum is the August number of Wood's Library, and will be found to constitute a very welcome addition to the whole series. The information contained in its pages is above all things practical in its character. The absence of all originality on the part of the author is compensated by his painstaking discrimination in regard to the recommendations of others. As a result, we have a treatise which differs very materially from such eminently personal works, as, for example, the manual of Allingham. While the latter is a treasury of vast personal experience, Kelsey's work is the result of diligent compilation, based on, comparatively speaking, but a limited amount of personal research. It is none the less valuable, however, on this account. In fact, it supplies more nearly the wants of the general practitioner in need of a competent and reliable guide-book for treating widely prevalent diseases, and it is in this sense that we can earnestly and cheerfully commend it to his perusal.

The International Encyclopædia of Surgery: A Systematic Treatise on the Theory and Practice of Surgery by Authors of Various Nations. Edited by John Ashhurst, Jr., M.D., Professor of Clinical Surgery in the University of Pennsylvania. Illustrated with Chromo-lithographs and Woodcuts. In six volumes. Vol. II. Royal 8vo, pp. 733. New York: Wm. Wood & Co. 1882.

The second volume of this great work is now before us. Its appearance has been looked forward to with keen interest, for the very excellence of the

first volume naturally suggested the query whether so high a standard could be maintained throughout the work. Judging by the volume just issued, this standard, if not excelled, has at least been equalled. And we could wish for no better earnest of the editor's intention to make the entire work the most comprehensive, the most reliable, and the most useful treatise on surgery in our language.

The first articles of the present volume treat of diseases, which, while in themselves local, may nevertheless be met with in any part of the body. Accordingly we find elaborate chapters on the different kinds of wounds, contusions, burns, abscesses, ulcers, and gangrenous affections. Of these the article on wounds from the pen of Thomas Bryant, of Guy's Hospital, is perhaps the most masterly, and in all respects satisfactory production.

The antiseptic method of treating wounds might have been dealt with at greater length in a work of such magnitude as the encyclopædia. For Listerism, though decidedly on the wane, must still be reckoned among the living issues of rational medicine. On the other hand, the various venereal diseases are considered with admirable thoroughness, the text being amply elucidated by beautifully executed colored plates. We know of no special textbook on venereal affections that contains fuller, clearer, and more practical descriptions of this common and important class of diseases than the present volume. Under the head of treatment we are pleased to observe, not a mere synopsis of the ephemeral recommendations found in current medical literature, but those time-tested and tried methods which result from the faithful investigations and matured experience of the best minds in the profession.

The closing articles of the volume are devoted to the discussion of the surgical diseases of the skin and its appendages, the diseases of the cellular tissues, and affections of the bursæ. These subjects mark the beginning of the special consideration of the diseases of the various tissues of the body, which is to be continued in future volumes.

In taking leave of the second volume of the encyclopædia, we may be permitted to indulge the hope that the forthcoming ones will not fall below their predecessors in point of general utility, interest, and importance. It is manifestly quite impossible that in a work resulting from the collaboration of so many minds, a uniform standard of excellence can be strictly maintained, or that certain repetitions shall not creep in. But within the natural limits thus prescribed, the editor and his associates have achieved all that is attainable, and certainly deserve the thanks and congratulations of the entire profession. The woodcuts and colored plates illustrating this volume are superior to those of the first one, an indication that the publishers are fully alive to the modern demands of the book-buying portion of our profession.

A Handbook on the Diseases of the Heart, and Their Homœopathic Treatment. By W. P. Armstrong, M.D. Chicago: Duncan Brothers. 1882.

As regards pathology, etiology, symptomatology, and diagnosis of cardial affections, this little treatise is a fairly well-written résumé of the subject. The treatment advised for these troublesome diseases is strictly in accordance with orthodox homœopathic doctrines, and will hardly be relied upon by those who hope to attain success in cardiac therapy. Digitalis in doses sufficient to produce decided effects does not, however, appear to be contraindicated by homœopathic dogma, and the homœopathic mind would seem to take kindly to prescriptions of "regular" doses of this powerful drug. We certainly have better works, and works in abundance on diseases of the heart, so that the present book is slightly *de trop* in medical literature. But as far as homœopathic writings go, it would seem to fill pleasantly a gap that has scarcely been perceived by the rational part of the profession.

Schema zur Forensischen Obduction. Mit in den Text eingedruckten Holzschnitten. R. Rehmann. (A Guide to Forensic Necropsies.) Braunschweig: Vieweg und Sohn. 1880.

This little pamphlet of eighteen pages will be found valuable by many as a practical guide for systematic post-mortems, especially those of medico-legal importance. The cuts are well done, and serve to illustrate points of interest in regard to the encephalon, the heart, and the fœtal circulation.

Grundriss der Anatomie des Menschen. Von Dr. J. Henle, Professor der Anatomie in Göttingen. Text, nebst einem Atlas von 286 Tafeln, zum Theil in Farbendruck. Braunschweig: Vieweg und Sohn. 1880. (Elements of Human Anatomy. By Dr. J. Henle, Professor of Anatomy at Göttingen.)

The above volume, a brief abstract of Dr. Henle's Anatomical Handbook, has been published in response to requests from various quarters, and is intended to accompany and explain the plates of his Atlas. The name of the author is a sufficient guaranty for the value of the book. It will be found especially useful by the student preparing for examination and the practitioner who wishes to rehearse knowledge with which he has ceased to be completely familiar.

A Practical Treatise on Diseases of the Skin. By Louis A. Duhring, M.D., Prof. Diseases of the Skin, University of Pennsylvania. Third edition, enlarged and revised. 8vo, pp. 685. Philadelphia: J. B. Lippincott & Co.

The last edition of this work has been noticed so recently that it is unnecessary at this time to repeat what we have said in a general way concerning its value as a thoroughly scientific and eminently practical text-book. Suffice it to say, however, that the present edition is considerably enlarged, that numerous and important additions have been made, more especially in the shape of new and valuable clinical material, while the therapeutical notes have been largely amplified from the personal experience of the author. The chapter on the anatomy and physiology of the skin has been rewritten.

Plica Polonica.—A report has been spread that the horrible disease known as the plica polonica has made its appearance in London, brought over by the traders in false hair from Poland. The disease is one of the most horrible kind, incurable, and rendering its victim an object as hideous to behold as the leper of the East. The hair, instead of dividing into fine and silky threads, conglomerates into thick matter, with only one thick root, which bleeds on being cut, so that no relief can be obtained save by cauterization of the whole mass. The report has caused a greater scare than any produced by the Fenians.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, September 13, 1882.

DR. E. C. SEGUIN, PRESIDENT, IN THE CHAIR.

ABSCESS OF THE LIVER IN A CHILD.

THE specimen was presented by DR. G. M. SWIFT, and was removed from a child two years and ten months old, at the New York Foundling Asylum. The nurse who had cared for the child since it was a year old said there had been nothing the matter with it until February last, when it had scarlet fever and diphtheria, from which diseases it made a fair recovery, and was in pretty good condition until about August 20th. At that time it was brought to the out-door department of the hospital, and was treated for acute entero-colitis, remaining under the care of this department until September 4th, when it was brought to the asylum in a state of collapse; the respiration was 32; the pulse was too small and frequent to be counted; an effusion was found in the right pleural cavity; the liver appeared to be enlarged, but it was thought this might be due to displacement from the pleuritic effusion. The child died within a few hours, and an autopsy was made on the morning of September 5th. On opening the abdominal cavity a large amount of serous fluid, containing fibrinous flocks, came away; the liver was enlarged, of a yellowish color, streaked with white spots, and at a portion near the diaphragm there had ruptured what proved to be an abscess, containing quite a large amount of pus. The abscess occupied nearly the entire right lobe. The liver was partly bound to the diaphragm. The spleen, also, was attached to the diaphragm. The right pleural cavity was about two-thirds full of sero-fibrinous pus. There were some adhesions between the lung and the pleura. The kidneys were pale, but normal. The pus from the abscess was laudable.

DR. C. HEITZMANN asked if the intestines were examined for the probable origin of the trouble.

DR. SWIFT replied they could not well be examined.

DR. DELAFIELD had not seen such a case in so young a subject, and he had found the record of but one like case, in which there was pyæmia and thrombosis of the liver.

DR. A. C. POST presented a specimen of

NECROSIS OF THE LOWER JAW,

which he removed from a patient about ten days before. The history was somewhat interesting with regard to the etiology of the disease. The patient was a man, about twenty-five years of age, who, about two years ago, had a bicuspid tooth extracted from the lower jaw. A considerable portion of the tooth, however, was left behind. About eighteen months afterward, in May last, he began to suffer from inflammation about the jaw, and not long afterward, an abscess having opened, these specimens of bone came away. After the removal of the remaining fragment of tooth the parts healed well.

Dr. Post also presented a specimen of

OMENTUM FROM A STRANGULATED HERNIA.

It was removed two weeks previously from a woman, a little under sixty years of age, who had had a tumor in the groin for a considerable period of time, but which had given no serious inconvenience until between two and three weeks ago. At that time the tumor became larger, painful and tender on pressure, and she vomited, the vomiting afterward assuming a stercoraceous character. She was unable to take any food, and the vomiting still continued when she entered the Presbyterian Hospital, on Wednesday evening of the same week. She looked pale and haggard, and ascertaining that the trouble was a strangulated hernia in the groin, Dr. Post urged an immediate operation, but consent could not be obtained until the next morning. It was a question whether the hernia was inguinal or femoral, but on cutting down upon it, it proved to be the latter. A small knuckle of intestine was shielded by omentum from the severe pressure to which it would otherwise have been subjected by the hard edge of the femoral ring. He was able to reduce the intestine without difficulty, for it had probably come down only recently, when the symptoms of strangulation first appeared. The omental hernia was cut away, the edges of the wound were brought carefully together after washing it with a carbolized lotion, and rather to his surprise the case had gone on well, with scarcely any bad symptom since. The temperature was very slightly elevated for two days after the operation; it rose a short time on the third day to 103° F., when probably there was a little intestinal irritation, but since that time the temperature had been almost normal, and the wound had healed mainly by first intention. The patient was having healthy movements from the bowel. There seemed to be some difference of opinion as to the expediency of removing the portion of omentum in these cases, but it was his practice always to do so when it was adherent, or much thickened, or had been in the sac long. With regard to the manner in which he secured the pedicle, he passed a cat-gut double suture, tied on both sides, then returned the stump, guarding effectually against hemorrhage.

THE HEALING PROCESS OF FRACTURED BONES.

DR. C. HEITZMANN said that ten years ago he made a number of experiments, in order to study the healing process of fractured bones, mainly on cats and dogs whose legs were broken, while they were under chloroform. Since then he had had a chance to examine the broken humeri of two children, thanks to the kindness of Dr. J. Lewis Smith, who supplied him with the specimens, one two weeks, the other four weeks after the injury, and found full coincidence with the specimens obtained from animals. All these fractures were complicated with a deviation of the broken ends of the bone, but not with an external injury. How the healing is going on, when the periosteum remains unbroken, is not as yet studied.

Immediately after the injury hemorrhage is present and blood fills the cavity between the broken ends. Beginning from the second day inflammation sets in, most intense in the tissues, which are most abundantly supplied with blood-vessels, *i.e.*, the periosteum and the muscles, while the injured bone shares in the inflammation, as a rule, only in a limited degree. The inflammation results in the formation of an embryonal or medullary tissue, which, toward the end of the second week after the fracture, leads to the formation of cartilaginous tissue, establishing the "provisional callus" of Dupuytren. The cartilage is in part hyaline and in part striated, holding plastids with coarse granules, compact

and shining, due to an active increase of the living matter. In the third week the cartilage tissue, in a number of foci, breaks down into medullary tissue again, which, owing to an active new formation of blood-corpuscles and blood-vessels, is freely vascularized. From this secondary medullary tissue at length arises bone-tissue, representing the "definitive callus" of Dupuytren. The newly formed bone-tissue is at first of the cancellous variety, therefore imperfect, while later, by repeated new formation of medullary tissue, the cancellous structure is replaced by regular compact bone. The healing, after months or years, is so perfect, that, were it not for the deviation of the fractured ends of the bone, no trace of the former injury would be visible.

He emphasized the fact that the healing process of fractured bones was identical in every respect with the normal process of formation of bone. Here, too, from the original embryonal or medullary tissue first cartilage arises, and in a certain stage of development the cartilage returns to the stage of medullary tissue, from which bone originates. No tissue is ever changed into another, unless by the formation of medullary tissue. For further particulars he referred to his book, "Microscopical Morphology."

In reply to a question by Dr. Wyeth, whether the cartilaginous formation developed from the embryonal tissue thrown out by the ruptured periosteum cells as well as that thrown out by the fractured bone-substance, he said it developed from all the embryonic tissue. Misunderstanding a question by Dr. A. R. Robinson, he denied the statement of some, that cartilage ever developed directly into bone. He claimed that there was always a preceding stage of juvenile and embryonic condition. Dr. Robinson, however, had asked whether the cartilage cells broke down and disappeared altogether, or whether they multiplied and returned to the previous embryonic condition. The latter was the answer.

REPORT OF THE MICROSCOPICAL COMMITTEE.

Dr. A. R. Robinson reported that the specimen of nasal polypus, presented at the last meeting in June, was an ordinary myxomatous tumor.

Dr. Wyeth presented a specimen of

ANEURISM OF THE RIGHT SUBCLAVIAN ARTERY.

In June last he presented a specimen removed from a patient who had an immense abscess, covering about a square foot surface on the back, due to necrosis of the last cervical and first two dorsal vertebræ. He knew not at the time what was the cause of the necrosis. Returning to the hospital yesterday, he found that the patient had died the day before from rupture of a small aneurism of the right subclavian artery, which had developed deep down under the first and second ribs. Doubtless the necrosis of the spinous processes of the vertebræ was secondary to necrosis of these ribs. The patient had been carefully examined by Dr. Wyeth, by the house staff, and by others of the visiting physicians, and there had not been the least suspicion or sign of an aneurism. There was solidification of the upper part of both lungs, as had been previously diagnosticated.

Dr. Post said he had had several cases of aneurism under his care in which no pulsation could be distinguished at certain periods, during which the existence of aneurism was doubted. The first case occurred many years ago in the New York Hospital. The patient had a large swelling in the inguinal region, and when he first came under his care he could distinguish pulsation. The tumor was flatter and less prominent than aneurismal tumors usually are, but pulsation was quite distinct. The case remained under observation for some time, and finally pulsation ceased altogether. It was submitted to a consultation of the surgeons of the hospital, and it was also examined by leading auscultators of the city and none could detect pulsation. Doubt was expressed as to the existence of aneurism. The patient suffered great pain, and the question was whether there was aneurism or deep-seated abscess. After consultation, he made an exploratory incision, cutting carefully layer after layer until he came to coagulated blood, when he ceased. Within twenty-four hours there was a gush of arterial blood and he cut down and tied the iliac artery. The patient died of peritonitis. Two other cases had occurred during the past summer. In one, the patient was a man, about sixty years of age, who had a tumor in the axilla, which he had noticed for a number of months, and which probably originated with an injury that had caused, it was supposed, fracture of the arm. There was a pulsating tumor, which could be emptied by pressure, on the subclavian artery. The pulsation ceased after a time, and, at a consultation, great doubt was expressed as to the existence of aneurism. The result of the consultation was unfavorable to tying the artery at that time. A few days afterward there was a copious hemorrhage. He then tied the artery just below the clavicle. There was extensive discoloration of the integument and tissues about the large axillary tumor, and a number of days after ligating the artery, the integument of the axilla sloughed. The patient would probably live, although he had lost much blood and had had a tedious time of it. The other case was due to an injury of the forearm, received six weeks before Dr. Post saw the patient. Hemorrhage at the time of the accident was controlled by pressure made by a physician. At the time Dr. Post saw the patient, the limb was very much swollen and hard, there was no pulsation, but the whole history pointed clearly to an injury of the ulnar artery, leading to a diffuse aneurism. He applied an Esmarch bandage, and cut down and exposed a cavity containing a large quantity of blood. He found the ulnar artery wounded, and tied it on either side of the wound.

Dr. H. J. Garrigues presented a specimen illustrative of

EXFOLIATIVE METRITIS.

The patient had diphtheritic ulcers of the vagina and of the uterus, which were treated by cauterization with chloride of zinc. For the ulcers in the vagina he used equal parts of chloride of zinc and distilled water; for the uterus an eight per cent. solution was injected, after first washing it out carefully with carbolized water. It was also washed out a second time after the injection of the chloride of zinc solution. She also had an offensive diarrhœa, from which she recovered under treatment. The vaginal ulcers healed almost completely, the offensive discharge from the womb ceased, but the organ remained very greatly enlarged, extending almost up to the umbilicus. From time to time the temperature would again run up, and on one of these occasions the uterus was again washed out with the carbolic solution, as had been done so often before with great benefit; but on this occasion she went into collapse and died in a few moments. At the autopsy, the uterus was found ruptured in two

places, anteriorly and posteriorly, the first rupture being three inches in length, the second less. At these points the walls had become as thin as a piece of paper, but the ulcers had healed perfectly. To the walls of the uterus were found adherent coils of the small intestine, and at two places there were fine canals leading into the intestine. More interesting still was a body, lying perfectly loose in the interior of the uterus, four inches long, two inches wide, and one inch thick. Microscopical examination showed that it was a part of the wall of the uterus which had been sloughed off by an ulcerative process which had burrowed beneath it. Muscular tissue of the womb could be distinctly seen, interspersed everywhere with inflammatory material. The condition should not be confounded with gangrene of the womb, an entirely different affection. As rare things tend to repeat themselves, so recently Dr. G—— had a similar case, the exfoliated part being a larger and longer piece of muscle. Evidently this body had acted as a valve, preventing the exit of the fluid during the injection, and had caused the rupture of the very thin uterine walls. This was a patient at Maternity Hospital. He had found the record of but two similar cases in the medical literature.

Dr. Heitzmann remarked that the muscular fibres were very plain, as the specimen had been perfectly preserved; and he asked whether this could be accounted for by attachment of the mass to the uterus at any point. Being informed that it was perfectly free within the uterine cavity, he asked Dr. Garrigues how long he supposed it had been detached.

Dr. Garrigues replied that the whole time from the commencement of the diphtheritic attack unto her death was two weeks.

Dr. Wyeth then suggested that the frequent injections of the disinfectant fluid might account for the high state of preservation of the specimen.

Dr. R. W. Amidon presented a specimen of

URINE, CONTAINING HIPPURIC ACID.

The patient was a gentleman, forty-three years of age, who up to about four years ago enjoyed almost perfect health. At that time he was very much troubled in business matters, and began to suffer from very persistent, almost continuous frontal headache. The summer following, his appetite became almost ravenous. Gratifying the appetite relieved the headache to a considerable extent, and that was about the only thing which would relieve it. In July, 1881, his appetite became still more ravenous, and was followed by gastric catarrh, from which, however, he recovered. He noticed, last fall, that using his eyes made the headache much worse, and several oculists were consulted. He was told by some physicians that he was suffering from phosphoruria, but Dr. Amidon did not find any phosphates in the several specimens of the urine which he examined until after it had been kept a very long time. The urine was alkaline, as was the specimen presented, but this was very little ammoniacal, notwithstanding it had been kept for some time. Nearly all the specimens which he had examined presented another not very common feature, namely, the presence of hippuric acid. The crystals were commonly in the form of rhomboidal prisms, though the ends were in some instances chisel-shape. They were very apt to collect in rosettes; they were not soluble in weak acid nor at all so in hydrochloric acid. He was much surprised in looking over the literature to find what various terms were applied to these crystals. It had been found that the quantity of hippuric acid in the human urine is increased by the ingestion of certain articles, as huckleberries, mulberries, benzoic acid, etc.

Dr. Amidon also presented a specimen of

SPERMATIC FLUID,

obtained from an unmarried male patient, forty years of age, who was subject to nocturnal emissions for a number of years. During the past five or six months, however, he had had none. He denied venereal excess, masturbation, or venereal disease. He had used alcohol in excess in his youth. During the past five or six years he had been having an emission, after stools particularly, and unaccompanied by an erection or sexual feeling. In this condition he came to Dr. Amidon, who told him at once that he had simple prostatorrhœa. He was surprised, however, subsequently, on examining some of the ejaculated fluid, to find that it contained spermatozoa. These were uniformly present. He improved under treatment by ergot, belladonna, and atropine, and at present sometimes passes over two weeks without an emission.

Dr. Heitzmann said the specimen and drawing presented by Dr. Amidon did not represent hippuric acid crystals, but simply phosphate of lime. Hippuric acid appears in the form of needles, and is very rare. He had seen it in but one case out of the hundreds which he had examined. Moreover, as the name indicates, urine containing hippuric acid should be acid, while the specimen presented was alkaline.

Dr. Amidon said the specimen presented could not be very alkaline, since, after long keeping, it had scarcely any ammoniacal odor, and it contained oxalate of lime. It was true certain authors agreed with Dr. Heitzmann's description of the hippuric acid crystal, but Dr. Amidon agreed with the very high authorities whose description of it corresponded with that of the specimen presented.

Dr. Wyeth remarked that a similar illustration would be seen in Flint's "Physiology."

The President remarked that the physicians who had examined this patient's urine, and had found phosphoruria, had, as was quite commonly the case, examined only one specimen from one period of twenty-four hours—after a mid-day or afternoon specimen.

With regard to the second case, Dr. Heitzmann had seen one instance in which a man had an emission just before micturition, and a number of surgeons here and abroad were unable to reach a diagnosis. On examining some of the fluid he found that it contained spermatozoa of a very peculiar shape. He found pus corpuscles with long cilia, resembling the tails of spermatozoa, as if the latter had migrated into the former, and the only admissible diagnosis seemed to be inflammation of the seminal vesicles. He asked whether Dr. Amidon had noticed any such peculiarity about the spermatozoa in this case.

Dr. Amidon replied that he found very few perfectly normal ones; there were many curled up, many with large heads, and many small ones.

Dr. Heitzmann then confirmed this statement on examining some of the fluid, and was of the opinion that the case was similar to the one just mentioned.

The President remarked that he had examined the fluid in cases of occasional involuntary emissions in a number of instances, and had generally found

spermatozoa, and had supposed it was of no pathological significance, but due to an overflow of the vesiculæ seminales. The case would probably be different, however, if the emission took place quite frequently.

Dr. Wyeth remarked that in some of these cases there was enlargement of the vesiculæ seminales, as had been illustrated by specimens presented to this Society, and the emission might sometimes be due to pressure of the distended rectum upon the enlarged vesicles.

Dr. William T. Belfield, present by invitation, showed some microscopical preparations of

BACILLI,

and made some remarks on the views entertained at the present time concerning their relation to different diseases, etc. As bearing on the possibility of diagnosing tuberculosis by the presence of these minute organisms in the sputa, the sputa of twenty-two different patients were submitted to himself and another gentleman for examination, without their knowledge of the history of the patients. They found the tubercle bacilli in all the specimens, less marked in two, and made a diagnosis of tuberculosis. This diagnosis had been verified by the physician of the hospital by physical examination in twenty of the cases, but in the last two mentioned the diagnosis was simply of bronchitis. Sufficient time had not elapsed to be able to determine whether in these two cases there might not have been commencing tuberculosis without sufficient signs to be recognized by physical examination.

A vote of thanks was offered Dr. Belfield for his interesting demonstration, after which the Society adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, September 25, 1882.

Dr. F. R. Sturgis, President, in the Chair.

Dr. W. F. Mittendorf read a paper on

MYOPIA AND THE NECESSITY OF ITS CORRECTION WITH GLASSES.

Myopia had justly been called a disease of civilization, and unless prompt measures were taken to check the injurious influences which led to its development, its spread must necessarily increase. Appreciating the importance of the subject, hundreds of the most competent observers had of late occupied themselves with its consideration, and it was only a few years ago that one of the ablest of them, Dr. E. G. Loring, presented to this Society the results of his labors in this field of scientific inquiry. Dr. Loring, however, confined himself especially to the causation of myopia, whereas the object of the present paper was to point out the necessity of preventing the progress of the disease by prompt attention and early use of glasses. Myopia had but little history, and it was only after the measurements of myopic eyes by Prof. Arlt in Vienna, in 1854, that we had had anatomical proof of its existence. It was really only after the invention of the ophthalmoscope that the scientific study of the subject became possible. It depended upon elongation of the eyeball, and certain anatomical points were then illustrated.

With reference to causes, it was, as a rule, an acquired condition, and one impossible to cure. It could, possibly, be prevented; but once established, we can only watch and see that it does not increase, and, above all, that the patient does not lose any power of vision. Do some eyes have a greater tendency to acquire myopia than others? Undoubtedly. Under this head two factors were considered: (1) heredity, and (2) debility or resistance of the sclera. The importance of heredity was illustrated by statistics obtained as the result of observations made by Dr. R. H. Derby and himself, and it became apparent that myopia occurred more frequently among Hebrew and German children than among American and English. The second or lack of resistance in the sclera was, perhaps, one of the most frequent and dangerous of all causes, and it was apt to last during the lifetime of some persons, and led to those cases of high degree of myopia too frequently followed by loss of sight. This condition might follow the debilitating diseases of childhood, and if other causes were brought into play, such as reading or close application of the eyes shortly after having measles, scarlatina, diphtheria, etc., it was a not infrequent result. An illustrative case was cited.

Another cause was some defect of the eyes, on account of which greater efforts than usual were necessary during the act of vision, especially for near objects. Irregular curvature of the cornea might be a cause, and an illustrative case was given. Other causes were mentioned, but the most frequent was use of the eyes in childhood with small and near objects.

The effects which errors of refraction would produce upon the mind of a child had already been pointed out by many observers, and also the beneficial influence of glasses in such cases. But, important as it was, it was not the greatest danger of myopia. It was the change in the interior of the eye caused by the nature of the trouble, the stretching of the more delicate inner structures of the eyeball, that was especially to be feared. It should be the chief object of the physician, when he met with cases of myopia, to prevent its increase. The author of the paper then explained how the changes were brought about, alluded to the most dangerous period in life for the development, and also for the approach, of the more serious complications of this affection.

In order that the eyeball may undergo change, the sclera must be soft and yielding, and that favorable condition existed when the child was growing, and especially so if there was a hereditary tendency to weakness of the sclera, or if the tonicity of the coats of the eye had been reduced by some general condition.

Another dangerous period was when the lens became harder and less elastic. The changes which take place in the inner structures of the eye were then pointed out, and special reference made to the changes occurring in the ciliary muscle. These were regarded as the most important. The histories of several cases of myopia which had been prevented by the early use of glasses from increasing, and with preservation of vision, were then related, and others in which it had been uncorrected, and terminated in loss of vision.

Dr. Mittendorf then referred to cases known as false myopia or spasm of accommodation, where the trouble did not depend upon the change in the eyeball, but upon disturbances of refraction caused by a spasm of the circular fibres of the ciliary muscles,

whereby the curvature of the lens was increased. With regard to prevention of myopia, the dangers to be guarded against were (1), the condition of the sclera, (2) avoidance of compression of the eyeball by the external ocular muscles, and (3) avoidance of intra-ocular pressure, namely: intense and long-continued accommodative efforts and fulness of the intra-ocular blood-vessels. Between the ages of five and sixteen, the eyes should especially be protected against strain, such as comes from too close application at school, overwork with the eyes after debilitating disease, and most especially if there was a hereditary tendency to the affection. The compression of the external ocular muscles was only to be feared when the child was occupied with small objects near at hand which demanded constant convergence. Reading and writing should not be continued for long periods at a time. The avoidance of intra-ocular pressure was to be secured, as much as possible, by avoiding tight clothing about the neck, the stooping position for long periods, studying before breakfast, etc., and the observance of general hygienic measures.

All these measures were not only to prevent the development, but to arrest increase after development had taken place. But there came a time, perhaps, when the eyes were irritable, and absolute rest with local treatment might be required. After the symptoms of irritation had disappeared, the amount of existing myopia should be ascertained by means of test-glasses and the ophthalmoscope, and glasses adjusted to meet the requirements in each case.

Dr. David Webster being called upon to open the discussion, said that owing to the lateness of the hour and the completeness of Dr. Mittendorf's paper, he had nothing to add, and gave his adherence to views which the author had expressed.

Dr. O. D. Pomeroy remarked that there remained but little to be said, yet there were a few points which, perhaps, might be worthy of mention. He had not been in the habit of giving myopic patients glasses for distance early to be worn constantly. He thought that the essence of myopic causation existed in tension of the ciliary muscle. A large number of cases of detachment of the retina depended upon myopia, and a high degree of myopia was a very serious condition. Among the causes not mentioned was the avoidance of glasses at the presbyopic age.

The Society nominated the officers for the ensuing year.

The President directed attention to the by-law, stating that members in arrear of dues were ineligible to hold office or to vote, and Dr. Jacobi urged that only those should be elected delegates to the State Medical Society who would make it a special duty to attend its annual meetings.

The Society then adjourned.

A Fashionable Panacea.—As an illustration of the value of the statement that "a good proportion of intelligent people employ homœopathic physicians," is the following: Dr. Forbes visited Paris in 1842 and learned that with the *élite* of the city a certain nostrum was held to possess astounding virtues. By means of some money he bought the formula for this wonderful nostrum, and found that it consisted "of a decoction of flint stones."—*Detroit Lancet.*

FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Eleventh Annual Session, held at La Rochelle, August 24, 25, 26, 1882.

M. Azam, of Bordeaux, President, in the Chair.

SECTION IN MEDICINE.

Over sixty physicians from different parts of France were present. M. Verneuil was made President-elect.

M. Tricout, of Rheims, opened the scientific work with an exhibition of some ingenious apparatus invented by him. It consisted of an ivory pessary to be held in place by bands running between the thighs, and so arranged as to adopt itself to every position of the body. He also showed a new form of suspensory bandage for the testicles, and an irrigator.

M. de Musgrave-Clay related an interesting case of

SUPPURATIVE ARTHRITIS OF THE ELBOW TREATED WITH ERGOT

internally, and temporary immobilization. The arthritis was in full suppuration when the patient, a child aged six years, came under treatment. He was put upon drachm doses of fluid extract of ergot. There was a rapid diminution of pain, of inflammation, and of pus. The dose was increased to nearly two drachms (75 centigrammes), when the patient's feet began to get cold. Suppuration had ceased, and the dose was gradually diminished. The cure was nearly perfect, there being only a slight interference with movement. This method of treatment was conceived and had previously been employed by M. Daboué, of Pau.

M. Maunay read a paper upon the treatment of the

VOMITING OF PREGNANCY

by cauterizing the neck of the womb. He related thirteen cases in which this operation had been successful in stopping the vomiting. In one case it had been a failure.

In the debate the dangers of so heroic a method of treatment were referred to, and the inhalation of oxygen was suggested, as recommended by Pinard, in cases which resist all other treatment. M. Henrot argued that some cases of vomiting were due to flexions or displacement, and that here a restoration to the normal position must be attempted before anything else is done.

M. Boucheron gave an account of his further researches into the cause of deafness. His view was that deafness in most cases is caused by a closure of the Eustachian tube; the air in the middle ear is then absorbed, which causes pressure from outside, interference with transmission of sound, and finally paralysis and atrophy of auditory nerve-filaments by compression.

In support of this view M. Boucheron told of a dog, deaf-mute from birth, which at the fifteenth month was killed and the ear opened under water. No air was present in the middle ear. The auditory nerve-filaments were atrophied. M. Boucheron compared deafness by otopiesis or compression of the internal ear to blindness from glaucoma, in both there being nerve-atrophy from compression.

M. Paul Laudowski read a paper upon "Morphinism and Morphiomania in France." He showed that there had been an increase in morphine-taking

of late years, also that there had been sudden increases after the war with Austria in 1866, and after the Franco-Prussian war in 1871. He employed the "extrait thebaïque" in treatment.

M. VERNEUIL said that persons with cancer were often morphine-takers, and were on that account more likely to be seriously affected by anæsthetics.

M. DRANSART offered a new theory as to the cause of

NYSTAGMUS IN MINERS.

It was that the trouble is due to fatigue of the elevator-muscles of the eye, produced by constantly looking upward, as miners are obliged to do. The theory, he claimed, was confirmed by physiological experiments. According to M. Dransart, anæmia is no more common in miners than in other laboring classes.

M. LENDET, of Rouen, read a paper upon

ALCOHOLIC GASTRO-ENTERITIS.

His conclusions were:

First.—The lesions of the alimentary tract due to the use of alcohol are generally present in stomach and intestine, but they may be more localized.

Second.—The quality of alcohol consumed contributes less than the mode and amount in which it is taken to determine the resulting form of disease.

Third.—They present different forms in different classes of society.

In the better classes alcohol is taken, perhaps, oftener, but in smaller quantities. Among laboring men alcohol is taken in large doses at rarer intervals.

Fourth.—In the better classes the form of gastro-enteritis is the catarrhal, and it is mild and chronic.

In the workmen it is often an acute, subacute, or chronic gastro-enteritis.

Fifth. — Nervous and mental troubles result equally in both classes.

Sixth.—Hepatitis and vascular troubles are relatively more frequent, but more chronic in the better classes.

M. VERNEUIL reported a case of luxation, with double fracture of the humerus.

M. ROUSSEL, of Geneva, read a paper upon

TRANSFUSION OF BLOOD.

According to him the chill which results after transfusion is an index of the reaction of the system, and is a favorable symptom. He injects sometimes as much as 300 grammes (℥ x.) of blood. The urine he considers to be the criterion of the quality of the injection, it being bad if there is albuminuria or hæmaturia. In acute anæmia, produced by a single excessive hemorrhage, transfusion is not necessary. It is indicated in anæmia produced by repeated hemorrhages.

M. VERNEUIL thought that transfusion of blood was a process at once difficult, dangerous, and useless. He recommended subcutaneous injections of ether as being equally efficient and far more safe and convenient. He admitted the success of transfusion in some cases, but did not think it due to the blood.

M. HENROT thought that transfusion was indicated in certain cases, and that it was better to use the natural stimulant, blood. He had employed transfusion considerably before he learned the value of ether and ergotine. Of late years these latter agents had entirely supplanted transfusion in his practice.

The session concluded with a paper by M. VERGER upon scorbutus in an infant of seven months. The disease is very rare at that age.

(To be continued.)

Correspondence.

BRONCHITIS AND INTERPLEURAL PLASTIC EXUDATION.[1]

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Teachers of physical diagnosis have told medical students, year after year, from Laennec's time to our day, and with scarcely a dissenting voice, that moist râles, when heard within the thoracic cavity during the respiratory acts, meant that mucus, blood, or serum was contained in the bronchial tubes. Further, they have forcibly inculcated that the character of the râles must vary in accordance with the relative fluidity of the exudation and the size of the bronchi in which air was inspired or exhaled. Within the pleura, when inflamed and its opposing surfaces rubbed together, were recognized friction sounds of different tonality and intensity. Sometimes, although rarely, these latter can be distinguished by the ear with considerable difficulty from abnormal sounds of the lung itself. Certain differential signs, happily, are given by most classical authors, to separate them more or less accurately. Thus, the fact that the interpleural râles are more superficial, more limited, less variable during successive respirations, or after a paroxysm of cough, differentiates them often in a sufficient manner. The locality in which they are heard is, also, at times of value in fixing their identity. Inasmuch, too, as the situation in the respiratory tract, where certain moist râles are produced, has been demonstrated experimentally, there would seem to be no good reason to doubt accepted belief unless morbid anatomy should show error of interpretation. This, in my estimation, it has not hitherto done. To support this affirmation, I have but to cite the very numerous cases of pulmonary œdema or congestion, with or without accompanying bronchitis, in which no inflammatory condition of the pleura is visible at the autopsy, and where, during life, the presence of generalized moist râles was undoubted. The preceding statements are simply intended to direct attention to the validity of what have long been recognized as established facts, and *not* to allow a plausible but, in my opinion, incorrect belief to gain vantage ground unchallenged.

Respectfully yours,
BEVERLEY ROBINSON, M.D.

NEW YORK, October 1, 1882.

COUNTY DELEGATES AND THE NEW YORK CODE.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: The *Medical Gazette* of August 26, 1882, contains an editorial which, though that journal was amongst those regularly received and read by me during my absence from the city, I happened to overlook, and to which my attention was drawn but a few days ago. It reads as follows:

"A TIMELY BUT MYSTERIOUS WARNING.

"A writer for one of our city contemporaries, who intimates that he is one of the 'stalwarts' who voted to lower the flag, but who conceals his name,

[1] Vide article with this title by D. M. Cammann, M.D., in THE MEDICAL RECORD of September 30, 1882.

says to the editor, 'I want you to warn the county societies of our State not to allow themselves to be propelled into undue action.' The suggestion is cool, elegant, and classical. They are to be 'warned' not to permit of the application of any *vis a tergo*, which shall propel them into undue action. But seriously, what boots it whether the impulse comes from behind or from before? In either case it might result in undue action. Violent attraction would seem as dangerous to the morals of the society as violent propulsion.

"This is, however, a nice metaphysical question, in the discussion of which we confess to a little mental confusion; and we suspect our readers will also. Perhaps the author will explain his meaning more fully; and it is hoped he will do it over his own signature, in order that his suggestions or warnings may have additional weight.

"We notice that the editor, in parenthesis, at the close of the correspondent's letter says, that he understands it and it is all right, and 'eminently sound.' Probably we ought to accept of this as a sufficient explanation."

As the writer of the above editorial chooses to remain anonymous, he ought not to blame his supposed adversary for corresponding without "his own signature." Moreover, it appears to me that the readers of the *Gazette* are entitled to all the mental confusion which is claimed for them. For the editorial does not state to which of the "city contemporaries" it refers, nor to which article or subject, nor when the publication alluded to made its appearance. The purchasers and readers of the *Gazette*—I am one of the many—may feel proud at its editor—their editor—"going for" somebody because of some blunder or shortcoming committed somewhere at some time or other, but there are certainly a great many who would be very much more pleased to learn what the editor is just castigating, what the incriminated article was, and on what subject, and where printed, and when. Without some definite explanations of that kind, the 'metaphysical questions" of "boots," "impulses from behind or before," "violent attractions," etc., will be almost as unintelligible to most of them as they have been to me.

As the readers of the *Gazette*, if there be any who do not read THE MEDICAL RECORD, cannot know what the above editorial alludes to, I shall say, if I am to judge by the quotation contained in the introduction, that it refers to a letter printed in THE MEDICAL RECORD of August 12th.

If I had been vain enough, Mr. Editor, to believe that by my signing the letter my suggestions or warnings might have "additional weight," I should not have authorized you either to print or withhold my name as you deemed proper. But, really, what I had to say appeared to me so simple and intelligible that the personal influence of any writer on the subject could amount to nothing, no matter who he was.

Now, as the *Gazette's* editorial claims not to have understood me, I shall repeat my meaning in a very few words:

First.—The abrogation of the Code of Ethics was a surprise to nobody. It was the subject of deliberation, through the course of a year, of a committee of five of the best known medical men of the State of New York, who had been appointed for that purpose.

Second.—It was generally understood that final action on the question would be taken in the session of 1882, and it *was* taken in a special meeting held on the second day of the proceedings.

Third.—The abrogation of the code was not the work of some specialists, hungry for consultations and greedy for more money.

Fourth.—That imputation ought never to be made by those who claim an honorable position in medical literature. The tone of their remarks resembles the questionable tactics of some ward primaries more than it does the decorous discussions of scientific publications.

Fifth.—It is a grave mistake on the part of some County Medical Societies to tie the hands of their delegates, and to force them to vote one way or the other. That is what they have done when they instructed their delegates for 1883 to vote for reversing the action of the meeting of 1882, no matter what they might hear and learn in the discussions proposed for the next meeting.

Sixth.—The only dignified action on the part of the County Societies is to send their delegates with *but one binding instruction, viz.: To attend the meeting in February next; to hear, and to speak, and then to vote according to their convictions, such as they will be after the several opinions and reasons will have been exchanged.*

That is all, Mr. Editor, I desired you to impress upon your readers when I sent you my note of August 12th, and if you permit me, I dare to express my firm belief that neither the *Medical Gazette* nor any other respectable journal will insist upon anything better than this, that in all *things concerning the profession of the State the voices of the profession shall be heard first in a stated meeting, and a fair discussion, and the votes counted afterward.* Calling their opponents hard names, accusing them of low motives, packing a jury of delegates, instructed beforehand that they must not allow themselves to be instructed, is unworthy of the profession of a country whose first principle is that of free speech and unbiassed discussion. I feel that those delegates who have accepted their offices for the next meeting of the State Society with the understanding that they must vote as they are directed by their absent friends half a year in advance of the discussion of the question to be voted upon, have permitted themselves to be lowered into a very unenviable and undignified position, and I trust that unless the County Societies rescind their own "instructions," the delegates will refuse to submit to their moral and intellectual servitude, and resign their humiliating offices.

Very respectfully,

A. JACOBI, M.D.

NEW YORK, September 29, 1882.

[There will be few of our readers who will not agree with our correspondent in believing that it is a grave mistake for a County Society to force its delegates to vote one way or another on any question before it is fairly discussed and before the different pros and cons are presented. We can hardly believe that any of the County Societies seriously intend to do this, or that any of the delegates named will so far forego their personal rights as to submit to such dictation. Each delegate has a right to free thought, free speech, free opinion, and free voting. Unless this much is conceded, an impartial and just decision can never be reached on any question.—ED.]

THE LAYMEN AND THE PROFESSIONS.—The common lay mind hates the lawyer, as the lay body objects to the doctor, and the soul is timorous of the parson.—*Blackmore.*

New Instruments.

AN IMPROVED WHALEBONE INSTRUMENT FOR TREATING TIGHT STRICTURES OF THE URETHRA.

By E. A. BANKS, M.D.,

SURGEON TO THE CLASS OF MALE GENITO-URINARY DISEASES AT THE BELLEVUE HOSPITAL OUT-DOOR DEPARTMENT.

Tight organic strictures, complicated at times with complete retention of urine, or engorged bladder with dribbling of urine, are of common occurrence, and likely to be met with in the practice of every one. The urgency, and at times the absolute necessity for the early relief of this trouble renders the means of its relief a matter of interest and importance. At the present time the most approved methods are the introduction of a whalebone bougie as a guide, and the passage over it of a tunnelled sound, or the use of a small, flexible, gum bougie screwed on to a steel shaft. Of these the former seems the best.

The combination of the whalebone filiform with the tunnelled sound forms an excellent instrument for the dilatation of most close strictures, but not for all. Now and then an old, tight, fibrous stricture will be met, possibly with eccentric orifice, or tortuous course, that offers such positive resistance to the above means as to render some other desirable. This desideratum, we believe, will be supplied by the present instrument.

The two accompanying cuts are intended as a comparative representation of two sides of the instrument, the right hand one showing a flattening of its conical portion that connects the point with the body. This flattening is of material advantage in its construction, as it enables us to limit the conical portion within a small space, and at the same time to obtain a necessary flexibility for passing the curved urethra. We are thus enabled to retain a long, fine point for easy passage of the stricture and harmless entrance into the bladder, and a body of material size for dilatation of the stricture. The proportions of the instrument I have used are: the point about four inches long, the flattened, conical part about two, and the body seven inches in length; the size, No. 7 of the American scale.

The instrument was devised to meet the needs of a case of a patient with an old fibrous stricture, who had previously undergone urethrotomy, but his stricture being neglected, had recontracted, and was very close. An attempt was made to pass a tunnelled sound over a whalebone filiform, but was met with such resistance that after a judicious trial with manipulation and force, I concluded to cease the effort and seek some easier means of meeting the difficulty. With this instrument the difficulty was overcome with ease and satisfaction, and we believe it will be found very useful in the treatment of all tight strictures.

New Marine Hospitals.—A site has been purchased for a new U. S. Marine Hospital at New Orleans, costing $35,000. New marine hospitals are also to be erected at Cincinnati, O., and at Cairo, Ill.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from September 23, 1882, *to September* 30, 1882.

Smith, Andrew K., Major and Surgeon. Leave of absence on Surgeon's certificate of disability, granted in Special Orders No. 131, August 22, 1882. Department of Arizona, extended two months, on Surgeon's certificate of disability. S. O. 214, A. G. O., September 14, 1882.

Bushnell, G. E., First Lieutenant, Assistant Surgeon. Granted leave of absence for one month. S. O. 147, Department of Dakota, September 7, 1882.

Spencer, William G., Captain and Assistant Surgeon. Granted leave of absence for four months, on Surgeon's certificate of disability. S. O. 219, A. G. O., September 20, 1882.

Hopkins, W. E., Assistant Surgeon. Relieved from further duty at Camp Washington, Gaithersburg, Md., and will proceed to Fort Adams, R. I., and resume his duties at that post. S. O. 168, Department of the East, September 22, 1882.

Powell, J. L., Assistant Surgeon. To report at Headquarters, Department of Texas, to temporarily relieve Assistant Surgeon P. Middleton as Post Surgeon and Attending Surgeon at Department Headquarters. S. O. 103, Department of Texas, September 20, 1882.

Carter, W. F., Assistant Surgeon. Relieved from duty at Fort Concho, Tex., to report to commanding Officer, Fort Stockton, Tex., for temporary duty as Post Surgeon. S. O. 103, Department of Texas, September 20, 1882.

Middleton, P., Assistant Surgeon. Granted leave of absence for one month, on Surgeon's certificate of disability, with permission to go beyond limits of the Department. S. O. 103, Department of Texas, September 20, 1882.

The New Seney Hospital in Brooklyn.—The corner-stone of the new Seney Methodist Episcopal Hospital was laid with appropriate ceremonies last week at Seventh Street and Seventh Avenue, Brooklyn. The hospital is the gift of George I. Seney, who also gave the lots on which it is to be erected. It owes its origin to an editorial, the substance of which was that Methodists should be more charitable, and should build hospitals and asylums of their own. During the next month after the publication of the editorial, a letter was received from George I. Seney, donating sixteen lots, valued at $40,000, for the site of the hospital, and also making

a cash gift of $100,000. A few days afterward this sum was doubled. The hospital, Dr. Buckley said, would be open to all—Christian or infidel, rich or poor. An address was then delivered by Dr. L. S. Pilcher, of the Building Committee, who spoke of the evils of hospitals. The hospital is to be built with isolated wards, and every possible device to secure pure air. It will accommodate two hundred patients.

THE MEDICAL COURSE FOR WOMEN at St. Petersburg, in connection with the Military Hospital, has been stopped, by order of the government.

THE MEDICO-LEGAL SOCIETY held its first fall meeting at Mott Hall on Wednesday, September 27th. A paper, which will be published in a future number of THE RECORD, was read by Dr. Graeme M. Hammond on "Death by Hanging."

After the discussion of the paper, the Society spent the time until one A.M., in a most edifying wrangle over the minutes of the ex-Secretary and the action of the Treasurer, Dr. E. C. Harwood. That gentleman had refused to pay a bill of $250 for printing, basing his refusal on a set of minutes signed by the then Secretary. The bill, however, had been endorsed by the Trustees and Finance Committee; it was shown also, that the minutes of the secretary were incorrect. The Treasurer was, therefore, instructed to pay the bill. The conduct of the Society was not in harmony with the simplicity of its conclusions. For four hours the bust of the venerable Mott looked down upon a choppy sea of waving hands and vehement expostulations. The atmosphere is reported clear now, however, and the society under the active (if, at times, too active) management of its able President will settle down to scientific labors alone.

AN ANTI-VACCINATION SOCIETY has been formed at Hartford, Conn. About a dozen persons constitute the organizing membership.

ERRATUM.—On page 361 of THE MEDICAL RECORD for September 23, 1882, in the item on "Lead Colic," the dose of extract of belladonna is given as "five centigrammes," which is correct, "or, gr. viijss.," which is manifestly an error. Five centigrammes is a little less than one grain.

ON IMPERFECT NUTRITION OF INFANTS.—The name of the author of "Imperfect Nutrition of Infants" (MEDICAL RECORD, September 16, 1882) should be Dr. E. M. Hermance, instead of Dr. E. M. Hermann, as printed.

WARNING AGAINST TYPHUS.—The following circular has been issued by the State Board of Health of New York: "The typhus contagion which is being spread by railway laborers, threatens much harm. The local boards of health in the three hundred and twenty-six villages and the nine hundred and forty-seven towns and twenty-four cities of the State, should require their health officers to be watchful and ready to adopt all necessary sanitary precautions for isolating and controlling this disease at its first appearance. Tramps should not be permitted to enter dwellings and lodging-houses as they wander about. They should be cleansed and controlled by Superintendents of the Poor. Sanitary officers should order whatever is necessary. Every typhus patient should be so quarantined and provided for as to prevent the spread of infection. All lodging-houses and dwellings where fever is suspected should be thoroughly cleansed; and wherever a case of typhus occurs the disinfection of the clothing, bedding, and sick rooms should be as prompt and thorough as in cases of small-pox. The sick and whatever pertains to them, as well as the remains of the dead from contagious diseases, must not be removed from one place to another without written permission of all the health boards of the several places.

THE YELLOW FEVER EPIDEMIC.—The following is a summary of the progress of yellow fever at Brownsville for the week ending September 30, 1882, compiled from the official returns in the U. S. Marine Hospital office:

Date.	*Cases.*	*Deaths.*	*Date.*	*Cases.*	*Deaths.*
September 24.....	2	0	September 28.....	11	2
September 25.....	5	1	September 29.....	3	1
September 26.....	5	0	September 30.....	4	0
September 27.....	0	0			
Total.....				30	4
Previously reported.....				1,870	103
Total during epidemic.....				1,900	107

On October 1st, there were 3 new cases and 1 death; October 2d no new cases were reported. There are about 100 sick in all within the sanitary cordon, including Brownsville and Matamoras. Since the decline of the fever there have been great efforts to break the sanitary cordon on the part of some of the merchants. The cost of the Sanitary Hospital work in the past two months has been $28,000.

An official report from Pensacola, Fla., by mail, has been received by the Surgeon-General, to include September 29, as follows:

Date.	*Cases.*	*Deaths.*	*Date.*	*Cases.*	*Deaths.*
September 22.....	43	2	September 26.....	60	2
September 23.....	36	5	September 27.....	60	6
September 24.....	39	5	September 28.....	36	2
September 25.....	55	2	September 29.....	52	11
Total.....				381	35
Previously reported.....				344	41
Total during epidemic.....				725	76

On October 1st there were 45 cases, 4 deaths; October 2d, 45 cases; 5 deaths. The Board of Health at Pensacola employs 120 nurses in addition to several Sisters of Mercy. Business is entirely suspended.

THE TRI-STATE MEDICAL SOCIETY of Indiana, Illinois, and Kentucky, closed a very successful annual meeting at Terre Haute, Ind., on September 28th. The following officers were elected for the ensuing year: *President*—Dr. William Porter, of St. Louis; *Vice-Presidents*—Dr. Jos. Eastman, of Indianapolis, Dr. James Letcher, of Henderson, Ky., and Dr. Chambers, of Charleston, Ill.; *Secretary*—Dr. Burton, of Mitchell, Ind.; *Treasurer*—Dr. F. W. Beard, of Vincennes, Ind. The society adjourned to meet at Indianapolis on the third Tuesday in September, 1883.

THE DEATH OF DR. WILLIAM PIERSON took place at his residence in Orange, N. J., on October 1st. Dr. Pierson was one of the oldest and most esteemed physicians in New Jersey. He was born in 1796. He belonged to a family of physicians, comprising his grandfather, Matthias Pierson; his father, the Hon. Isaac Pierson, for some years a member of Congress; himself, and his son, William Pierson, Jr., all of Orange. He was for thirty years the Secretary of the New Jersey Medical Society, and afterward its President. During his long life he was prominent in public matters as well as in his profession, having been a member of the New Jersey Legislature between 1835 and 1840, and from 1849 to 1852 sheriff of Essex County.

Original Lectures.

ON THE TREATMENT OF DIPHTHERIA.[1]

By PROFESSOR DUGARDIN BEAUMETZ,

PARIS, FRANCE.

Part II.

We have in this group (*i.e.*, those that locally modify through selective elimination) to study three medicaments—chlorate of potassium, copaiba, and pilocarpine. Chlorate of potassium is a remedy which has been and is now very much employed in the treatment of diphtheria. Barthez, Isambert, and many others have considered chlorate of potassium a medicine without a rival in the treatment of membranous angina, and quite recently Seeligmuller has maintained that if the chlorate be rightly and methodically administered, it will with certainty cure every case of diphtheria.[2]

Without denying that chlorate of potassium does have a very favorable action on the mucous membranes of the pharynx and larynx, without denying the solvent action of this medicament and its power as a local alterative, it must nevertheless be borne in mind that this salt has no specific virtue in the treatment of diphtheria. At the same time, of all the local modifiers it is one of the best, and I cannot too highly recommend it for both local and internal use; being eliminated by the buccal and pharyngeal mucous membranes, its utility as a local alterative does not end with its ingestion.

Meanwhile I ought to call your attention to two points; first, the slight solubility of the salt. At the ordinary temperature of the air, one hundred parts of water dissolve but five parts of chlorate of potassium. You must, then, in prescribing it, keep within these proportions, if you would have a solution without precipitate. Moreover, when you give this medicine internally, remember its toxic action on the heart, and do not exceed a certain dose. Quite recently Brouardel has reported cases of death from the internal employment of chlorate of potassium.

Copaiba and cubebs have been introduced into the therapeutics of diphtheria by Dr. Trideau, of Andouille.[3]

In his estimation these medicaments have so specific a value in the treatment of diphtheria, that by their methodical employment one could be almost certain to obtain a cure in all his cases. The trials made in our hospitals for children, especially by Cadet de Gassicourt and by Archambault, have shown that unfortunately this is not the case, and that, if in certain instances an amelioration was obtained, in others this kind of treatment fatigued the stomachs of the patients, and put them in very bad condition for supporting the tonic medication so necessary in such cases.

Copaiba and cubebs are given internally in the form of syrup or in the form of "saccharolés," as Delpech prepares them, and their therapeutic action is explained by the elimination of these balsamic substances on the surface of the pulmonary and pharyngeal mucous membranes.

It is the same modifying action which is obtained by subcutaneous injections of pilocarpine, so much extolled by Guttman,[1] and with which, when the first trials were made, such astonishing results were obtained; those, for instance, which Lereboullet has reported (*Bullet. de Thérap.*, July, 1881).

Unhappily, here again the hopes which were awakened by this medicament have not been realized, and if we can rely on the results obtained by Archambault, this medication by pilocarpine is dangerous rather than useful.

In the same group of drugs we must place sulphur and the sulphites, and the preparations of eucalyptus. The first of these medicaments has been counselled by Jadin, Barbosa, Ullersper, Alban Lütz, and by Fergus, the second by Walker.[2]

I have finished this long enumeration of the local medicinal agents of diphtheria, and you see, gentlemen, that besides ice, buccal and pharyngeal injections of solutions of chlorate of potash or lime-water, and pulverizations of carbolic acid, all other means employed are inefficacious or dangerous.

This result should not astonish you, for diphtheria being a general disease, it is impossible that any

---

[1] Delivered in the Hôpital St. Antoine, and translated, by permission, from advance sheets, by Dr. E. P. Hurd, Newburyport, Mass.

[2] He uses the following solution:

℞. Pot. chlor. ..... ʒ ij.
Aquæ ..... ʒ vj.

M. Signa.—Give every hour from a teaspoonful to a tablespoonful, according to the age and constitution of the patient.

He believes that this saturated solution of chlorate of potash exercises a local and general effect on the march of diphtheria: local, as having a caustic action, and as causing disaggregation of the false membranes in the buccal and faucial cavity; general, in restoring the oxygen which the bacteria have taken from the blood, and in destroying the bacteria. He does not leave unnoticed the action of chlorate of potash on the heart, and the dangers which may result from its administration. Cadet de Gassicourt has experimented, in his hospital service, with chlorate of potassium, cubebs, and salicylate of sodium. He has given the chlorate of potassium in the dose of ʒ jss. daily, and has never reached the large doses advised by Seeligmuller. The chlorate of potassium has given the best results. Out of fifteen cases treated by this remedy alone, all got well. Out of seven treated by cubebs, or copaiba, six got well and one died. Out of five treated by salicylate of soda, two died (Seeligmuller: On the Treatment of Diphtheria by Solutions of Chlorate Potass., Bull. de Ther., T. xcii., p. 392, 1877; Cadet de Gassicourt: Bull. de Therap., T. xcii., p. 481, etc.).

[3] Du Traitement de la Diphtherie par le Cubèbe et le Copahu (Gaz. Hebd., p. 186, 28 Mars, 1877), and other citations. This is his manner of administering these remedies. He gives once, twice, or three times in the twenty-four hours the following potion, the patient being an adult:

℞. Pulv. cubebs ..... ʒ ss.
Syrup ..... ʒ iij. and ʒ ijss.
Malaga wine,
Water ..... āā ʒ v.

M. Fiat Mist.

When the cubebs does not suffice, he advises the following "dragée," or pill:

℞. Copaiba, solidified (Mialhe) ..... gr. vj.
Pulverized cubebs ..... gr. ijss.

M. For one dragée, or pill. Signa.—Give twenty to thirty of these a day to an adult. To children give as many dragées per day as they are years old.

[1] The following is Guttman's formula for children:

℞. Chlorhydrate of pilocarpine ..... gr. ½.
Pepsine ..... gr. x. to xij.
Acid hydrochloric ..... gtt. ij.
Distilled water ..... ʒ j. and ʒ v.

M. Signa.—A teaspoonful every hour.

In the case of adults the quantity of pilocarpine in the above mixture is increased to half a grain, and the quantity of pepsine to one-half drachm. Dose as above. Out of eighty-one cases of diphtheria, Guttman reported eighty-one cures.

Demme believes that pilocarpine does not act favorably, except in cases of catarrhal laryngitis, or catarrhal angina, being without efficacy in diphtheria. He advises to inject under the skin the following doses: For a child less than a year old, one milligramme (one-sixtieth grain). For children from one to ten years, five milligrammes. When the doses of pilocarpine are too long continued, according to Demme, they enfeeble the heart muscle.

The method of Guttman has given good results in the hands of Lax, Williams, Lereboullet, Lepidi, Chioti, and Dehio. But others have failed to obtain such favorable results. Archambault, at the Hôpital des Enfants, derived no advantage from it. Schmidt pronounces this method of treatment injurious rather than beneficial. Neumeister, Alfodi, and others are of the same opinion, and it is fair to conclude that no certain curative action can be attributed to it.

[2] Jadin employs sulphur internally and externally—externally under the form of pulverizations, and internally as the *mel-sulphuris*. Barbosa prescribes insufflations of the flowers of sulphur every three hours. Fergus uses strong gargles of sulphurous acid, and inhalations of the vapor of burning sulphur. Walker advises large doses hourly of tincture of eucalyptus globulus in syrup.

local treatment, however powerful, can cure it and prevent its manifestations. Our local treatment, then, is influential only in combating the self-infection provoked by the false membranes, and in diminishing the inflammation of the pharynx, thus allowing the patient to be fed throughout the whole course of the disease. This humble but useful part is all that any local treatment can fill.

Let us now examine the general treatment proposed against diphtheria.

Ignorant of the very nature of the malady, we possess no general specific medication for this affection, and the constitutional treatments in vogue are based partly on hypothetical notions, partly on the necessity of supporting the patient in the struggle going on between his organism and the disease from which he is suffering.

Among the hypotheses which have been made respecting the nature of diphtheria, one of the most satisfying is certainly that of the parasitic origin of this affection, and we shall find here justification for most of the antiparasitic remedies which we have already seen employed locally against diphtheria. I shall call your attention only to the preparations of sulphur, and the acids, carbolic and salicylic.

Sulphide of potassium has been advised by Maunoir, Senf, Chaussier, Klaproth, Bienfait (of Reims), and, more recently still, by Fontaine. As for the sulphites and hyposulphites, they have been for the most part employed in Italy, where Polli has demonstrated their antiseptic properties. Giacchi, who has, above all others, generalized this method, makes use of sodium sulphide in lotions, gargles, and lavements, and of magnesium sulphide for internal administration.[1]

As for carbolic and salicylic acids, it is to Bernier, of Bournonville,[2] that we owe the greatest number of favorable observations respecting the internal use of the former. The second has been the subject of experimentation in Germany by Wagner and Karl Fontheim.[3] But here, also, when we submit these therapeutic methods to the rigorous observation of our hospitals, we still see—as has been the case with other treatments—that their curative effects are far from being demonstrated, and that antiseptic preparations given internally have no certain therapeutic efficacy.

I do not speak of the dangerous modes of treatment, such as blood-letting, mercurial alteratives, and alkalies in large doses. These therapeutic measures are deplorable, for they are not only impotent to prevent the development of the disease, but they weaken the patient, and place him in unfavorable conditions for recovery. Let, then, all antiphlogistic medication (including, of course, antimonials and alkalies) be put aside as certain to be harmful rather than beneficial.

We have then remaining only the supporting treatment, which, though of itself not affecting directly the *materies morbi*, yet enables the patient to struggle against the general affection from which he is suffering. This tonic medication is of such capital importance that it ought to take the precedence of all other modes of treatment, and every therapeutic measure, however energetic and promising, which disturbs the digestive functions, already impaired in such cases, ought to receive unsparing condemnation.

Give your patients milk, concentrated broths, generous wines, alcoholic potions; in a word, the supporting treatment in all its forms. But, unfortunately, you are likely to meet two obstacles; on the one hand, the anorexia which so often accompanies diphtheria, on the other, the difficulty of swallowing which your patients experience; and you ought, especially when treating children, to exercise all your patience, all your energy, all your will, to make them take the wine, the milk, and the broth which you prescribe.

I have thought of employing the hypodermic method in those cases where the patients cannot or will not take food and stimulants, and I have practised on my patients, adults and children, hypodermics of ether, and especially of the double benzoate of caffeine and soda; the latter has appeared to me to have some curative efficacy.[1]

I say *has appeared*, for it is very difficult to judge of the results of such treatment, since we reserve it exclusively for the most severe cases. Under the influence of these injections we have seen the pulse improve in strength and the animal heat reappear; moreover, no injurious local effect is perceived; it is, then, a method which deserves new trials, that its value may be definitely known.

Diphtheria is one of the most contagious diseases. William Ogle has lately shown us the mechanism of this contagion;[2] therefore you will understand the

---

[1] The physicians of Geneva have employed sulphide of potassium. A common practice is to give from seven to fifteen grains in divided doses during the twenty-four hours. Here is a common formula in Geneva:

℞. Pot. sulphid..... gr. xiv.
Syrup..... ʒ ij. and ʒ v.
M. Signa.—A teaspoonful every two hours.

Fontaine substitutes calcium sulphide, five grains to a child two years old, ten grains to adults. Giacchi gives sulphite of magnesium, internally in the dose of ʒ iss. daily. He also uses lavements of sulphite of soda, about ʒ iss., rubbed up in an equal quantity of syrup of poppies, and in a pint of water. Schotlen, of Dresden, has employed in diphtheria the neutral sulphite of magnesium (proposed by Polli in infectious diseases). He dissolves seventy-five grains in four ounces of water; dose, a teaspoonful every two hours. Remarkable results have been claimed—the most malignant cases cured in three or four days, etc. It has been recommended to touch the false membranes with a solution of sulphite of soda in glycerine.

[2] Bernier: Methode phenique dans le traitement du Croup et de l'Angine couenneuse (Soc. de Therap., 1880). Externally by gargles and spray; internally in subcutaneous injections and potions.

[3] Karl Fontheim: Journal für praktische Chemie, 1875 T. ii., p. 57. He employs the salicylic acid in the following manner:

℞. Salicylic acid..... ʒ ss.
Alcohol..... q. s.
Aquæ..... ʒ vj.
M. Signa.—Take twice a day a tablespoonful of this solution. Paint the fauces with a strong solution of salicylic acid.

Laube, of Leipzig, and Edel employ in the treatment of diphtheria inhalations of turpentine and injections into the mucous membrane of carbolic acid. These injections are made twice or three times a day into the tonsils with a Pravez syringe, about half a syringeful at a time. Every hour one or two large spoonfuls of port wine are given, and bladders of ice are applied to the neck.

The following is the treatment of Lolli (an Italian physician), who claims great success in the management of this disease:

1. Never cauterize or deplete, whether by blood-letting, purgatives, or emetics.
2. The nourishment throughout the disease must be substantial.
3. Favor the cutaneous functions.
4. Paint the throat with the following mixture:

℞. Lime-water..... ʒ viij.
Liquor ferri sesquichloridi..... ʒ j.
Acid. carbolic..... ʒ ss.
Honey of roses..... ʒ iv.

M. Fiat Mist.—For painting the diphtheritic patches.

[1] Prepared by Tauret by roasting together caffeine with the acids benzoic, salicylic, and cinnamic. He has thus obtained double salts of the benzoate of caffeine and soda. These salts contain 61 per cent. of caffeine. Dugardin Beaumetz has administered subcutaneously solutions of benzoate of soda and caffeine containing fifty centigrammes of the salt per cubic centimetre. These solutions have never produced any local irritation (Tauret: Sur la Cafeine, Soc. de Ther., Séance du 28 Décembre, 1881, p. 253; Dugardin Beaumetz: Comptes Rendus de la Société de Therapeutique, 1881, p. 257).

[2] William Ogle: Observations on Outbreaks of Diphtheria in Rural Districts (St. George's Hospital Reports, vol. ix., p. 701, 1877-1878). The Dissemination of Diphtheria at Funerals (Boston Medical and Surgical Journal, October, 1876). The following are the results of Ogle's study *à propos* of the contagion of diphtheria: 1. The most attenuated forms of diphtheria and those which have the most benign ap-

importance of prophylactic treatment, and the best of all means of prevention is isolation of the patients.

In the hospitals for children, we have already succeeded these late years in effecting this isolation of diphtheritic patients; unfortunately this is not the case with all our hospital services, and you see often in the infant wards [of the Hôpital St. Antoine] diphtheria declare itself among the little inmates in consequence of the presence in those wards of some diphtheritic or croupy child.

This isolation, then, is an imperative duty which you cannot too strongly urge, and when in a family you have diagnosticated a case of diphtheria, your first obligation is to send away the other children and allow only those to remain about the premises whose services are absolutely necessary in taking care of the patient. No matter how mild the case may seem to be, you must not abate the rigor of this isolation, for the mildest cases may communicate the disease in its most malignant form.

Do not forget, moreover, that physicians and nurses are not exempt from attacks of this disease; and each year we see inscribed on the tablets of marble (veritable golden book of medicine) the names, increasingly numerous, of attachés of the hospitals, who, victims of their professional devotion, have died, smitten by the terrible scourge.[1]

It is necessary, then, that those who have the care of the sick person should be provided with everything which can ward off or prevent the spread of the disease. Therefore, antiseptic liquids are indispensable. Disinfectant lotions of carbolic acid, of phenol, of thymol, of antiseptic vinegars, for all objects which have been in contact with the patient; destruction of all false membranes contained in the expectoration; frequent airing of the room; a phenated atmosphere—all these means ought to be put in use. Do not forget also to have careful surveillance, during epidemics, of schools, chapels, and other places where children congregate, and which are unhappily so often foyers of diphtheritic contagion.

In finishing, allow me, in a few words, to sum up the treatment of diphtheria. You must first be right in your diagnosis, and this is not always easy. I need not here recall to your minds the symptoms of diphtheria, but where you will be very likely to go astray is in distinguishing the simple anginas which are attended with a pultaceous deposit from diphtheritic angina. You know, in fact, that amygdalitis is sometimes the cause of development of creamy points on the tonsils, and the diagnosis is often extremely difficult. You must wait before pronouncing definitely concerning the nature of the disease till the march of the affection has enlightened you.

When you have a case of diphtheria to deal with, you should commence by isolating the patient, then you should clear the throat of false membranes, whether by ice given internally, whether by irrigations of lime-water or lactic acid; you should touch the back of the throat with solutions of chlorate of potash or perchloride of iron, very dilute; in fine, always from the point of view of local treatment, you should make your patient live in an antiseptic atmosphere, by pulverizations (with the steam atomizer and spray-producer) of carbolic acid or solutions charged with thymic acid. You should give internally potions containing quinine or alcohol. You should administer broths, wine, and especially milk. In fine, all the elements of the tonic treatment should be employed. Such is the treatment of diphtheria, and in particular that form of it known as membranous angina. This treatment will sometimes give you considerable success, but never forget that from the standpoint of therapeutic results the morbid genesis of diphtheria exercises a predominant part, and that according to localities and circumstances you will sometimes have remarkable success, and sometimes all your efforts will fail, despite the zeal, the devotion, and the activity which you put in practice.

I do not wish to terminate this long lecture without indicating some of the complications of diphtheria. First, the extension of diphtheria to the skin, when the latter is denuded. This is a point of some interest, in that it contra-indicates in diphtheria the revulsive treatment. There was once a time when vesicatories were used to combat certain of the manifestations of diphtheria, and especially those that affect the pulmonary apparatus. To-day this disastrous medication is completely abandoned, since this denudation of the skin enables the diphtheria to extend its ravages.

This fact should make you examine with care the state of the skin in your patients. Quite recently, one of my externes, M. Gaston, contracted diphtheria at the hospital. One of the first symptoms was the appearance of a false membrane upon a wound acquired at an autopsy, then the diphtheria invaded the larynx, but mildly, and to-day our student is completely cured.

The second complication to which I wish to call your attention is diphtheritic paralysis. You have just seen a good example in our wards. It concerned the cook of the Hôpital Trousseau, who had diphtheria in a grave form, from which he recovered. This man had been gone a month to the Asylum for Convalescent Patients, when he returned with a paralysis which soon became general, affecting even the diaphragm and intercostals. You remember our consternation in presence of this man who was suffering asphyxia under our very eyes. I caused artificial respiration to be practised by the procedure which consists in extending the arms above the head; then I used electricity, and not obtaining the results which I expected, I injected subcutaneously one-thirtieth of a grain of strychnine. This injection seemed, to our observation, and in

---

pearances may, by their contagion, be the point of departure of the most severe cases in other subjects. 2. The public schools are the most powerful instrumentalities in the dissemination of diphtheria, proving the "foyer of contagion" in the seven epidemics which he studied. 3. The *materies morbi* seems to cling for indefinite periods to habitations; in school-houses that had been closed for months in consequence of an epidemic of diphtheria which prevailed among the scholars, he has known the disease to break out again as soon as the building was reopened and the children returned to their places. Churches and places of worship become similarly focuses of contagion, and remain so for indefinite periods. 4. The contagious principle adheres for a long time to the clothing and persons of those who have once been infected and who have recovered. Children who have had the disease have been isolated for six weeks, and even ten weeks, and have given the disease to their companions when they have gone back to school. 5. The ordinary period of incubation is from one to six days (eleven days in a single case). 6. One attack does not give any immunity from successive attacks. 7. Below twenty years of age the chances of contagion are fifty per cent.; above twenty, fourteen per cent. take the disease. Little girls are more susceptible to the contagion than boys (forty-eight per cent. for girls, twenty-eight per cent. for boys). Between the ages of three and twelve the susceptibility to the disease is the greatest. The corpses of individuals who have died of diphtheria have been known to communicate the disease: from the report of the Medical Society of Suffolk County (Boston Medical and Surgical Journal, October, 1876) it would appear that funerals may be sources of contagion.

[1] The Administrator of Public Charities has caused to be placed in the hospitals of Paris tablets of marble, on which are inscribed the names of internes and externes attached to these hospitals who have succumbed to a contagious disease, cont acted in the exercise of their functions.

the opinion of the patient, to have an excellent effect, and from this moment he began to have power to breathe, and to-day the cure is complete.

You can put this practice into usage in similar cases, and you can employ electricity, stimulating frictions, the preparations of strychnia; in fine, all the means at your disposal to augment muscular contractility.

So far, gentlemen, I have supposed that diphtheria has only affected the isthmus of the fauces, and I have considered only membranous angina. Unhappily, false membranes invade other points, and in particular the larynx and respiratory passages, determining accidents which require new therapeutic procedures. These I shall consider in the next lecture, in which I shall treat of croup.

Original Communications.

ACUTE MILK-POISONING.[1]

By E. F. BRUSH, M.D.,

ATTENDING PHYSICIAN TO THE NEW YORK INFANT ASYLUM.

"MANY of the diseases affecting the digestive organs in infancy are nothing more nor less than milk-poisoning. This is absolutely the cause of *cholera infantum*. I think we should be justified in dropping entirely from our nomenclature the term *cholera infantum*, and calling the disease which has hitherto borne this misleading name by its real term, "acute milk-poisoning." We would thus simplify the treatment by keeping before the practitioner the true cause of the disease, and no other suggestion would be necessary to indicate that the poison ought to be stopped. This is not done now, nor do the text-books point out the absolute necessity of this being done. There is no doubt, too, it will not be done as long as we account for the disease by teething, excessive heat, brain troubles, and so forth. When I tell you, gentlemen, that I have looked to the health and feeding of more than two hundred children this summer, and have not lost one by any acute intestinal disturbance, you may concede to me the right to speak; and when I have given you the facts winnowed from a year's observations of diseases caused by milk, I cannot but feel you will agree with my conclusions.

Even if we had not facts it seems to me that we could theorize to the same conclusions. Our cows are secreting milk abnormally, and I use the word "secreting" in the sense we understand it physiologically. We keep up the activity of the mammary gland from parturition to parturition, this is, through heat and pregnancy. This process being carried on through generations in the bovine race has resulted in the mammary becoming an excretory gland. When a milking cow eats food which would cause diarrhœa in other animals, she simply gives more milk, and the bowels are seldom much disturbed; but the poison is conveyed to the infant. As on this fact much of my argument is based, and to show that it is no new fact of which I am the solitary observer, I quote the following statement from J. P. Norton, M.A., Professor of Scientific Agriculture at Yale College: "All the effects of poisoning may be produced by the milk without the cows being apparently affected by the pasture." Now the conditions that render milk poisonous are:

1st. *Feeding.*—The sudden change from the dry food of winter to the full flush of grass, picking up green fruit, eating brewers' grains which make the milk more albuminous and therefore more prone to putrefaction with the increase of summer temperatures, eating poisonous weeds, and drinking poisonous stagnant waters.

2d. *Treatment.*—Dairy farmers endeavor to have their cows calve in spring time when the grass is plentiful, because then the feeding is cheapest and the amount of milk to be got is greater. Now if a cow calves in May, she is usually in heat again in forty days, this brings the period to the last of June or the beginning of July. If she were allowed to become pregnant then, her calving time would occur too early next year to get the flush of milk at grass time. Consequently she is allowed to worry and quite often excite the entire herd. This condition affects milk so perniciously that cheesemakers exclude it from the factory; the odor sometimes is perceptibly putrid, and almost always easy to detect when the milk is heated in a water-bath. Again, the milk is affected when the cow takes the bull. I have found by observation of my own cows that the milk following the act is always decidedly acid. In the subsequent pregnancy there can be no doubt that the nutritive quality of the milk is lowered. Last, but not least in the treatment of milch cows as a cause of poisonous milk, is the cruel abuse to which they are subjected.

3d. *Diseases which space will not at this time permit me to enumerate.*—I will, however, here record my observations on a very common disease in milch cows—common because it occurs frequently and requires little or no treatment, and the milk thus affected finds its way to the market, to convey poison to the children. Last winter I made an experiment on one of my own cows. I bruised one quarter of the udder, thus producing traumatic garget. This often occurs in pastures by the cow striking the udder against stumps and the like. I found the milk from the gland in the affected quarter for a number of days stringy, lumpy, and pus-like, but always alkaline. The milk from the three unaffected quarters presented no abnormal appearance; but, while the traumatic condition existed, was always decidedly acid. When this condition had lasted four days, I gave to one of my own children, aged sixteen months, about four ounces of this acid normal-appearing milk. This was at five o'clock in the evening. The child fell asleep, but was awakened in two hours, crying, apparently with stomach-ache. She was kept awake till past midnight, and a large quantity of acid was voided *per rectum*. The next day the bowels were slightly disturbed. It is easy to imagine if four ounces had this effect, what would be the condition if the child had been fed continuously on such milk.

Returning to the results of treatment, I will cite the following case: One Saturday afternoon, while watching some boys playing ball on the common, I noticed a herd of ten cows feeding in an adjoining lot, attended by the owner, a milkman. Suddenly a cow came running to the herd and mounted the first cow she reached. The owner of the herd picked up some stones and pelted the offending cow, but was unable to drive her away. She continued to mount the cows as they came near her, till finally the entire herd became excited. Then a woman, the owner of the bulling cow, came and attempted

[1] Read before the Westchester County Medical Society, September 12, 1882.

to drive her home, but could not do so. Then her boy, a lad of ten, armed with a big stick, came and pounded the cow considerably, but without separating her from the herd. Finally, the old man made his appearance, carrying in his hand a heavy whip. He walked up to the cow, gently holding out his hand as if to feed her, and when close to her laid on the whip quite severely, with the effect of calming her immediately. She trotted for home, he running behind her, giving her a blow every time he came close enough. When she was in the yard, a small enclosure, he beat her for several minutes, and after she was in the stable I could hear an occasional blow. This all occurred just before milking-time. I was deterred from making an attempt to prevent this cruelty, because of the opportunity thus presented to observe the effect of milk, from a cow thus treated, in the feeding of children. This occurred in my own immediate neighborhood, and I knew that if any children were taken sick I would hear of it. As soon after the occurrence as possible I called on my friend Dr. Campbell, and related the affair to him, asking him to find out who received milk from the cow, as the owners were patients of his. On Sunday evening he was called to see a child, eight months old, who had been attacked on Saturday night with sharp pains. It had been kept awake all night; it had suffered mild attacks of diarrhœa during the summer, but had never before been disturbed during the night, the attacks always passing away with treatment. This attack, besides keeping the child awake, was accompanied by constant vomiting, which had not characterized any of the previous attacks, and there had been eighteen movements of the bowels in twelve hours, mostly green and undigested milk, an occasional discharge of dirty, mud-colored, watery, and offensive material. The child was very sick, and developed profound symptoms of *cholera infantum*. The doctor inquired on what the baby had been fed, and the answer was, "The bottle, with the milk of one cow." On further inquiry, he learned the milk had been procured from the above-related cruelly abused cow. The child recovered because the poison was stopped, although he was sick for several days.

This accidental observation is not an unusual occurrence; it, or something like it, is happening every day, though we may not be able to follow it up so closely. Take, for instance, the small dairy, with its four or five cows, not sufficient to pay the expense of keeping a bull. The rutting period occurs in the hottest weather; one of the farm hands is directed to drive the cow to the bull, perhaps a distance of two or three miles. Usually he is armed with a big stick, and the cow, especially in this condition, is loth to leave the herd without some emphatic persuasion. She is prodded, attacked, run round the corners, and the ordinary farm-laborer, when he has run fifteen minutes, is apt to get mad. There is no doubt that cases of this kind, if we follow them up, would reveal a like result of acute milk-poisoning.

The following cases of acute milk-poisoning, arising from causes not discovered, are interesting as illustrating this condition.

On a Sunday afternoon a friend of mine called me hurriedly to see his child, a baby ten months old, and bottle-fed. As he thought it was dying, I obeyed, and was soon at the house. On my arrival I found the child in a profound tonic convulsion. I learned from the parents that I was called in the absence of their regular physician, who had seen the child three hours previous. The sickness had commenced the day before. When this physician had seen the child that day, he inquired on what it was fed, and was told "milk and one of the patent foods." He approved of the diet, and left some medicine. The parents had no idea the child was very sick, so they fed it, and it went to sleep. They went down to dinner, but returning afterward to the room where the baby was, they found it struggling in a convulsion—the convulsion it was in when I came. I immediately wrapped the child in a cold, wet blanket, and endeavored to get a little brandy into its mouth, abstaining from any other treatment, as I knew the attending physician would be in immediately. He came a few minutes after my arrival, when I surrendered the case to him. The father wished me to stay, and I did so, simply watching the case. When the child was recovering from the convulsion it vomited several large masses of solid caseine, and its bowels were moved several times. When the convulsion had completely subsided I took my departure, but was again called between six and seven in the evening. When I reached the house the child was dead.

On the next day (Monday) I was called to see a child, nine months old, bottle fed, who received his milk from the same farm, and had been suffering from a severe diarrhœa since the preceding Friday. I found the child very sick, vomiting and purging. The alvine discharges were mostly green and watery, occasionally mud-colored. I directed that he should receive no milk under any circumstances whatever, but be fed on beef solution and oatmeal-water, and receive every hour a teaspoonful of the following:

℞ Tr. opii..... ℥j.
Tr. ferri..... ℥viij.
Aqua..... ʒj.

The next day I found there had been no abatement in the number of movements of the bowels, but there had been no vomiting. I changed his food to kumyss and he required no farther treatment till two weeks later, when I put him on other food simply for economy. He has continued to do well ever since. Is there any reason why we should not call these cases "milk-poisoning"? One with treatment and a continued use of the milk died; the other, with no treatment to speak of but stopping the milk, made a good recovery. I cite these cases not because they were the only ones observed, but because occurring simultaneously, and getting their poison from the same source, they illustrate the necessity of calling the disease from which they both suffered "acute milk-poisoning."

These are some of the conditions that are regularly every year swelling the rate of infantile mortality. Usually the beginning of summer complaints in fed babies is at the time when imperfect, worm-eaten green apples are falling; it is continued through the rutting, bulling, and conceiving period, to reach its fiercest condition when the pastures are dried by the usual autumn droughts, when the cows eat the poisonous herbs that they had avoided when the grass was green and plentiful.

Some years ago in the Alleghany districts, owing to some poisonous herbage, the cows secreted a milk which was poisonous. As this region was remote from a city market, the natives were compelled to consume their own milk, and were not long in finding that a disease from which they all suffered was caused by the milk, its use was quickly stopped and every visitor to the district was advised to abstain

from it. They had no statistical tables to consult, and did not therefore find that the sickness increased as the thermometer rose; they had no way of accounting for the disease except from its simple cause, milk, and therefore they called it simply "milk sickness," and invoked the power of the government to suppress it.

We physicians of Westchester County, surrounded as we are by the thousands of cows that supply the city with baby-food, are in a position to teach the city teacher the truth regarding the cause of the most fatal malady from which the city child suffers during the tedious heats of summer. I have once before appealed to you to bestir yourselves in the question of procuring legislation to regulate the milk supply.

Although no advance has been made, I do not lose hope, but appeal to you still.

Let us make ourselves familiar with the sources which supply the milk to the babies under our care. The dairy farmers are sadly in need of intelligent instruction, none of the works designed for their use teach them the dangers of poisonous milk. Even our boards of health are not treating the subject intelligently. There is much to do. All the conditions producing poisonous milk are not yet discovered, but we can teach what we *do* know, and while thus teaching may discover new facts.

MOUNT VERNON, N. Y.

ON THE PROPER METHOD OF EXECUTING THE SENTENCE OF DEATH BY HANGING.[1]

BY GRÆME M. HAMMOND, M.D.,

INSTRUCTOR IN DISEASES OF THE MIND AND NERVOUS SYSTEM IN THE NEW YORK POST-GRADUATE MEDICAL COLLEGE, PHYSICIAN TO THE DEPARTMENT FOR NERVOUS DISEASES IN THE METROPOLITAN THROAT HOSPITAL, ETC.

ON every occasion that the executioner performs his duty upon criminals sentenced to be hanged by the neck until they are dead, the newspapers teem with sensational accounts, headed by the most agonizing phrases in large letters, of the terrible sufferings the executed individual is supposed to have undergone. The hangman, if he does not succeed in breaking or dislocating the neck of his victim is held up to public execration as a bungler, and he is accused of having slowly strangled him, at the same time inflicting much unnecessary suffering. These descriptions harrow the minds of the tender-hearted, and not only produce a great deal of undeserved sympathy for the condemned, but tend to disgust many strong-minded and sensible people with the death punishment. As one of the consequences, much ingenuity is expended in devising means for insuring the dislocation of the neck, the idea being entertained that if this is accomplished the executed person does not writhe or suffer, but dies without muscular contractions and without pain. The object of this paper is to inquire into the facts connected with the questions to which I have referred, and to suggest the proper manner of executing the death penalty upon criminals sentenced to be "hanged by the neck until they are dead."

As intimated in the foregoing remarks, there are two distinct ways of causing death, by the execution of individuals, according to our present methods.

In the first, which is by far the oldest, and which was the mode contemplated when the punishment of hanging by the neck was first adopted, the subject is strangled. The air is cut off from entering his lungs. The vessels of the neck, which carry the blood to the brain and return it to the heart after it has fulfilled its office, are violently and suddenly compressed so that the circulation is interrupted. In early times the malefactor who was obliged to undergo this punishment stood on the ground, and with the noose around his neck and the rope thrown over the limb of a tree, was lifted up in the air and left hanging till life was extinct.

At a later period he stood on the rung of a ladder placed immediately under the gallows, and at the critical moment was pushed off by the executioner. Or he remained erect on the cart in which he was driven from the prison to the gallows, and at a given signal the vehicle was driven away and he was left hanging by the neck to the beam above him. In the American army this has been the method generally adopted when hanging has been the punishment. Major André suffered death according to this manner, and during the Mexican war many deserters were executed in a similar way. Lynchers, who take the law into their own hands, employ the cart, or, perhaps more frequently, throw the rope, one end of which is fastened around the supposed criminal's neck, over the limb of a tree and then pull him from the ground.

In Turkey and other eastern countries strangulation is effected by means of the bowstring. A loop is made in the string attached to a strong bow. The victim's neck is placed within it, and then the springing of the bow acting upon the cord constricts the neck and death soon follows. Among the ancient Jews a loop of a strong cord was placed around the neck of the condemned, and then several persons pulled at each end till life was extinct.

In endeavoring to break the neck of the person to be executed, two methods are employed. In the one he is lifted suddenly and with force from the ground while the rope is around his neck. In the other he falls through a trap suddenly sprung, and is left dangling in the air. By either of these methods strangulation is effected with more or less completeness, and sometimes the second cervical vertebra is dislocated and the odontoid process pressing upon the spinal cord is supposed to cause instant death. The trap is said by Calkins[1] to have been the invention of a London surgeon at the period of the Restoration.

The Rev. S. Houghton, M.D.,[2] for the purpose of securing dislocation of the neck, studied the subject with great thoroughness, and proposed a formula for regulating the counter-weight and the distance of the fall. Among the first trials of it, however, was the case of a man whose head was actually jerked from his body. Death usually ensues by strangulation, but the process is a bungling and tedious one. By the New York method of jerking the body into the air by releasing a heavy weight, it is rarely the case that the neck is broken, and strangulation is not neatly and expeditiously effected. I am clearly of the opinion that in order to obtain a speedy and painless death it is neither necessary nor desirable that the neck should be dislocated. On the contrary, this should never be attempted, for its accomplishment does not in the least facilitate the desired result, but the efforts in this direction always

[1] Read before the New York Medico-Legal Society, September 27, 1882.

[1] Judicial Executions of Capital Crimes, Quarterly Journal of Psychological Medicine, vol. iii., 1869, p. 297.

[2] Philosophical Journal, 1866.

lead to imperfections in securing rapid and certain strangulation, which is, I think, not only the speediest and most certain method of inflicting capital punishment, but is at the same time also totally painless.[1]

For the support of these views I have to advance the opinions and investigations of others, as well as more recent investigations of my own.

Lord Bacon[2] says that he remembers to have heard of a gentleman who, being curious to know what the sensations of hanging were, hung himself by mounting on a stool and then dropping himself off, thinking, of course, that he would be able to regain the stool as soon as he liked; but this he was unable to do, and he was only released by a friend who was present. On being asked what he had suffered, he said that he felt no pain, but at first he saw round about him the appearance of fire burning; that was succeeded by an intense blackness or darkness, and then by a kind of pale blue or sea-green color, such as is often seen by fainting persons.

Montagnac, who was saved by Marshal Turenne from death by hanging after the rope had broken, said that in an instant all sensation ceased and that a vivid light, beautiful beyond expression, seemed to fill all space.

Fleischmann[3] performed upon himself several experiments for the purpose of ascertaining the sensations produced by hanging. He found that a sense of great weight was experienced, together with a feeling of abolition of all sensibility and a hissing noise in the ears. The first experiment which he instituted lasted two minutes.

Taylor[4] says: "Death from hanging appears to take place very rapidly and without causing any suffering to the person. It is observed that in those who are criminally executed there are often violent convulsions of the limbs and trunk. There is no reason, however, to believe that the individual suffers pain any more than in the convulsions of an epileptic fit."

On recovery, there is an entire loss of consciousness in both cases.

Tardieu,[5] on information supplied to him by Jacquemain, physician-in-chief to the prison Mazas, where many successful and unsuccessful attempts to commit suicide by hanging were made, makes the following remarks relative to the sensations attendant on the act:

"At the moment that the body, hanging by the cord, or by other material, is left to its own weight, a great degree of heat is felt in the head, loud noises of a musical character are heard, the limbs seem to have acquired an extraordinary weight, and then all sensation is abolished. Sometimes, also, from the first moment the individual experiences no feeling of any kind, as many of those who have been resuscitated have declared in the most positive manner. I think this is more frequently the case than is ordinarily believed. In such cases there is immediate syncope. I have never had the least evidence to show that the opinion generally entertained is correct, that during the first moments of hanging there are voluptuous sensations. . . . .

"Then the second stage begins. It is marked by convulsions, by spasmodic contractions of the muscles of the face, by contractions of the pupils, and by contortions of the eyeballs, which give to the countenance a horrible expression. It is to hide this that in those countries in which hanging is still in use as a punishment, care is taken to draw a cap over the face. The convulsive movements become general, and all the limbs, especially the lower extremities, are thrown into violent convulsions."

Tardieu expresses the opinion that death certainly takes place within ten minutes. Taylor thinks that after five minutes resuscitation is possible. Obviously, the duration of life depends upon the care taken in adjusting the noose so as not only to compress the vessels, but to abruptly close the trachea so as to prevent the access of air to the lungs. Those alleged cases of recovery after the body has remained suspended for half an hour or longer, are regarded by the best authorities as resting on insufficient evidence.

In hanging, death takes place either by asphyxia or apoplexy, or both. As Taylor remarks, if the cord is loose or applied too high up on the neck, a small quantity of air may still reach the lungs, and life will be prolonged till the slower death by apoplexy takes place. The main object of the executioner should be to adjust the noose in such a manner as to close the windpipe at once, so as to produce immediate asphyxia. Usually, both apoplexy and asphyxia result if the execution is properly accomplished.

According to Remer, of 83 cases of death by hanging, 9 were by apoplexy, 6 by asphyxia, and in 68 both conditions existed. Of 85 cases collected by Casper, in 9 there was apoplexy, in 14 asphyxia, and in 62 both conditions.

My own experience was somewhat similar to that obtained by other observers, except in the fact that strangulation was not carried to that point at which respiration ceases entirely. My object was more particularly to demonstrate the painlessness of the operation than to show the existence of any new sensations. With the assistance of two medical friends, I was partially strangled in the following manner: After being placed in a sitting position in a chair, a towel was passed around my neck and the ends twisted together. Of course with every twist of the towel very forcible compression was made on the entire circumference of the neck. One of my friends was entrusted with the operation of twisting the towel, while the other was stationed in front of me, in order that he might watch my face, and at the same time make the necessary tests of the cessation of sensibility.

My sensations from the first twist of the towel may be briefly stated as follows: I first noticed a sensation of warmth and tingling, beginning in the feet and quickly passing over the entire body; vision partially disappeared, but there was no appearance of any colored lights. My head felt as if about to burst, and there was a confused roaring in the ears, such as is heard when the ear is placed against the opening of a shell. I suffered no loss of consciousness, and was fully able to tell my friend whether I felt any pain from the knife thrusts he was inflicting upon my hand. In one minute and twenty seconds from the commencement of the operation all sensibility was abolished. After a few minutes' rest, a second trial was made in the same manner as before. This was followed by symptoms similar in character to those mentioned in the first attempt, except that sensibility ceased in fifty-five seconds.

[5] Études médico-legale sur la pendais n. etc., p. 7. Paris, 1870.

A stab with a knife, sufficiently deep to draw blood, was indicative of no sensation whatever.

Taking into consideration my own symptoms, and the accounts of those cases previously described in this paper, it is obvious that the proper and orderly way to execute the law in the case of a person condemned to death by hanging, is not to let him fall or to jerk him into the air, but to stand him on the ground, or on a suitable platform, and to adjust the noose carefully around his neck below the larynx. If he is made to fall through a trap or is lifted suddenly from the ground, this important end can never be assured. The noose is almost certain to become displaced, and hence death is not so sudden as it ought to be. Having arranged the noose properly, the condemned person should be raised from the place on which he is standing by pulling on the rope, which should pass over a pulley fixed to a beam above, and he should be allowed to hang for thirty minutes. The rope should be soft and flexible, so as to fit closely to the neck. Probably one of cotton or flax would be preferable to the hempen cord usually employed. Carried out in this manner, an execution by hanging will be effectually and mercifully performed. The condemned would undergo no physical or mental suffering from the moment the suspension began, and his life would be taken as speedily and with as much freedom from horrible events as the circumstances of the case would allow. It would be better with persons weighing under one hundred and fifty pounds to attach a weight to the feet, so as to insure a sufficient degree of traction on the cord. It is supposed by many that the dislocation of the neck produces instant death; such, however, is by no means certainly the case. There are instances on record in which the vertebræ of the neck have been dislocated and recovery has taken place. Moreover, even when death does occur, it is no more instantaneous than when asphyxia is accomplished, and there is no greater freedom from convulsions. In some recent cases of hanging there were no convulsions of the limbs, and yet the neck was neither dislocated nor broken.

Of these things we may be positively sure, that from the instant suspension takes place there is no sensibility to pain, and that the convulsions which ensue are no more evidence of pain than are the movements of a decapitated chicken. They are such as always ensue with insensibility when the blood-vessels of the neck and the trachea are suddenly closed.

The Influence of Early Feeding on life, both infant and adult, is very great. Inquiries made in Germany concerning the comparative vitality of children under various methods of feeding, exhibit some peculiar results. Thus of 100 children nursed by their mothers, only 18.2 died during the first year; of those nursed by wet-nurses, 29.33 died; of those artificially fed, 60 died; and of those brought up in institutions, 80 died to the 100. Again, taking 1,000 well-to-do persons, and 1,000 poor persons, there remained of the prosperous after five years, 943, while of the poor only 665 remained alive; after fifty years there remained of the prosperous 557, and only 283 of the poor; at seventy years of age there remained of the prosperous 235, and but 65 of the poor. The total average length of life among the well-off class was found to be fifty years, as against thirty-two amongst the poor.—*Students' Journal.*

THE EXEMPTION OF PLUMBERS FROM ZYMOTIC DISEASES.

By F. A. BURRALL, M.D.,

NEW YORK.

This communication originated in an attempt to explain the exemption of plumbers from zymotic diseases by inferences drawn from Pasteur's experiments in the prevention of *charbon* among animals. Inasmuch as the inoculation of sheep with the cultivated *bacillus anthracis* prevented anthrax among them, it seemed to me that plumbers perhaps underwent a kind of inoculation or seasoning which made them impervious to zymotic disease. Some persons have believed that this freedom of plumbers from such diseases shows that severer emanations are not unhealthful, since this class of artisans must appropriate an unusual quantity of such emanations while at their work, and yet they do not seem to suffer seriously. But observation and clinical experience have demonstrated conclusively that broken waste-pipes and leaking sewers are a cause of zymotic disease, whatever may be the scientific explanation of the fact, and it does, therefore, seem strange that such diseases as diphtheria and typhoid spare that craft which is apparently so exposed to them.

On second thought it seems to me that the laws concerning germ inoculation are not yet sufficiently established to serve as a basis for inference, and I will therefore leave this suggestion of a possible cause of immunity without following it further at present, hoping that others may be led to think upon the subject and throw more light upon it when further experiments afford a better ground for deductions.

If we examine the causes of death among plumbers in New York during 1879 and 1880, as is shown in the annexed list, kindly furnished me by Dr. Roger S. Tracy, of the Metropolitan Board of Health, we shall be surprised to notice how few of the deaths are from those diseases which are regarded as intimately connected with the development of germs. It is true that phthisis heads the list, and some might regard the large mortality from it as sustaining Koch's views of its zymotic origin; but Koch's views are still *sub judice*, while the cold and dampness to which plumbers are exposed are causes which more readily explain the relatively large mortality among them from pulmonary disease. Here is the list of deaths, 64 in number: There died of phthisis, 22; pneumonia, 10; apoplexy, 3; Bright's disease, 2; nephritis, 1; perinephretic abscess, 2; cardiac disease (valvular), 2; cardiac hypertrophy, 1; rheumatism and cardiac disease, 1; chronic hepatitis, 1; fatty liver and pulmonary abscess, 1; cirrhosis (intemperance), 1; pernicious intermittent, 1; cholera morbus, chronic nephritis, 2; general paresis, 2; epilepsy (fell with face in pillow), 1; sarcoma, left superior maxilla, 1; insolatio, 1; syphilis (melancholia), 1; fractured skull, 1; burns, 1; amputation for caries of femur and knee, 1; drowning, 1; suicide (pistol), 1; stricture and urinary infiltration, 1; peritonitis, 1; cerebro-spinal meningitis, 1; total, 64.

It is estimated that there are in New York about 3,000 plumbers. During 1878 there were 4,466 deaths from phthisis in the city, and 2,288 from pneumonia. In 1879 there were 4,343, and 2,554 deaths from the same respective causes. Hence the number of deaths from these diseases among plumb-

ers is much above the general average, which is about one in seven for phthisis, and one in 11.09 for pneumonia.

It is a well-known fact that plumbers are not exempt from maladies which are caused directly by the character of their work. They suffer from attacks of nausea, diarrhœa, and vomiting during the performance of some of their duties, in which the exhalations are unusually offensive. Whether these attacks are merely the result of a nervous impression upon the special senses, or temporary blood-poisonings, is not clear; at all events they are generally of short duration, and, as the statistics show, not mortal.

Admitting, then, that zymotic diseases are a result of exhalations from waste-pipes and sewers, and that the records do not show plumbers to be especially liable to such diseases, how can we explain the fact?

I think an explanation is suggested when we consider the different circumstances under which the plumber is exposed to mephitic exhalations compared with other members of the community. He is in contact with them while awake and temporarily, others as a rule when asleep. It is well known that the body during sleep is in a condition of diminished defence against noxious agents, and the exposure is not intermittent but steady for several hours. Therefore I would explain the plumbers exemption from zymotic disease, while others of the community suffer from it, by the proposition that others are *in a continued exposure during a condition of diminished physical resistance*, while the exposure of the plumber is intermittent and during wakefulness.

I can understand that at the present time, when the air is vocal with the hunt for germs, the excessive mortality among plumbers from phthisis and pneumonia will be considered as additional evidence of the parasitic nature of these diseases which are already on the list of suspects. But I am writing only on the basis of established facts, and while impressed with this large mortality from diseases which some associate with the presence of a parasite, cannot make inferences from conclusions not yet established.

48 West Seventeenth Street.

Curing Disease by Anointing with Oil.—The mountain evangelist, Rev. Mr. Barnes, having ousted Satan from a number of Western strongholds, has attacked Cincinnati. His campaign may attract medical attention, since he cures disease as well as saves souls. His method is to anoint with oil, at the same time uttering a brief prayer. A reporter, interviewing him, asked if he had cured many diseases in Indianapolis. "There were," he said, "some very remarkable cases. One was that of an old man, almost helpless with rheumatism, who was obliged constantly to use crutches. He was a member of the Roberts Park Methodist Episcopal Church. He was anointed with oil, and his faith took hold on Christ for healing, which occurred almost instantly. The next day he came to the church without crutches, and testified before the assembly of the healing, and declared he could run a foot-race, and praised the Lord with all his might. Another case was one of a woman subject to spasms for years, and many others." Here Mrs. Barnes declared it to be so common a thing in their experience that the wonder is, not that the persons are healed, but that all Christians do not at once go to Jesus when they are sick.

THE RECOGNITION OF MICROCOCCI.

By GEO. M. STERNBERG, M.D.,

Surgeon U. S. A.

The assumption by Dr. Gregg (The Medical Record, August 19th) that Oertel, Ebert, Klebs, Wood, Formad, and others who have studied diphtheria by the experimental method, are unfamiliar with the appearance of coagulated fibrin, because they do not find it necessary to refer to it in giving an account of their observations relating to micrococci, does not seem to call for any reply from me, and I doubt whether the gentlemen referred to will think it necessary to come forward in their own defence. Nor do I consider it worth while to make myself the champion of the well-known micro-organisms whose existence is called in question by Dr. Gregg.

The only object of my first communication was to show that modern science offers very definite and satisfactory tests for the recognition of micrococci. This being established, we must judge of the value of the observations of particular individuals from our knowledge of their skill as microscopists, pathologists, etc., or from the record which they give us of the methods employed in their researches.

A desire to be brief caused me to be less explicit in my first communication than may have been desirable, especially as regards the chemical tests relied upon for the recognition of micrococci. I therefore, somewhat reluctantly, find myself seated for the purpose of writing a second paper upon the same subject.

The chemical tests referred to in my previous note depend upon the fact that micrococci are *unicellular vegetable organisms*, having a limiting envelope of cellulose which resists the action of caustic alkalies and of strong acids,[1] while fibrin is dissolved by these reagents.[2]

Other tests of less value, but which, nevertheless, aid greatly in the recognition of micrococci, depend upon the action of various staining reagents, and especially of hæmatoxyline and the aniline dyes,[3] by which they are deeply colored. It is true that fibrin and precipitated albumen are also stained by the aniline dyes, but by the use of high powers—*e.g.*, the $\frac{1}{12}$ in. homogeneous immersion objective of Zeiss—the experienced eye can readily distinguish micro-organisms, whether spherical, rod-shaped, or spiral, from fibrils and granules of fibrin.

With lower powers, even experienced observers are liable to make mistakes if color-tests and morphological characters are relied upon.

This was long since pointed out by Cohn, who calls attention to the fact that the slender filaments of coagulated fibrin resemble closely filamentous bacteria.[4]

Klein, with the honesty which characterizes the true man of science, has even pointed out the fact that in one of his earlier researches he mistook "the products of coagulation of some albuminous or kindred material" in the pustules of sheep-pox for the mycelium of a fungus.[5]

The larger rod-shaped micro-organisms, such as the bacillus of anthrax, are easily distinguished by moderate powers—250 to 500 diameters—when they

are stained with methyl violet, and their recognition is so simple a matter that a novice in the study of this fluid could scarcely fail to recognize them, when present, as foreign elements. The difficulty would be greater for slender filamentous forms, such as the spirillum of relapsing fever—*Spirochæ Obermeieri, Cohn*—and the septic vibrin of Pasteur, were it not that these organisms present the character of active motion, which at once distinguishes them as living parasites when they are found in the blood.[1]

The recognition of micrococci is, however, admitted by all to be a more difficult matter, and those who have given the most attention to the study of these minute organisms are agreed that the test by cultivation in a sterilized fluid is the most reliable one, and that it should be resorted to in all cases of doubt. The value of this test is not likely to be weakened, for those who are familiar with the most approved methods of conducting culture experiments, by the ingenious attempt of Dr. Gregg to make the observed facts conform with his theory.

For the benefit, however, of those who are not so familiar with the literature of the subject as Dr. Gregg claims to be—he is "not a little amused" at my remark that his statements "could hardly come from one familiar with the literature of the subject"—I will briefly mention some of these facts.

Blood drawn with proper precautions from the circulation of a healthy animal, with a sterilized vessel, and kept in a culture oven at the normal temperature of the human body, remains free from micrococci and other micro-organisms,[2] and the fibrin contained in it does not in coagulating assume the form of spheres joined in pairs, in chaplets, etc. But upon the introduction of a small amount of fluid containing micrococci recently developed in a culture-solution, and having the morphological and chemical characters already referred to, the blood is quickly—within twenty-four hours—pervaded with a multitude of similar spheres. The spheres may be propagated in a culture-fluid (Pasteur's or Cohn's fluid) which neither contains fibrin, albumen, nor any other animal product.

By virtue of this power of self-multiplication these spheres are recognized as living organisms, and by their resistance to the action of various reagents which dissolve the limiting membrane of animal cells, they are recognized as vegetable organisms.

These micrococci are widely disseminated in nature, and are found in abundance in normal human saliva, upon the surface of mucous membranes generally,[3] and in pus from open wounds.[4]

They may be demonstrated by the use of good objectives and by staining with methyl violet, in the smallest drop of saliva or of mucus which can be obtained from the buccal cavity of healthy persons.

That they are also present in diphtheritic exudation occurring in the fauces, is proved by direct observation and by culture-experiments, and was *à priori* to have been anticipated, in view of the fact previously stated, viz., their constant presence in the buccal secretions of healthy persons.

[4] See Plates 1, 2, 3, 24, in Cheyne's work, l. c.

Finally, the writer has made numerous photo-micrographs[1] of micrococci obtained from the various situations named and from fluids in which they have been cultivated, and he would challenge Dr. Gregg to produce photo-micrographs of fibrils and granules of fibrin which resemble these micro-organisms sufficiently to justify his assumption that they are identical with them.

A REPORT OF CASES OF REMOVAL OF A PORTION OF INTESTINE.

By WILLIAM FULLER, M.D.,

GRAND RAPIDS, MICH.

LATE PROFESSOR OF ANATOMY, BISHOP'S COLLEGE, MONTREAL, CANADA.

I THINK that a record of the following cases will be of service, because on several occasions I have seen such cases abandoned as hopeless by surgeons of reputation.

On September 4, 1881, I was called to see a Mrs. V——, aged fifty, residing in this city, who had been suffering from a strangulated femoral hernia for four days, being reduced to a state bordering upon collapse by pain and vomiting. An exploring needle introduced into the tumor disclosed an odor of putrefaction and a discharge of a turbid reddish color. I informed the family that the only possible hope was in a removal of a portion of the intestine, to which they consented.

She was placed under chloroform, an incision made down to the sac, which was separated from the surrounding tissues and opened. The sac contained a fœtid, purulent, reddish-brown fluid, and a knuckle of small intestine, which was adherent to the sac by lymph in a partially broken-down condition. The intestine was of a purplish-green color; it was carefully separated from the sac, opened, and the finger introduced, in order to dilate the abdominal opening, and to facilitate the separation and withdrawal of the bowel from the abdomen, which was done to the extent of about an inch beyond the lines of demarcation, at which points it was extremely friable, and was torn, notwithstanding that the greatest care was exercised.

The intestine was divided a little beyond each extremity of the slough, and a double linen ligature was placed around the mesentery. The mesentery was divided beyond the ligature, and with it five and one-half inches of the bowel removed.

The intestinal tube was closed by a continuous stitch of linen thread (carbolized shoemaker's thread), with care that the mucous membrane was entirely enclosed, and the peritoneal coat in apposition. The ends of the thread were cut short, and left inside the intestine. The bowel was returned into the abdomen, the sac divided close to Poupart's ligament, and the wound left wide, with a rubber drainage-tube inserted into the abdomen around the ligatures. The dressing consisted of a flannel cloth wrung out of moderately hot water, applied over the wound and lower part of the abdomen, and frequently changed as the necessity required.

An opiate, weak brandy-and-water, and a moderate quantity of liquid diet were prescribed and retained.

Vomiting ceased, and her general condition improved almost immediately after the operation, which was completed about 7 P.M., and required about half an hour to perform.

September 5th.—She was in a very critical condition. Temperature, 102°; feeble, rapid pulse. She had frequent eructations by little effort of a yellowish fluid, and the abdomen was moderately distended with gases.

September 6th.—Condition about the same. Temperature, 100°. Bowels more distended, eructations less frequent, however, and she retained brandy-and-water, and lastly coffee with a little milk. As she was rather upon the improve in her general condition, I thought it best not to interfere with the tympanitis. I should have tapped the intestines if the respiration had been seriously embarrassed, but I concluded that the distended folds of intestine formed a necessary support to the wounded portion, and by adhesion tended to prevent the escape of the contents into the peritoneal cavity. She passed wind per anum on the fourth day, and a natural stool in about a week after the operation. The ligatures and long strings of mesentery and cellular tissue came away from time to time, and the wound was cleansed daily with a weak solution of carbolic acid. Her recovery was uninterrupted, and in six weeks she was doing housework.

The hernia was radically cured, and has remained so for a year. I was assisted by Drs. Maxim, McPherson, and Winters, of this city.

April 14, 1882, I was called to see Mrs. B——, aged sixty-two, of Alpine, also suffering from a femoral hernia, strangulated for four days. She was much in the same condition as the former case, though there was no evidence of decomposition upon puncture of the sac. The hernia could not be reduced. An incision was made, the sac isolated and opened as in the former case. It was found to contain omentum, a knuckle of intestine, and reddish serum. The intestine was not adherent, of a deep purple color, and the blood apparently coagulated in the vessels. The portion of omentum was tied and cut off, a fold of thread was passed through the mesentery, and the intestine returned into the abdomen. This was done with the view of giving the strangulated bowel an opportunity to recover, and if it did not, I hoped, by means of the thread, to withdraw it again for excision. The sac was not cut off, but left projecting above the integument, in order that the opening into the abdomen could be easily found. The operation was made at 2 P.M. An opiate was given. She passed a comfortable night, vomiting occasionally, which was attributed to the chloroform.

I was informed that she passed flatus, but upon examination for myself in the morning I observed that it came from the wound. I found, also, that it was impracticable to withdraw the intestine, on account of the swelling around the opening; nor did I make any attempt, since I thought that any shock to her system, however slight, would diminish her chances of recovery. I gently withdrew the thread and put in a drainage-tube as far as I could. She was very weak on the 15th and 16th; her treatment and condition much the same as in the former case. She was much improved on the 17th. The abdomen was very little distended, on account of the free escape of gases from the wound, which gradually ceased after a few days, and she had a natural stool about the eighth day. No fæces came from the wound that we observed. She was under the care of Dr. Coon, who resided near her, and who assisted me at the operation. Her recovery was uninterrupted from that time. Dr. Coon cut off the sac four or five days after the operation. The hernia was not cured, and a truss was applied.

In July, 1877, I removed four inches of intestine from a child fifteen months old, which was followed by recovery. The child was subject to fits of colic since its birth, and the mother stated that she had often perceived a lump in the epigastric region, which rose during the fits and passed away in the intervals. When I saw the child, a distinct roll could be felt along the left transverse and the descending colon, as far as the superior strait of the pelvis; and upon introducing the finger, a hard, fleshy substance could be felt in the upper part of the rectum, which was dilated, and the anus flabby. The child was continually straining and vomiting, and was much exhausted. I could not, by every means that I knew, reduce wholly the invaginated intestine, and the same condition would presently recur from the continued straining of the child. I then drew the extremity outside the anus, and upon examination found that the hard, fleshy tumor was an old invagination of the bowel; that the peritoneum was united above, and the enclosed sac was filled with fluid. I immediately cut it off up to the attachment, which was strong, so that no stitches were required. The bowel was returned, the invagination reduced, and, for security against a return, a pad on the left side and a bandage were applied. The child recovered without any further trouble, and was relieved of the recurring fits of colic.

MEDICINAL DOSES AND THEIR RELATION TO THERAPEUTICS.

By N. L. NORTH, M.D.,

BROOKLYN, N. Y.

That medicine is not yet an exact science is easily demonstrated. A cursory examination of any work on Materia Medica will indicate a lamentable lack of knowledge in regard to the precise method of action of medicinal agents, and show, as well a, general indefiniteness as to the proper amount of an individual article necessary to produce a specific result. After making due allowance for the differences of age, sex, temperament, climate, etc., there is yet apparent a want of exactness as to the dose in relation to the effect desired, which is altogether puzzling to the younger student in medicine, and distasteful and unsatisfactory to the older practitioner. The habit or custom of speaking of a particular article of the Materia Medica as a *tonic*, *stimulant*, or *sedative*, or otherwise, without reference to the quantity used, is, as it seems to me, so far misleading that it ought to be discontinued, except, perhaps, in a leading way, to designate the general character of the article in question. There can be no doubt to-day that a proper dose of a medicine may be given with remedial effects to a person suffering from a condition of system such as another dose of the same medicine may have caused. For instance—given a person in a certain condition—administer a gramme of ipecac and vomiting will result; again, to the same person, with excessive emesis, give three milligrammes of ipecac and his vomiting will cease. To another give a gramme of colocynth, and expect excessive drastic catharsis, with cramps and colic; and then to the same person, suffering from severe peristaltic action of the intestines, give five milligrammes of colocynth and relieve the pain.

Facts like these call for explanation. If we confine our thoughts to the old channel, and expect to find that each article used as a medicament will produce certain results, differing in *degree only* as we change the dose, the explanation will be difficult. It is not my purpose in this article to attempt to explain the general *modus operandi* of medicinal agents. I desire to impress the fact that different doses of the same medicine will produce widely different results, to the extent in some cases, possibly in many—especially in *reactive* doses—of results apparently antagonistic. Bear in mind the simple philosophical axiom that "action and reaction are equal and in opposite directions," and these results are easy of explanation. I am aware that just here comes in the pretended proof of the unscientific and ridiculous dogma of "similia," etc., of the homœopaths. I am not prepared to say, however, that the *indefinite* infinitesimal dose of a similar is less scientific than the *indefinite* larger dose of a dissimilar.

Three to five milligrammes of ipecac will, by a gentle tonic action, stimulate a deranged stomach into normal activity, while ten centigrammes, or even three, if assisted by a like amount of opium, as in the Dover's powder, will extend beyond the stomach and produce a sudorific action. A gramme of ipecac will produce such violent activity as to result in emesis. In precisely the same relative proportions and doses the different results attributable to colocynth may be understood.

To a lack of the proper recognition of *definiteness* in the different doses when different results are desired, may be charged the harm done by the abuse of quinine, as it is now, in many cases, so empirically and unscientifically administered. The primary effect of quinine is tonic. In moderate doses, say from three to fifty centigrammes—having reference to age, sex, condition, etc.—it is eminently tonic, producing activity in the capillaries, and creating a general tone and energy in the systemic circulation. In the above doses, repeated so often as to become cumulative, or in the larger doses of from thirty to sixty centigrammes, given less often and during the interval of an attack, it is an antiperiodic, and then in the enormous reactive doses of a gramme and a half to two grammes it is an antipyretic. It is here, in the matter of the use of quinine to reduce the temperature, more especially, that a word of caution seems to be needed looking to a reformation in the manner and time of its use, lest the folly of half a century ago of the careless resort to one medicine in almost every disease, whether rationally indicated or not, be repeated today by substituting quinine for calomel.

As the homœopathist, in the rare case of his honestly adhering to his irrational dogma of the similars and infinitesimal potencies, falls into the habit of watching symptoms, and so gives his patient an infinitesimal *like* to cure a *like*—really doing nothing—while nature cures or kills the patient, so may it not be possible that the "regular practitioner," falling into the easy habit of resorting to the thermometer, and when it indicates excess of temperature prescribing quinine, and persisting in its use, at the risk, in some cases, of harming rather than helping his patient? A special diagnosis, under such circumstances is of but little importance. A general name, as "malarial fever," or "typho-malarial fever," will do for all the diseases arising from decomposing vegetable or animal matter, and "pneumonia" for all the forms of the inflammatory affections of the lungs or bronchial passages will be quite enough to satisfy the patient and his friends, and then, how easy the routine—note the temperature, and finding it above normal prescribe *quinine indefinitely* but *persistently*. Perhaps the patient may complain of "bursting headache," or there may be complete delirium! What matter? The temperature is high—push the quinine. Finally a *reactive* dose is reached, the powers of nature yield, and the patient either dies in collapse, or gradually rallies from the prostrating effects of the disease or the medicine, or both, and by careful nourishment convalescence is established and he recovers.

The reactive or antipyretic dose of quinine is a remedy potent for good or for evil; and, like venesection, should be used with great care after careful diagnosis and with direct reference to its powerfully sedative action.

A tonic dose of quinine should never be given to reduce the temperature; it will have only the opposite effect. Again, a tonic or antiperiodic dose of quinine, as a rule, should not be given during the exacerbation of a fever.

Many diseases have symptoms in common; prescribing for symptoms, without reference to a careful diagnosis of the disease, is as dangerous as it is unscientific.

Many remedial agents produce results widely different, often antagonistic, according to the quantity given. The selection of the *dose* of a remedy is quite as important as the choice of the *remedy* itself.

Progress of Medical Science.

Rapidly Progressive Cirrhosis of the Liver.—Dr. Victor Hanot relates at length, in the *Archives Générales de Médicine* for June and July, 1882, four cases of cirrhosis of the liver in which the symptoms differed somewhat from those usually observed in this disease. The duration of the malady varied, in the different cases, from two to six months. There was in every instance an elevation of temperature from 1° to 2° C. From the commencement more or less pain was complained of in the right hypochondriac region. Ascites appeared early, sometimes even before any noticeable enlargement of the subcutaneous abdominal veins. There was also, early in the course of the disease, œdema of the inferior extremities, and even of the hands and forearms. The subicteric hue of the skin, mucous hemorrhages, and ecchymoses were much more marked than we usually find in cirrhosis, though less in degree than are seen in acute yellow atrophy. The patients emaciated rapidly, and death overtook them suffering from profound cachexia, weakening of the mental powers, sometimes going on to coma, and a subnormal temperature. At the autopsy the gross appearance of the liver was that of ordinary cirrhosis. It was small, granular, sclerosed, and of a chamois yellow color. The microscope also showed the ordinary appearances found in cirrhosis, but in addition there was seen to be a fatty degeneration of the hepatic cells. This was not a mere granulo-fatty infiltration, but most of the cells were found to have disappeared and to have been displaced by little drops of oil. In some cases a single drop was seen of nearly the size of the cell itself.

The Embryology of the Eye.—In the third article of his series on the development of the eye, published in the *New York Medical Journal and Ob-*

stetrical Review for September, 1882, Dr. William C. Ayres, of New York, considers the choroid, the ciliary body and the iris, the retina and the optic nerve, and the optic chiasm. Whereas J. Arnold has not been able to detect blood-vessels in the locality of the future choroid in embryos of 9 mm., the author has observed the whole primary ocular vesicle surrounded by a system of vessels, running at least one-fourth through the corneal tissue, or between the lens and the primary epithelium of the cornea, the ectoderm. The formation and origin of this system of blood-vessels he thinks very important, since they certainly represent the earlier stages of the choroid, and demonstrate most positively that neither the choroidal tissue nor its pigment can have any relation to the ocular vesicle. Also, since the choroidal tissue is formed from the mesodermal elements immediately around these vessels, and from them alone, the pigment epithelium of the retina can have no relation to the uveal tract except one of apposition. The development of the choroid is summed up by saying that it takes its origin from the original mesodermal tissue which surrounds the primary ocular vesicle, and is, consequently, a formation *in loco*. At first its cells are not arranged according to any order, but subsequently a distinction occurs which is completely analogous to what takes place in the cornea in the formation of its basilar membranes. The choroid and sclera are continuous in early embryonic life, but they are afterward separated, just as the anterior chamber was formed —viz., by the production of holes and meshes. In the case of the anterior chamber the process becomes complete, and a free space exists, whereas in that of the choroid it does not become so, and the peculiar loose connection which we find between the choroid and sclera results. The pigment of the choroid is of late origin, and is formed in the same way as that of the iris and ciliary body. As regards the ciliary body and the iris, in embryos of 17 mm. in length, we notice that the end of the secondary ocular vesicle is rounded off, and it is so placed that the line of separation between the two layers runs almost parallel to the optical axis. A little later than this the end becomes pointed, and the external layer lengthens out so as to present its outer surface directly to the front, whereas, before, this position was held by the tissue which joined the two layers together anteriorly. He lays much stress on this condition, or rather this peculiar step, in the development, since it is, in his opinion, the key-note to the formation of the iris. And it has been overlooked by most authors on the development of this membrane. At 33–36 mm. the pigment layer has developed so much more than the inner one that, the latter not being able to separate from the former, a loop has been produced, so that the end of the vesicle is now made up of two layers of cells, both of which have come from the outer or pigment layer of the ocular vesicle. The mistake is often made, he remarks, of supposing that the posterior chamber runs up to the pupillary margin of the iris as a free space, but this is not true, and the reason for it we see in the manner in which the iris is formed. In the case of the retina, soon after the primary ocular vesicle has been completely formed we find it projecting far out into the mesoderm, and approaching the ectoderm, at each successive stage of increase in its volume of tissue, until it has nearly reached the external layer of the head of the fœtus. This layer it never reaches, however, and there can always be seen a thin strip of tissue between it and the ectoderm. Kessler and some others insist that an actual contact occurs, but this the author has never been able to see in any one of the many specimens he has examined in regard to this special point. On the contrary, there is always the tissue just referred to between them, and this tissue, though very transparent, and capable of being stained but very slightly with any of the various coloring materials known to microscopic technology, can always be seen, on close examination, to contain cells and intercellular substance. There are many peculiarities to be noticed in the formation of the pigment, both of the retina and of the uveal tract. Some authors contend that they come from the same source, and Dr. Ayres thinks that perhaps they do, but not in the sense those authors seem to set forth. The retinal pigment is to be found at an early stage, even before the two layers of the secondary ocular vesicle have come in contact with one another. It always occurs in the shape of dark-brown points, so to speak, and always on the inner part of the outer wall of the secondary vesicle, where it remains situated in a closed cavity produced by the two walls of this vesicle. These walls never become broken at any point so as to admit of this pigment "*wandering*" from its original place of formation, and, consequently, it can never be concerned in the production of any portion of the eye where the retina does not play a part. The development of the fovea centralis is considered to be still a matter of great uncertainty.

TREATMENT OF ASCARIDES LUMBRICOIDES. — Dr. Guermonprez sums up a long article on lumbricoides thus:—1. Worm-seed (whose action is not to be confused with that of santonin) is by far the best medicament for killing as well as expelling round-worms. 2. Santonin does not kill the worms outright, it excites them to livelier movements, and these may reflexly stimulate the intestine so as to expel them; but they may also only exaggerate the evil if there is obstruction. 3. Santonin is, therefore, by no means always to be chosen. It does no harm if the worms are young and not numerous; if they are mature and many it may be dangerous even in reasonable doses. 4. The purgatives usually given with vermifuges probably do more than the latter to cause expulsion of the worms; simple evacuants will often suffice. 5. Ordinary hygienic means directed to overcoming the lymphatic cachexia of the patient, or simple change of food and abode, may at times be enough to rid him of the worms without any medicine whatever. 6. Hence our treatment should not be the mere routine administration of santonin, but should be determined by the circumstances of the case. Change of air, and of diet, and simple evacuation, are not to be forgotten.—*The Practitioner* (London), September, 1882.

THE ACTION OF CALOMEL ON FERMENTATION AND ON THE LIFE OF MICRO-ORGANISMS.—A paper with this heading appears in the last number of Hoppe-Seyler's *Zeitschrift für Physiologische Chemie*, by N. P. Wassilieff, who, after noting the high estimation in which calomel has been always held in disordered conditions of the bowels, especially in children, points out the absence, with one or two exceptions, of any experiments to show or explain the cause of its influence. Voit, indeed, as long ago as 1857, observed that albumen and blood mingled with calomel were capable of being kept for days without any indication of putrefaction, and Hoppe-Seyler

made some similar observations; but besides these, few, if any, researches have been made on its action. In M. Wassilieff's experiments, calomel was added to the fluid obtained by acting on albumen with gastric juice, and to that obtained by acting on albumen with pancreatic juice; and he satisfied himself that the albumen-digesting ferment of both these fluids was not damaged by calomel—peptones in the one instance, and leucin and tyrosin in the other, appearing as usual:—but that the presence of this substance prevented the formation of the secondary products, such as indol and phenol. Neither hydrogen nor hydrogen sulphide formed in the fluids containing calomel, whilst they were abundantly produced in the others. In like manner, the author experimented on the effects of calomel on the fat-digesting and the amylolytic ferments of the pancreas, and found that it had no modifying influence upon them, but that it arrested the changes which followed their completion, entirely preventing, for example, the butyric acid fermentation and putrefactive processes. He hence arrives at the conclusion that calomel acts differently on the formed or organized and the unformed or unorganized ferments, permitting the action of the former to proceed unchecked, but completely preventing the action of the latter.—*The Practitioner* (London), September, 1882.

PARALYSIS RESULTING FROM INJECTIONS OF ETHER.—In an article on this subject in the *Journal de Médecine de Bordeaux*, of June 25, 1882, Dr. Arnozan details a number of cases, from which he draws the following conclusions:

1. Injection of ether into muscles produces paralysis of these organs.

2. These paralyses bear a marked analogy to certain peripheral paralyses, as, for instance, of the facial nerve. There is suppression or diminution of faradic excitability, augmentation of galvanic excitability (reaction of degeneration), and return of voluntary movement before that of faradic excitability.

3. Such paralyses are cured spontaneously, but slowly. Their cure by the application of galvanic currents is much more rapid. A number of questionable points remain to be determined. Does ether cause these paralyses by acting upon the nerves or upon the muscles? It seems from clinical analogy that the nerves are involved; but on the other hand, how is it that ether injected without particular reference to this point should have invariably come in contact with the nerve-trunks? Must some lesion of the nervous terminations be admitted? These are questions which experimentation upon animals and microscopical observation alone can solve.

CONGENITAL INTESTINAL OBSTRUCTION. — Mr. A. Pearce Gould relates a case of congenital intestinal obstruction. A. B——, a female, aged three days, was brought to Westminster Hospital on August 5, 1881, because, in spite of several doses of castor-oil, it had not passed any meconium or motion. It had vomited several times. The child was thin, but showed no outward deformity. The anus was normal, and the last joint of the little finger could be passed into the rectum, which appeared to be closed over above it. No fulness or tumor to be felt in the pelvis per rectum. A catheter and probe were each stopped about one inch from anus. Belly distended, its walls œdematous; a little ascites. At 1 A.M., August 6th, Mr. Gould opened the belly above left Poupart's ligament. A coil of distended small intestine presented, and no coil of large intestine could be brought into the wound. So the former was carefully stitched to the edges of the incision and then opened, and a large quantity of meconium escaped. The child died twenty-one hours afterward. At the autopsy no trace of peritonitis was found. The cæcum and lower four inches of ileum, and four inches of colon, were filled with a firm, whitish substance of the consistence of cheese, firmly applied to, but not united with, the mucus membrane. In the colon beyond this plug were found several masses of milk-white, firm mucus. Below this the colon and rectum were empty, and firmly contracted to the size of a clay tobacco-pipe stem. Above it the small intestine was distended with meconium and gas. It was pointed out that there was here no fault in development, but obstruction from a plug. From the white color of this plug it was assumed that it was deposited by the third month of fœtal life, as bile passes into the duodenum at that time. Mr. Gould also insisted on the advantage of opening the belly in the groin in all cases of congenital intestinal obstruction, in preference to lumbar colotomy, which would have been impossible in this case. The obstructing mass was formed of inspissated mucus, which showed that in that case the glands of the large intestine must have acted some time before birth.—*The Practitioner* (London), September, 1882.

ERYSIPELAS PROPAGATED THROUGHOUT THE DIGESTIVE TUBE.—In *La France Médicale*, M. Rendu reports a unique case of erysipelas contracted through contagion, and spreading through the entire alimentary canal. The disease originated at the site of a scratched acne pimple on the left cheek.

As regards the buccal cavity there was from the beginning no doubt as to the character of the trouble. The progressive swelling of the lips and tongue, together with the dysphagia and angina, indicated the propagation of the cutaneous dermatitis, which upon the mucous membrane of the cheeks and lips presented identically the same characteristics as upon the skin. The next day, nausea and vomiting indicated that the stomach was effected; the following day symptoms of a violent enteritis predominated, viz.: excessive tympanitis, colic, and profuse and fetid diarrhœa. This tympanitis and diarrhœa persisted, with alarming intensity, for five days, and did not begin to decrease until the end of a week. It was then that sharp pains, perineal swelling, and all the symptoms of a phlegmon appeared. In three or four days an abscess accordingly formed at the margin of the anus. Considering this in connection with the appearance later of a submental cervical abscess, the author concluded that intestinal erysipelas had existed.

ALCOHOLISM AND STRYCHNIA.—According to M. Luton, of Rheims (*Bulletin de Thérapeutique*), one may observe in alcoholics a veritable excito-motor inertia of the spinal cord, capable of lessening the generally so marked effects of strychnia. Thus in individuals suffering from acute alcoholism, this drug may and must be given in large doses to insure success. While in some cases three centigrammes of the sulphate of strychnia, injected by demi-centigrammes in the course of a day, suffice to relieve an attack of delirium tremens, in other instances more will be required. To an individual affected with delirium tremens symptomatic of a varioloid, M. Luton has given hypodermically in fifteen hours seven centi-

grammes of strychnia sulphate, with real benefit and without accidents of strychnism. M. Luton is of the opinion that in the alcoholic, because of an acquired tolerance, there is no absolute limit to the employment of strychnia. The principal point is to divide the dose so as not to inject more than a centigramme at a time. An interval of two hours suffices to exhaust the primitive or dangerous effects of the poison. It is necessary also to watch the patient closely, and to stop the remedy as soon as the delirium has ceased, and sleep has appeared; for from this time on inertia of the cord no longer exists, and the cumulative effects of the drug might otherwise suddenly manifest themselves.

Treatment of Galactorrhœa and Incipient Mastitis by Strapping.—Dr. E. Schwarz (*Centralblatt für Gynäkologie*, July 1, 1882) reports the cure by strapping of a case of galactorrhœa which had resisted all the commoner modes of treatment. The patient had originally suffered from a suppurative mastitis. The abscess had been opened and iodoform applied. The abscess proper healed readily, but the incisions failed to do so. They, as well as the nipple, discharged milk in considerable quantity. The volume of the breast was increased, and there was moderate tenderness. Anæmia supervened, and the health of the patient was depreciated to an alarming extent. The author finally hit upon the expedient of lessening the blood supply to the affected breast by strapping. By this means he hoped to diminish the hypersecretion. After washing and drying the breast, strapping was applied as follows: Two strips were applied to the tip of the mamma, above and below the nipple, in such a manner as to leave the latter, and a small horizontal ellipse around it, uncovered. The strips thus formed an elliptical figure. Their extremities ended on the sides of the mamma, that of the lower one above, and *vice versa*. A second ellipse was then applied, overlapping the first to one-half its width. Six or seven of these were applied, of which the last embraced the base of the breast, its ends terminating on the skin of the thorax. Finally, the nipple itself, with the surrounding small space, was covered. Every point of the mamma, above and below, was thus covered by a double layer of strapping, and at the crossings on the sides by more than two layers. Almost immediately after the application, the breast had diminished in size, from the tightness of the strapping. There was no pain during the time occupied in putting on the plaster, or thereafter. By the next day only a few drops of milk had appeared through the strapping. The mamma had become so diminished in size that a new application became necessary, followed by a third, two days later. Three more applications sufficed to bring about the cure of the dermatitis, arrest the hypersecretion, and close the fistulæ. The affected breast now was less in volume than the other. Other procedures had been abandoned on application of the first strapping. In a case of incipient mastitis mentioned, the author, after resorting to others without success, employed the above procedures; but in addition suspending the breasts by two long strips passing over the shoulder. The operation caused no additional pain, but, on the contrary, pain entirely ceased after the lapse of half an hour. A cure resulted after the two additional applications at intervals of two days. In a third case a threatening abscess was aborted. Schwarz draws attention to these points: That the strapping must be carefully applied as described; that the plaster must adhere well; that a constant equable pressure must be exerted, and that the strapping must be renewed when it becomes loose, this generally occurring daily at first.

Large Pancreatic Cyst—Laparotomy—Death.—In the *Wiener Medicinische Presse*, No. 45, an interesting case of cyst of the pancreas is described. The patient, a woman, aged thirty-six, was received into a Vienna hospital, and on examination the abdomen was found to be unequally distended by a tumor. The latter extended two handbreadths above the umbilicus, was tolerably movable, exhibited indistinct fluctuation, and reached down as far as the true pelvis. The growth had originated in the upper abdominal region nearly three years before; it had grown steadily and been mistaken for an ovarian cyst. On February 27, 1881, Rokitansky performed extirpation. After incision of the linea alba to the extent of nine inches, a quantity of ascitic fluid escaped. The tumor was adherent anteriorly with the large omentum and the posterior wall of the stomach, and behind with the transverse and descending colon. In the separation of the transverse colon, the intestine was torn to the extent of nearly one inch; the rent was immediately closed with five sutures. Fifty ligatures were necessary to arrest the hemorrhage from severed adhesions. Separation of the omentum caused a laceration of the cyst and a partial discharge of its fluid into the abdominal cavity. After dilatation of the opening, five quarts more of a brownish-red fluid escaped. At the end of a two hours' operation, the patient was so collapsed that a total extirpation was out of the question, on account of remaining extensive adhesions. The part of the tumor which had been freed from its connections was subsequently encircled by Chassaignac's écraseur, the chain was fixed by a Péan's clamp, and the growth removed above the chain. The stump was then fastened to the upper angle of the wound. Soon after the operation meteorism and offensive discharge from the abdominal cavity set in, necessitating the introduction of a drainage tube, through which the abdomen was washed with a one-half per cent. carbolic solution; the sac of the cyst was similarly treated on the next day. On the sixth day fecal masses escaped from the tube and alongside of it; on March 9th death supervened. The autopsy revealed purulent peritonitis, and on the posterior wall of the remainder of the sac a group of long, shaggy, discolored, and very soft excrescences about the size of a dove's egg. The other walls were pretty smooth, only thickened in parts by low protuberances. This part of the cyst was connected with the pancreas in the following manner: The head of the organ was distinctly demonstrable, but the body was intimately adherent to the posterior surface of the cyst as a thin layer one-twelfth of an inch in thickness; further to the left it gradually emerged into it so that the tail of the organ was wanting. Injection of the pancreatic duct showed it to be extant in the head and body; numerous branches could be filled with the injection where there was no parenchyma in the cyst wall. The cyst fluid was dark red, turbid, alkaline, and contained a large quantity of granular masses of lighter shade; its specific gravity was 1.014, and some of its ingredients were hæmoglobine, serumalbumen, serumglobin, inorganic salt, cholesterin, and paralbumin.

A Marble Bust of Virchow has just been completed for his Pathological Institute.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, October 14, 1882.

HIGH-PRESSURE EDUCATION.

In a recent issue of the *New York Herald* appears a suggestive letter from a school-girl who is a victim of the prevalent high-pressure system in our public schools. By way of a prelude to some remarks which seem to be called for on the general subject of education of the rising generation, we cannot, perhaps, get more directly at the points at issue than by making several quotations from the communication in question. In the first place, here is the enumeration of the daily routine: "My studies are arithmetic, algebra, geography, astronomy, grammar, United States history, general history, etymology, spelling, and composition; then drawing, reading, writing, and singing by note. Every little while I am obliged to have an account of some celebrated person or place learned well enough to write on a slate."

The manner in which the necessary amount of mental labor is performed to master the many different tasks assigned gives the clue to the nervous strain which almost invariably follows. If the public understood it as well as the profession, the absurdity of the system would need no reproof. That such things are allowed to go on under the sanction of what has been generally considered the best school system in the world, proves quite conclusively that arguments against it are still in order, and that the profession has a duty to perform in the premises which must be persistently and conscientiously performed. But we have this account of the method and amount of study necessary to the end to be attained, and it is fair to suppose that it may be the experience of hundreds of young girls in a like situation:

"After spending a long, wearisome day in a close school-room, trembling every minute for fear I shall forget some date in history or rule in algebra, I walk home, a distance of three short blocks—the only exercise I have except at lunch time, with a short recess in the forenoon in a crowded school-yard. As soon as I arrive at home I sit down to work out my number of algebra problems, which I would not mind if I wasn't so nervous and tired. After that comes my spelling, twenty review words of former grades, and twenty historical, geographical, or astronomical names, which take quite a long time to hunt up in their respective text-books. Then next in the order of exercises is a long history lesson, with such lists of names and dates that it makes my head swim to look at them. I study the civil war, together with the explorations and early settlements. By the time I lay down my book to have supper my head feels as if it would burst. I hastily swallow my food, thinking all the time of how much more I must jam in somehow before I can rest. I hurry to two chapters of geography, and while studying them think, 'O dear! I don't half know that history yet!' and I have got astronomy and an account of Solyman to find in an encyclopædia, history, or elsewhere, besides preparing the definitions of a reading lesson, with the notes about the author. I study and search in histories and text-books until I am about worn out. I do not dislike study, but object to being obliged to work until twelve o'clock every night."

When we consider that the pupil, like others of her class, is probably a young girl in her teens, passing through those physical changes which are necessary to her future development, when mind and body should be subjected to the minimum amount of strain, no words can express the abhorrence of a system which is so utterly in defiance of all the well-recognized laws of health.

It has often been said that the tendency of American methods is toward one extreme or the other. Our public schools can within bounds be admirably managed, but the commissioners seem to be carried away with the insane idea that no amount of mental work which can be forced upon the already overburdened scholar can do any harm. The fact that some may struggle up to the required standard seems to be a sufficient reason why all must. If half the parents had a proper idea of the actual daily mental work that is expected of their children, they would possibly be more than astonished to think how one small head could hold it all. At the bottom of this pernicious system of crowding is the desire of making the best show of work on the part of the teachers, who are oftentimes strained as badly as their scholars. Each teacher must maintain a certain percentage of well-drilled scholars under penalty of discharge or reduction in her own grade. The consequence of all this is easily seen in both the worn-out teacher and overburdened scholar, and these are to be found in large numbers in every public school in this city. But reform can only fol-

low the creation of a proper public opinion on the subject, and to such an end our efforts must constantly tend, and so we must never tire in repeating an old story, until the time may come to be heard.

A THEORY OF FEVER.

It has been quite positively determined that in fever there is an increase in the consumption of oxygen and in the elimination of carbonic acid gas, which increase corresponds with a more active tissue-change.

The cause of this febrile activity has been attributed to certain ferments or to micro-organisms. These are supposed to float in the blood, and to be carried to the various tissues which they excite into greater metabolic changes.

No theory of fever can be thought complete, however, unless it takes into account the influence of the nervous system. That there is a definite, localized thermic centre in the brain or lower ganglia, must still be doubted, but that there are nerves which influence animal temperature is very well proved. The great source of heat is the muscles, which probably produce at least seven-eighths of the whole. It must be efferent nerves running to muscles, therefore, which chiefly carry the influences regulating heat-production in animals.

Professor M. Zuntz has advanced the hypothesis that in fever there is an excitation of these nerves, and that it is through this means that high temperatures are produced. The tired, aching feeling of fever patients, the rapid waste of muscular tissue, the muscular tremors of initiatory chills are instanced in support of such a view. But the author has, in addition, made some highly ingenious experiments to test its correctness.

He curarized rabbits so as to paralyze the motor nerves, and presumably all the efferent nerves going to muscles. The animals were kept at a fixed temperature by placing them in a bath. Artificial respiration was performed. The amount of oxygen consumed and of carbonic acid gas excreted were measured. Injections of hay-infusion or of septic blood were then made, and the gas exchange again measured. It was found that there was no increase in any instance. There was, therefore, no increase in the tissue change, and it was inferred that this was due to the paralysis of the thermic nerves (which necessarily act by increasing tissue change) by curare. Control experiments were performed, which showed that the injection fluids used produced fever with all the attendant phenomena in other rabbits.

Professor Zuntz admits the incompleteness of the proofs of his theory. He might, perhaps, have found much confirmatory evidence of the nerve-hypothesis of fever in American literature, if he had been better informed regarding it. Few are disposed to doubt that the nervous system plays an important part in febrile phenomena. Zuntz's hypothesis, however, is incomplete in that it ignores the influence of nerves in producing a peripheral tetanus of the blood-vessels, and thus lessening radiation of heat.

SLAUGHTER-HOUSE EXAMINATIONS.

The importance of facts to be obtained by a careful and systematic examination of animals slaughtered for food has hardly been recognized in this country. Reports of such examinations made in other countries have frequently been found to contain most valuable information. In particular, the city of Augsburg may be instanced. For some years the investigations of Inspector Adam have been widely quoted by Flemming and others. Recently the *Journal of Comparative Medicine* gives some important data obtained from the same source. Among 66,731 animals brought to market in the year 1881, there were 12,269 cattle, of which 246, or 2.01 per cent., were found tuberculous. This ratio is much smaller than is generally supposed to exist among American cattle. But further, the amount of tuberculosis varied greatly, and in most cases was not extensive enough to injure seriously the quality of the meat. In fact, only eighteen animals out of the two hundred and forty-six were condemned as unfit for food. The tubercles were confined to the lung in 142 cases, to the pleura in 37 cases, to the lungs and pleura in 68 cases. In 59 cases there were also tubercles in the liver.

Thus the important fact is brought out that in no case were tubercles found in parts of the body (except the liver) used as food.

Further facts bearing upon the infectiousness of the milk of tuberculous cows are given. Among 24,901 calves killed, when under the age of four weeks, no tubercles were found. Now, about five hundred of these must have been sucking the milk of tuberculous mothers, yet with apparently no injurious effect. And furthermore, the age of the tuberculous cattle was, with the exception of twenty-three, over three years. The conclusion is, that cattle, at least, are not infected in the ordinary sense, with tuberculosis by feeding upon the milk from diseased mothers.

THE ANTISEPTIC TREATMENT OF TYPHOID FEVER.

At a meeting of the Société Médicale des Hôpitaux, June 9th, M. Ferrand presented the candidate's thesis of Professor Desplat, of Lille, upon the comparative action of carbolic acid and salicylate of soda. The views presented were that the above drugs were excellent antipyretic and antialgesic agents—sure, rapid, and permanent in their action, but, at the same time, easily eliminated, and, therefore, but slightly dangerous. Except in acute rheumatism, M. Desplats did not find any marked difference in their action.

The discussion which ensued turned upon the use of carbolic acid in typhoid fever. Thirteen members took part and related their experience. Three or four did not commit themselves; the remainder agreed in saying that the drug in question, used as recommended, had a dangerous tendency to depress the system, and to produce pulmonary congestion, exhausting sweats, and albuminuria or polyuria.

It was unanimously voted that the use of carbolic acid in typhoid fever, when given as recommended (in half-gramme or gramme doses by enema twice a day), was dangerous, and without effect upon the course of the fever.

Dr. Ramonet, Physician-in-Chief at the Military Hospital of Boghar, in Algeria, has contributed an article upon the use of carbolic acid in typhoid fever, expressing directly contrary views to the above. He is a follower of Desplat, except that he uses smaller doses, generally not more than two grammes per diem, by injection. The effect, he says, is to lower the temperature nearly 4° F., and to produce a most favorable change in the progress and symptoms. He has treated forty-one cases, with a mortality of only two, or 4.9 per cent. The average mortality from this disease in the army is twenty-one per cent.

On August 22d, at the Academy of Medicine, M. Vulpian read a paper upon the use of salicylic acid in typhoid fever. M. Vulpian based his therapeutics upon the theory that there is a *bacillus* of enteric fever in the intestine, and that this *bacillus* ought to be ferreted out and killed with an antizymotic. Having tried iodoform, boric acid, phenate of soda, and salicylate of bismuth with no effect, he finally settled upon salicylic acid. This in daily doses of two or three grammes was ineffective, but in doses of six or seven grammes daily (gr. xl. to gr. l. every two hours!) most satisfactory results were obtained in a lowering of the fever and a general amelioration of symptoms. M. Vulpian concluded that this drug, without being curative, had an undoubted modifying influence upon typhoid fever. He thought also that salicylic acid taken by the mouth might act as a prophylactic. The discussion which followed brought out very little. It was only evident that M. Vulpian's views were theoretical, and that the clinical tests of his reputed remedy were not at all conclusive. Salicylic acid has been tried in Germany and America with no very good results, as yet reported.

THE HEALTH OF LONDON.—The death-rate of London during the two summer months reached the extraordinarily low figure of 13.45 per 1,000. That the city is less healthy in winter we might infer from the statement that the weight of the soot hanging over London on a winter's day is fifty tons, while that of the carbon dioxide is two hundred and fifty tons.

Reviews and Notices of Books.

THE MULTUM IN PARVO REFERENCE AND DOSE BOOK. By C. HENRI LEONARD, M.A., M.D. Detroit: The Illustrated Medical Journal Co., 1882.

THIS appears to be a useful little work, containing, along with the usual list of things for reference, the doses of the latest remedies and preparations.

LABOR AMONG PRIMITIVE PEOPLES, showing the Development of the Obstetric Science of the Day, from the Natural and Instinctive Customs of all Races, Civilized and Savage, Past and Present. By GEORGE J. ENGELMANN, A.M., M.D. Fifty-six Illustrations. St. Louis: J. H. Chambers & Co., 1882.

WE can hardly praise too highly Dr. Engelmann's interesting work, which is a contribution both to anthropology and obstetrics. The author describes what he announces on the title-page; but he also supplements his descriptions with many cuts, which greatly add to the interest and intelligibility of his subject. We have no space to review the conclusions made, although they are novel, and will doubtless excite enough debate. Dr. Engelmann thinks that the modern dorsal decubitus is unphysiological and bad. He recommends the semi-recumbent posture, along with more liberty of movement to the parturient woman.

TWO HARD CASES. Sketches from a Physician's Portfolio. By W. W. GODDING, M.D. Boston: Houghton, Mifflin & Co., 1882.

IN this little book, Dr. Godding establishes his reputation as a graceful and pleasing writer, if not as a psychological expert. The first "Hard Case" is a patient which the author had under treatment for some time. There is a pathos in the story and a simplicity and charm in the way it is told, which should rank it as a classic.

The second "Hard Case" is Guiteau, of whom we venture to think that enough has been said.

THE HUMAN BRAIN, Histological and Coarse Methods of Research. A Manual for Students and Asylum Medical Officers. By W. BEVAN LEWIS, L.R.C.P. (Lond.). London: J. & A. Churchill, 1882.

THIS book presents a concise summary of methods of examination of the nervous centres. It contains much that may be found elsewhere; but, on the whole, supplies a want, and will be found very useful. Dr. Lewis is clear and accurate in his descriptions, which are accompanied with good illustrations. Several new methods of examination are given.

TRACHEAL MUSIC.—The French journals, under the title of a "curious phenomenon," describe a flageolet player who charmed all his hearers by his musical performances at the recent fair held at Neuilly, near Paris. He had formerly suffered from an attack of diphtheria. Tracheotomy was performed, and the silver tube which was introduced at the time of the operation, and kept stationary by means of a circular pad, now serves the musician of Neuilly as a natural aperture through which he breathes, and so successfully that his flageolet playing was enthusiastically applauded by all present.—*British Medical Journal.*

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 5, 1882.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE Librarian, Dr. E. D. Hudson, Jr., reported that since the last stated meeting 1,429 bound volumes and 2,966 medical journals had been donated to the library.

The Statistical Secretary, Dr. F. V. White, reported the death of Dr. J. B. Reynolds, and Dr. Clements, one of the founders of the Academy.

DR. E. G. JANEWAY, then read a paper entitled,

CASES BEARING ON DIAGNOSIS AND LOCALIZATION OF CEREBRAL DISEASE AND THEIR DIFFICULTIES,

in which he directed attention especially to some of the difficulties encountered in making a differential diagnosis between cerebral and general diseases. A second group of cases was reported with reference to the general question of localization of cerebral lesions.

Of general diseases, fevers, more particularly typhus, might easily be mistaken for cerebral disease, on account of its marked cerebral symptoms, petechial eruption, etc. A case was cited, and, besides illustrating the difficulties of making a diagnosis, it showed the importance of investigating with reference to the patient's surroundings, hygienic and otherwise. The *duration* of the disease he regarded as an important point, and if it should be found that this had been from twelve to fourteen days, the probabilities were decidedly in favor of typhus fever in the very doubtful cases.

Acute ulcerative endocarditis might resemble both typhus fever and cerebral disease; for emboli from the cardiac lesion might give rise to petechial spots and also to brain symptoms. Should definite paralysis or aphasia be developed, suspicion should at once be awakened and careful examination made with reference to the existence of cardiac disease. An illustrative case was reported.

Malarial diseases were not often mistaken for cerebral disease, although the converse was not true, for tumor of the brain, abscess, or lepto-meningitis might be attended by symptoms, such as periodicity in the occurrence of certain phenomena, which made the whole clinical history closely resemble that of different malarial fevers. Illustrative cases were given.

Pneumonia and pleurisy had been mistaken for cerebral disease, the former especially, and very commonly in children. This arose chiefly from the occurrence of convulsions, one or more at the outset, headache, rigidity of the muscles of the neck, irregularity in the febrile movement, etc. In all cases symptoms referable to the chest should be carefully watched and thorough physical examination made repeatedly.

Bright's disease of the kidneys, more especially of the contracted variety, was liable to be mistaken for cerebral disease. Illustrative cases were given. One case was reported which illustrated the great difficulties sometimes encountered in making a diagnosis, and when made it was not sustained by the autopsy. A lad, sixteen years of age, wild with delirium, was admitted to Bellevue Hospital. He had had two convulsions; one several months previous to, and the other ten days before admission, and he had been treated for "kidney trouble." There were pain in the muscles upon pressure, marked rigidity of the muscles at the back of the neck, contracted pupils, marked choked disk in both eyes, good hearing, no evidence of paralysis, urine retained, not suppressed, Cheyne-Stokes respiration, and death. Diagnosis of basilar or cerebral meningitis was made. At the autopsy the spinal cord was found to be normal, and also the brain, except one of the lateral ventricles, which contained a clot three inches long, two wide, and one thick, due to rupture of a miliary aneurism in the wall of the ventricle, and there was also double hydronephrosis.

With reference to the question of *localization of cerebral disease*, we were obliged to decide, in the first place, whether probably the disease produces the symptoms, or whether they are due partly to the irritation or the softening secondary to the cerebral lesion, such as tumor, etc. Several cases were then reported which illustrated the difficulties liable to be encountered, and, at the same time, showed that localization of lesion could, in a certain proportion of cases at least, be definitely determined.

DR. E. C. SEGUIN opened the discussion and said that to him Dr. Janeway's paper had been very instructive, more particularly that part which dealt with the difficulties in making a differential diagnosis between general diseases, accompanied by well-marked nervous symptoms, and ordinary cerebral disease; for in many of these cases there was extreme difficulty in reaching a correct conclusion, and especially when the question of the existence of renal disease was involved. In those cases he regarded it as sometimes impossible to avoid the double diagnosis of kidney affection and cerebral symptoms due to miliary aneurisms.

ETIOLOGY OF CEREBRAL HEMORRHAGE.

He had been particularly interested in the case of the young man reported by Dr. Janeway, for it suggested the change of view which had occurred concerning the etiology of cerebral hemorrhage. The time was when it was held that the chief lesion which gave rise to cerebral hemorrhage was atheromatous degeneration of the arteries, whereas it depended, as many at the present time believed, upon a more extensive or more organic degeneration, accompanied by the formation of these miliary aneurisms, and such degeneration might be present in youth as well as in the middle period of life. The more recent view explained many cases which heretofore had been looked upon as irregularities or anomalies. He also believed that further investigation would demonstrate that the symptoms now attributed to that great delusion known as *cerebral hyperæmia*, could be satisfactorily explained by the existence of the general degenerative changes which were accompanied by these lesions in the cerebral blood-vessels. He had been a strong supporter of the doctrine of cerebral localization, and was interested in the fact that the cases reported by Dr. Janeway showed that he also was favorable to the belief that a probable diagnosis of location of lesion could be made.

DR. J. C. DALTON thought that papers such as Dr. Janeway's, which told us something of the difficulties surrounding the subject of localization, were desirable just now, rather than cases which

point definitely to coincidences between the loss or disturbance of particular functions and the injury or destruction of particular parts of the brain. Cases of the latter variety were extremely satisfactory and entertaining in a great many ways. When he recollected the great anticipations which were offered at the time the doctrine of cerebral localization was first brought forward by Broca, afterward supported by the brilliant physiological experiments of Hitzig, and followed by remarkable pathological corroborations, as well as further evidence from physiologists, it seemed as though a new era had commenced in the study of the brain, and that ultimately the brain would be mapped out as definitely as it had already been done by the phrenologists for another purpose. For a number of years the anticipation seemed to be a just one, and success attended the labors of different observers. At the same time difficulties began to show themselves, and they were such as could not be ignored. Many cases had been collected from experimental physiologists and pathologists, in which particular portions of the brain had been found diseased or destroyed, corresponding precisely with the loss or disturbance of the functions over which these affected portions had been supposed to preside. There were also many cases, as doubtless pathologists would agree, of just the opposite character; cases in which symptoms pointed toward lesions in certain regions of the brain, but autopsy proved that they were not there but elsewhere, or perhaps absent entirely. He did not for a moment imagine that there was any contradiction between physiological and pathological facts; there were only difficulties, and these difficulties would, he had no doubt, be the source of more valuable and certain information when the subject was more fully understood. The first difficulty which presented itself to the experimental physiologist was the extraordinary fact that when a part of the motor tract of the brain was cut out, and muscular paralysis produced upon the opposite side of the body, the muscular paralysis was not permanent. The fact, of course, must be explained, and the question was, How shall it be accounted for? Many explanations had been offered, but perhaps the clumsiest of all was that other parts of the brain took the function; at least it was unsatisfactory. One of the most striking results of physiological experiment was the loss of vision following destruction of the gyrus angularis, but here also the loss was not permanent. The most ingenious explanation which had been offered was that by Munk, who said that after removal of the angular convolution the loss of vision that followed was only apparent; that the animal saw but did not understand; that finally it came to understand, and then gave evidence that it saw objects placed before the eye. Dr. Dalton thought that although the explanation was ingenious, it was somewhat in deep water. He then referred somewhat in detail to the experiments made by Goltz, and concluded that the book required a second reading, in order that the reader might be certain that he fully understood the author's conclusions, and also to convince himself that the author had always made correct conclusions from his own premises.

The discussion was continued by Dr. W. R. Birdsall, referring to two cases of tumor of the brain, which he believed sustained the doctrine of localization, and by Dr. H. Knapp, who was asked to speak particularly concerning optic-neuritis as an aid in diagnosis. He said that his knowledge of the subject was too fragmentary to warrant him entering into the general discussion. As to the value of optic neuritis as a guide in diagnosis of cerebral disease, his opinion concurred with a statement which Huguénin had made lately, namely, that disturbances of functions in the nerves of special sense do not assist us in cerebral localizations, as many morbid processes in different parts of the brain, for instance almost all tumors, cause a diffuse chronic inflammation at the base of the cranium, which is propagated to the nerves. Dr. Knapp remembered cases where under symptoms of cerebral irritation double optic neuritis was visible, with total blindness and deafness on both sides—the senses of smell and taste were not sufficiently examined—hearing was restored on both sides, but the vision only on one, although both optic disks, after the auroretinitis had passed, showed the same appearance of atrophy. These differences might possibly be accounted for by assuming different degrees of intensity in the inflammation of different nerves, perhaps also by the peculiar structure of the intraocular end of the optic nerve at the tamnia cribrosa, where, perhaps, a slight increase of pressure might produce a strangulation permanently deleterious to the nerve-fibres, where, by a little less pressure the strangulation might do only temporary injury.

The discussion was closed by Dr. Janeway, who referred to additional cases illustrative of points brought out by those who had spoken on the subject.

The Academy then adjourned.

NEW YORK SOCIETY OF GERMAN PHYSICIANS.

OBSCURE ABDOMINAL TUMOR.

Dr. Meyer exhibited a patient, aged fifty-five, and gave the following account of his case: Many years ago he had had intermittent fever. Two years since he had temporarily suffered from pains in the back. About six months ago he had a first attack of hæmaturia, and since then seven attacks of a similar kind. His weight had rapidly decreased fifty pounds.

The only physical sign of disease was a smooth, rounded mass projecting beneath the left hypochondriac region. The question was, did this correspond to an enlarged spleen or a tumor of the left kidney. He thought that it was most probably a primary malignant neoplasm of the kidney. In establishing a differential diagnosis in cases of this kind, it became important to determine the exact position of the descending colon. If the latter were found to overlie the tumor, splenic enlargement might be excluded.

Dr. Jacobi said that the growth, doubtless, involved the kidney, and was either a sarcoma or cancer, most probably the latter. The system seemed to be more tolerant of sarcoma than cancer, the former but rarely leading to hæmaturia. He did not consider the position of the descending colon a matter of practical importance, since it was commonly either adherent or compressed, and could scarcely be inflated.

TROPHO-NEUROSIS OF HAND.

Dr. Seessel exhibited a patient who had undergone an operation for fungoid disease of the metacarpus some eight months previously. When the incisions had healed, the muscles of the forearm became atrophied, the pharyngeal joints began to

swell and grow rigid, the finger-nails underwent discoloration, and fetid hyperedrosis, principally of the palm of the hand, was developed. These trophic disturbances were not to be regarded as of vaso-motor origin. Similar changes might be induced artificially. In this connection he referred to the following facts: 1, peripheral hyperæmia resulted from section of the sympathetic; 2, stimulation of this nerve, on the other hand, produced anæmia; 3, tropho-neurotic changes could be artificially produced by irritation of the sympathetic in fasting animals. Similar phenomena had long since been observed by oculists.

Dr. Knapp, referring to neuro-paralytic ophthalmia, remarked that it was not directly due to tissue metamorphosis, but resulted from irritation.

Dr. Gerster said that trophic disturbances had been repeatedly witnessed after exsection of the elbow-joint, leaving a powerless limb, which could not be restored to functional activity by the usual methods of massage and faradization. It was for this reason that König, of Göttingen, had in some such cases advised and practised amputation in place of exsection.

Dr. Rudisch had seen a large number of cases of muscular atrophy, of rheumatic or traumatic origin, at the German Dispensary. Active local treatment had very often resulted in complete restitution of function, or at least considerable improvement. In his opinion there was a local or peripheral, and not a central cause for the atrophy in such instances.

MYELOID SARCOMA OF HUMERUS.

Dr. Gerster presented a specimen of the above, with the following history: A young man sustained a fracture of the external condyles of the humerus. This he had treated by external applications without medical advice. After some time he noticed an articular swelling, and thereupon applied for treatment. A peculiar kind of crepitation was discovered, and floating bodies were presumed to exist in the joint. During the course of the operation the true nature of the disease was revealed, and the limb accordingly removed by amputation.

BURSAL CYST OVER THE TUBEROSITY OF THE ISCHIUM.

Dr. Gerster also presented a specimen of a cyst removed from the buttock of a man. The sac was about the size of a child's fist. It had started from an inflammatory proliferation of the bursa over the tuberosity of the ischium. Owing to the thick layer of subcutaneous fat in this region, the feeling conveyed by palpation of the tumor was that of a fibroma, or fibro-lipoma. The walls of the sac were of unusual thickness.

CYST OF THE PANCREAS.

Dr. Garrigues presented this specimen. (See Medical Record, March 18, 1882.)

Dr. Gerster remarked that he saw no reason why the tumor just presented should be regarded as a pancreatic cyst. It was probably an ovarian tumor, and the fact that the growth was found high up in the abdomen, did not militate against such a view. Since the pancreas was found entirely healthy, he could not understand why the tumor was to be regarded as one involving that organ.

Dr. Garrigues replied that he must maintain his opinion in regard to the pancreatic nature of the cyst. The latter had no connection with any other organ. He was not certain that the pancreas was quite healthy, because it had not been removed and was thus not examinable. In the cystic fluid he discovered filiform corpuscles, which he had never before seen elsewhere. And finally he had convinced himself that both uterus and ovaries were in all respects normal.

SIMPLE METHOD FOR THE DETERMINATION OF ATMOSPHERIC OXIDIZERS.

Dr. Caillé alluded to this method, which had been recently proposed by Dr. John Long, of Evanston, Ill., for the local registration of certain atmospheric conditions in all parts of the country. The practical point of hygiene involved in the matter was to be found in the relation which oxidizing agents bore to disease germs. In view of the modern tendency to ascribe pathogenic significance to various products of putrefaction and fermentation, it became important to determine just how they were affected by atmospheric ozone and similar gases, and in what quantities these gases existed. The word ozone, he explained, was here used in a collective sense for various oxidizing agents present in the air.

The presence or absence of these gases might be supposed to exercise an appreciable influence over the origin, spread, and termination of epidemics or endemics of infectious diseases. In regard to the method itself, it consisted merely in suspending strips of paper in the air, saturated with iodide of potassium and starch, guaiac extract, and oxide of thallium. The intensity of discoloration produced, by comparison with a previously prepared scale, would thus directly indicate the point to be ascertained.

INTRACRANIAL SARCOMA.

Dr. Gruening presented a specimen of spindle-celled sarcoma of the cranial cavity, accompanied by the following history: The patient was a young man, aged twenty-seven. He was admitted in June, 1881, to the Mt. Sinai Hospital, complaining of suddenly occurring headache, visual disturbances and vertigo, followed by an impairment of his memory. Optic neuritis was present, as well as partial aphasia, and paralysis of the abducens on the left side. The case progressed to complete blindness; hemiplegia of the left side was developed, and the patient died comatose.

At the autopsy a brain tumor, which had been supposed to exist during life, was found. The cerebral convolutions were much flattened. The dura mater was adherent at the base, and at one point there was erosion of the bone. The neoplasm itself occupied the left side. In its growth and development it had encroached mainly on the middle and lower lobes, the frontal lobes, and the region of the island of Reil. Microscopical analysis showed the growth to be a gliosarcoma.

Papylitis was found in both eyeballs, but the optic nerves were healthy, showing that the disease had not progressed from within. Various explanations had been offered to account for the occurrence of papylitis. Graefe had attributed the phenomenon in question to stasis in the retinal veins, resulting from pressure upon the sinus cavernosus. The transmission of such pressure, he supposed, took place through the superior ophthalmic vein. Dr. Gruening thought that, in view of the anastomosis existing between the latter vessel and the anterior facial vein, Graefe's theory could not be upheld.

According to Schwalbe, stasis occurred as the result of a communication existing between the sub-

arachnoid spaces, and the canal between the sheaths of the optic nerve. But in Gruening's case no fluid was found in this locality. Benedikt finally ascribed the papylitis to intracranial irritation, producing vaso-motor disturbances.

Dr. Rudisch remarked that the sudden occurrence of headache rendered the differential diagnosis between apoplexy and encephalitis, and cerebral tumor, quite difficult. He also laid stress on the power of the brain to acquire tolerance of slowly progressive pressure. In this connection he related a case of tumor of the brain, in which the patient had been able to perform her work a day before her death. Finally he said that disease of the terminal portion of a nerve was by no means rare; as instances of this kind he need only mention trismus, tetanus, and reflex paralysis.

Dr. Gruening replied that these diseases were in no sense analogous to papylitis. The terminal expansion of the optic nerve was the retina, which was found healthy in the case he had described.

SARCOMA OF BRAIN—DEATH FROM APOPLEXY.

Dr. Caillé presented a specimen of brain tumor, removed from the body of a woman aged thirty. The immediate cause of death was cerebral apoplexy. The woman had been ailing about eighteen months with symptoms of constant headache and vertigo, and frequent attacks of nausea. On examination she was found to have strabismus and diminished sensibility on the right side. There were also noticed the following signs: Unsteady gait, defective memory, partial aphasia, and voracious appetite, occasional rise of temperature and attacks of mania. The urine seemed normal. At times she would appear to be well, and cease to complain. Such intervals would last a week or ten days, to be followed by a return of her former troubles. Her death was sudden, almost unexpected. At the autopsy a large sarcoma was found in the left hemisphere. It occupied about the region of the corpus callosum, and extended from the corpus striatum into the inferior cornea. In the centre of this neoplasm a recent hemorrhagic clot about the size of an English walnut was discovered.

Dr. Tausky showed a uterine polypus which he had removed from the cervix, the operation being attended by profuse bleeding. In this connection he questioned the efficacy of the liquor ferri persulphatis as a hæmostatic.

Dr. Mundé said that the application of the iron compound was a safe procedure only when cervical hemorrhage called for interference. He believed it to be dangerous when used within the wound. For the latter purpose a mixture of equal parts of glycerine and liquor ferri seemed preferable.

REMOVAL OF CYST OF THE BROAD LIGAMENT.

Dr. Mundé presented a cyst of the broad ligament which he had removed from a woman twenty-two years of age. The patient had consulted him a short time ago with regard to a tumor in the abdomen. She had been married about a year and a half, and during the past year had noticed an increase in the size of the abdomen on the right side, which at the time he saw her had attained about the size proper to pregnancy at the seventh month. During the last three or four months her health had become impaired; she had grown thinner, and was decidedly anæmic in appearance. On external examination of the abdomen he found a uniformly fluctuating tumor, apparently a monocyst. The sound, passed into the uterus, revealed retroversion. The diagnosis of ovarian cyst was made, probably a monocyst. Aspiration was not resorted to, for the reason that in the only case in which he had made use of it inflammation was excited within the cyst, decomposition of its contents took place, peritonitis developed, and he was compelled to perform ovariotomy under very unfavorable circumstances, the result being death on the sixth day, from septic pyæmia. He had no reason to suppose the present case was one of cyst of the broad ligament, the patient's history, her anæmic condition, and the physical examination pointing to cyst of the ovary. It was true, it had been said that unilocular cysts of the ovary did not attain a size larger than an adult's head, but there were exceptions to this rule. Even had he known beforehand that the case was one of cyst of the parovarium, it was probable he would have operated, for the reason that, although a number were cured by tapping, an equal or larger number refilled, and finally required an operation for their removal.

On opening the abdominal cavity but one adhesion was found to the omentum, which was divided. The cyst was then punctured, and there flowed forth a clear, slightly bluish-colored fluid, which led him immediately to remark that it was, without doubt, a cyst of the broad ligament. After the cyst was emptied of its contents (about five quarts of fluid) the pedicle was sought for. The tumor was found to be firmly attached to the pelvic cavity on the right side, and could not be enucleated from its peritoneal envelope without undue force. It was therefore cut off, and the edges of the stump were united with those of the abdominal wound by silk sutures. A drainage-tube, consisting of the barrel of a hypodermic syringe, to which a piece of rubber tubing was attached, was introduced instead of the regular drainage-tube, which was found to be altogether too long. All antiseptic precautions were taken with the exception of the use of the spray. The patient rallied well; the temperature at no time rose above 101° F., nor the pulse above 96°. The stitches were removed between the tenth and the fourteenth days the patient left her bed on the sixteenth, and the private hospital, to go to her home, on the twenty-third day. Six weeks after the operation she had gained a great deal in weight, and the wound had entirely closed, except a very small opening, into which the smallest-sized drainage-tube was still introduced. The case was interesting principally with regard to the difficulty of diagnosis. Had tapping been resorted to it could not, according to the recent investigations of Dr. Garrigues, have led to a positive diagnosis between cyst of the ovary and of the broad ligament by a microscopical or chemical examination of the contained fluid. The only positive differential means—namely, the presence of the ovary by the side of the tumor—could not be appreciated in this case.

CERVICAL SPONDYLITIS.

Dr. Brandeis related the history of a supposed case of this kind. The patient was a young lady of seventeen, who had been under treatment for chronic otorrhœa. Pain in the throat was also complained of. Examination revealed a small elastic swelling behind the left palato-glossal arch. Peritonsillitis being suspected the swelling was punctured, which gave the patient some relief. Two days later a second puncture was made and a few drops of pus exuded. Pain in the left shoulder then set in, and pressure on the spinous process of the third cervical

vertebra produced very severe distress. The swelling had now attained considerable size, and upon being again punctured a large quantity of pus escaped. Two eminent physicians saw the patient in consultation. One gentleman pronounced the case to be one of spontaneous spondylitis associated with retropharyngeal abscess. The other, however, believed it to be an instance of hypostatic abscess originating in disease of the Eustachian tube.

DR. JACOBI said that an ordinary pharyngitis or tonsillitis might lead to superficial caries of the vertebral body. The prognosis in such cases was good.

DOUBTFUL CASE OF VARIOLOID.

Dr. Jacobi reported a case of this kind, in which he was unable to make a positive diagnosis during the first four days of the disease. A woman, fifty-five years of age, was admitted to Bellevue Hospital suffering from acute nephritis. After recovering from this attack, she was again taken sick with a chill; her body was profusely bathed in sweat and covered with a sudamina-like eruption, the face being free. Her temperature ranged from 101° to 105° F.; the urine contained albumen and renal elements. On the fourth day her face became covered with numerous pustules, not entirely characteristic in appearance, but sufficiently so to establish the diagnosis. Dr. Janeway had stated that similarly doubtful cases were not rare.

INTESTINAL OBSTRUCTION FROM FECAL IMPACTION.

DR. SCHWEDLER related the history of a man, aged sixty-three, whose death was due to intestinal obstruction. The patient was anæmic, and a sufferer from chronic constipation. It was his custom to take a saline aperient once a week. On February 6th he complained of pain in the abdomen. Absolute rest, and the administration of ice and morphine, gave him relief. Two days later he vomited several times, and developed collapse. He rallied again under appropriate treatment. An obstruction in the superior part of the small intestine was suspected, although nothing definite was detected on a careful examination. On February 11th he vomited fecal matter, and soon died. At the autopsy, the ileo-cæcal valve was found completely clogged up by numerous small lumps of hard fecal matter. The small intestine had a bluish-red color, the parietal peritoneum was of normal appearance, and the visceral peritoneum was found in a state of acute hyperæmia.

CHEAP BRANDY AND ABSINTHE are the cause of a large proportion of cases of insanity in parts of France. The United States Consul at La Rochelle, in his report on French brandies, points out the fact that no pure brandy is now made in Cognac and the district adjacent. He says that German alcohol distilled from potatoes is imported, doctored, and sold for brandy, and that the French artisans and peasants, who formerly used light wines, have of late years used much of this so-called brandy. He says: "Its characteristic effect is to produce an intoxication in which the patient is especially inclined to rage and physical violence, while hopeless insanity is the inevitable consequence of persisting in its use, even for a relatively short period of time." It is at least worth the physician's while to know that there is no such thing as pure cognac now.

FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Eleventh Annual Session, held at La Rochelle, August 24, 25, 26, 1882.

M. AZAM, OF BORDEAUX, PRESIDENT, IN THE CHAIR.

(Continued from page 417).

SECTION IN MEDICINE.

M. CARRET read a paper on the

ETIOLOGY OF GOITRE.

His view was that goitre only manifests itself along an isothermal line of a certain altitude. The primary cause he believed to be a *bacillus* living in the soil. This organism he had not yet discovered, however.

In the discussion, M. BOULOAK-BACHI cited some interesting facts, to show that drinking-water played a prominent part in the etiology of the disease in question. At Rheims the inhabitants used to get their drinking-water from wells; goitre was then frequent. Since aqueduct water had been introduced it had entirely disappeared.

M. DAGRÈVE described a peculiar tumor of the neck, frequent in singers, resembling goitre, but due to anæmia, and yielding readily to iron.

M. EDWARD LANDOWSKI read a paper on the

PROPHYLAXIS OF PHTHISIS,

in which he took the ground that that disease is contagious. He insisted upon the importance of early diagnosis and of isolation.

M. DE MUSGRAVE-CLAY also thought that phthisis should be regarded as contagious, and isolation attempted.

M. HENRI HENROT read a paper of much scientific importance upon

A CASE OF MYXŒDEMA.

A patient suffering from this disease died at the hospital in Rheims. Post-mortem examination showed profound and extensive lesions of the vegetative nervous system, hypertrophy of the pituitary body, of the renal gland, and of the sympathetic, both ganglia and their branches being greatly enlarged. There were bony scales upon the pia mater over the medulla. In other organs there were found many exostoses on the bones, hypertrophy of the liver and kidneys, and also of the submucous and subepithelial connective-tissue. On the other hand, there was atrophy of the heart and of the whole muscular system, and diminution in size, by almost one-half, of the blood-vessels. The autopsy, apparently, throws much light upon the nature of this curious disease. During life there were no visceral troubles, but a paresis of sensibility, general and special. The hypertrophies were due to an infiltration of cells in the interstices between the proper cells of the tissue. The atrophy was due to compression by growth of the connective-tissue. The inference from this case is that myxœdema is due to a disease of the sympathetic nervous system; also, that the renal gland and pituitary body are parts or appendices to this system. The fact that in fishes, which have much mucoid tissue, the pituitary body is quite large was introduced in further support of this view.

M. L. H. PETIT read a paper in which he tried to show that

HEMORRHAGIC SMALL-POX

was due generally to the fact that the patient, when attacked, already had some disease or degenerated tissue.

M. Nepveu defended the view that

RESECTIONS OF THE JOINTS FOR DISEASE

are generally useless, or worse; that though death may not result the cure is very imperfect. He instanced 60 cases of resection of the wrist, in which there were 3 deaths, while in 6 cases amputation was necessary; in 8 the functional result was bad, in 13 medium, and in 15 good. Among 6 cases of resection by Billroth, 5 died, phthisis supervening afterward. An exactly similar experience is related by Verneuil, who is now strongly opposed to resection.

M. Ollier, of Lyons, said that for five years he had held the same views as those of Nepveu. Since the introduction of antisepsis, however, he thought that the indications for resection for traumatism had diminished, while those for disease had increased. Resections should not be done, however, before the twelfth year, nor after the fortieth. The only point at issue practically, therefore, was whether resection should be performed in the scrofulous between the ages of twelve and forty years.

M. Lecler, of Romtlac, and M. Henrot, reported cases of spontaneous gangrene of the foot, cured by the thermo-cautery and antiseptic dressings.

M. Vovard, of Bordeaux, reported an almost uniform success in the treatment of

MENINGITIS IN CHILDREN,

by using iodide of potassium internally, and the application to the scalp of croton oil, mixed with a blistering cerate. M. Vovard did not clearly show that his cases were always meningitis, certainly not of a tuberculous nature.

M. Rigabert reported two cases of "Generalized Vaccine Eruption," and M. Monod described his "Treatment of Recto-vulvar and Recto-vaginal Fistulæ." This consisted essentially in first cutting entirely through the whole recto-vaginal partition; then performing perineorrhaphy.

M. Duplony reported his experience with the "Injection of Acetic Acid in Epitheliomata." He made his injections into the substance of the tumors and the surrounding zone.

M. H. Bernheim, Professor of Clinical Medicine at Nancy, described

A NEW FORM OF TYPHOID FEVER,

which he called the "cardiac form." It embraced that class of cases in which without appreciable cause there comes on a paralytic accession of the heart's rapidity ending in death. It may exist at the beginning of the disease, or may come on later, and may or may not be accompanied with other adynamic symptoms. Professor Bernheim thinks that this peculiar form of the fever is due to the direct action of the specific poison upon the cardiac centre. It acts like digitaline in toxic doses. This similarity explained why digitalis was not only useless, but even dangerous in typhoid fever.

M. Aubert, by tests with pilocarpin ointments, found that needle pricks through the skin remain open sufficiently to absorb pilocarpin for two or three days. His inference was that surgeons who had slight abrasions or pricks on their hands should bear in mind that substances can be absorbed through them for the time specified.

Buchanan, of bogus diploma memory, has finished his term of imprisonment and is abroad again.

Correspondence.

BRONCHITIS AND INTERPLEURAL PLASTIC EXUDATION.

To the Editor of The Medical Record.

Sir: Permit me to reply briefly to Dr. Robinson's letter in the last Record. Should we be checked in seeking after truth because Laennec gave the weight of a great name to certain views of the origin of râles, and teachers of physical diagnosis have adopted these views year after year?

Accurate as Laennec was as an interpreter of facts, he was still more accurate as a recorder, and his "talent and discrimination" in reporting cases "appear equally conspicuous." Now in all the cases except two reported in his works on the chest,[1] in which fine râles were heard ante-mortem, pleuritic adhesions were found post-mortem. These two exceptions are the following: At the lower part of the right lung behind, "there was a slight crepitous rattle," and on post-mortem examination "the lower lobe was indurated and posteriorly it was as hard as liver." (Case VII.) Therefore no air could enter the lung when the crepitous rattle was heard. The condition of the pleura is not mentioned, nor is it in most of his other cases, except where adhesions are recorded. In the second case, the day before death there was "crepitous rattle, barely perceptible at the inner edge of the scapula." On post-mortem examination "the indurated lobules formed slight prominences on the surface of the lungs." (Case IV.) No other mention is made of the condition of the pleura, but it is easy to conceive that a pleura studded with prominences could not be in a normal condition. The amount of plastic matter necessary to produce a "barely perceptible crepitous rattle" might easily, too, have been absorbed between the examination and death which occurred on the following day.

In every case recorded by Lorris in his work on phthisis,[2] in which fine râles were heard, pleuritic adhesions were found post-mortem.

Some experimenters have shown that by "injecting into the bronchia liquids of different density, râles are produced;" but others have shown that by throwing salt into the fire, or rolling a lock of hair between the fingers, crepitation is produced. Now facts such as these only prove that certain sounds are produced under certain conditions, and not that they are not produced under other conditions. Such evidence is only presumptive, but the following is, I think, conclusive:

In 1879 a commission was appointed by the United States Government, having for its object the "stamping out of contagious pleuro-pneumonia among cattle." In August of that year Dr. Leaming was invited to make examinations of some of these cattle, and his diagnoses were to be tested by post-mortem examinations performed immediately.[3] In every case where râles had been heard pleuritic exudation was found, and where pleuritic exudation was found there had been râles. In six of these cases one lung was completely consolidated, therefore no air could enter and no râles be pro-

[1] Translation of Laennec on the Chest by Dr. Forbes, 1850.

duced in them. In none of these cases was there "splenization" or "softening."[1]

I have not been able to find any carefully recorded cases of œdema of the lungs, in which an examination made a short time before death revealed crepitant and subcrepitant râles, which did not also show pleuritic adhesions post-mortem.

As to the differential signs of pleuritic and pulmonary râles having been given by most classical authors, I leave to others more learned than I am to decide. I have been led to believe that, until within a few years, all râles were supposed to be of interpulmonary origin, and such being the case, if most classical authors have given the differential signs of interpleuritic and interpulmonary râles, they have performed a remarkable feat.

Respectfully yours,

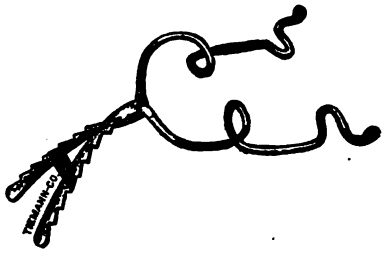
D. M. Cammann, B.A., M.D.

New York, October 9, 1882.

New Instruments.

THE SCHWATKA VARIABLE-TENSION EYE SPECULUM.

This speculum, the invention of Lieut. Schwatka, of the United States Army, and manufactured by Tiemann & Co., is well explained by the accompanying illustration.



The branches that pass under and clasp the eyelids can be of any of the various forms that may suit the ideas of different operators. It is in the lever branches that open and close the former that the essential novelty of the instrument is found. These levers are reflected back on to the same side as the branches they respectively operate, so that their closure opens the branches, and *vice versa*. They are serrated on their outer edges, which indentations are made to firmly receive a rubber band that is the power in opening the speculum, and which power may be made variable by simply slipping the band along the serrations according to the well-known principles of the lever. It is evident that more than one band can be used and increased power be obtained, but as now made, the single band at the end of the levers is sufficient to almost break the finest-made instruments when attempting to close the branches, and is therefore sufficient. The crowns of the teeth are somewhat rounded, making it easy to slip the round rubber band along them to any point, and even during an operation. That fineness of touch so common among oculists, acquired by the manipulation of such delicate instruments as are necessary in their profession, will here materially assist them in properly adjusting this instrument for any operation.

[1] Oral communication of Dr. Leaming.

The advantages claimed for this instrument are its simplicity, which is evident on a glance at the illustration, there being nothing of the instrument whatever in the way of the operator, since the levers are placed directly against the skin. The power is elastic, and as a consequence, the patient seldom complains of pain, as in the case of the positive motion speculums, especially at the inner canthus of the eye. It is more like that of a muscle overcoming another, and in minor operations, where the pain of the operation does not overcome that of the ordinary speculums, its benefits are marked. It might be well to add that this instrument has been placed in the hands of specialists and pronounced successful.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from September 30, 1882, *to October* 7, 1882.

Williams, John W., Major and Surgeon, now on leave of absence, to proceed to San Francisco, Cal., and report in person to the Commanding General, Military Division of the Pacific, for duty in Department of the Columbia. S. O. 228, A. G. O., September 30, 1882.

Waters, Wm. E., Major and Surgeon. To report in person to the Commanding General, Department of the East, for assignment to duty. S. O. 228, A. G. O., September 30, 1882.

Irwin, B. J. D., Major and Surgeon. On being relieved as Attending Surgeon, Headquarters Military Division of the Missouri, to proceed to Whipple Barracks, Arizona, and report in person for duty as Medical Director, Headquarters Department of Arizona. S. O. 228, A. G. O., September 30, 1882.

Forwood, Wm. H., Major and Surgeon. Relieved from duty in Department of the Platte, and to report in person to the Commanding General, Military Division of the Missouri, for duty as Attending Surgeon at those headquarters. S. O. 228, A. G. O., September 30, 1882.

Smith, Andrew K., Major and Surgeon. Relieved from duty in Department of Arizona, and on expiration of present sick leave to report by letter to the Surgeon-General. S. O. 228, A. G. O., September 30, 1882.

Burton, H. G., Captain and Assistant Surgeon. Granted leave of absence for four months. S. O. 229, A. G. O., October 2, 1882.

Loving, Leonard Y., Captain and Assistant Surgeon. To be relieved from duty in the Department of the Missouri, to report in person to the Commanding General, Department of the East, for assignment to duty. S. O. 228, A. G. O., September 30, 1882.

Turrill, Henry S., Captain and Assistant Surgeon. To be relieved from duty in Department of the East, and to report in person to the Commanding General, Department of the Platte, for assignment to duty. S. O. 228, A. G. O., September 30, 1882.

Moseley, E. B., Captain and Assistant Surgeon. To report in person to the Commanding General, Department of the East, for assignment to duty. S. O. 228, A. G. O., September 30, 1882.

Skinner, John D., Captain and Assistant Surgeon. To be relieved from duty in Department of Arizona, and to report in person to the Surgeon-General. S. O. 228, A. G. O., September 30, 1882.

POWELL, J. L., Assistant Surgeon. Relieved from duty at Fort Stockton, Tex., and to report at Headquarters Department of Texas, for temporary duty as Post Surgeon, San Antonio, Tex., and Attending Surgeon at Department Headquarters. S. O. 103, Department of Texas, September 30, 1882.

SHUFELDT, R. W., Captain and Assistant Surgeon. To proceed to Jackson Barracks, New Orleans, La., and report to the Commanding Officer thereat for duty. S. O. 93, Department of the South, September 26, 1882.

CARTER, W. F., Assistant Surgeon. Relieved from duty at Fort Concho, Texas, and to report to the Commanding Officer, Fort Stockton, Tex., for temporary duty as Post Surgeon. S. O. 103, Department of Texas, September 29, 1882.

OWEN, WM. O., JR., First Lieutenant and Assistant Surgeon. To proceed to Fort Townsend, W. T., and report to the Commanding Officer for temporary duty at that post. S. O. 138, Department of Columbia, September 22, 1882.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending October 7, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

DR. GEORGE M. STERNBERG, U. S. A., asks us to publish the following important corrections: Page 316, first column, forty-fifth line from top, for *less* read *more*. Same page, second column, third line from bottom, for 0.5 *per cent.* read 0.05 *per cent.* The same correction must be made in lines ten and nineteen from bottom, same page and column.

DR. MORELL MACKENZIE, the distinguished laryngologist, of London, has been visiting New York during the past week, and has been the recipient of many hospitalities from the leading men in the profession here. He also received similar attention in Philadelphia. At the latter place, Dr. J. Solis Cohen tendered him a brilliant reception on Tuesday evening, and in this city, on Thursday evening, a dinner was given in his honor at Delmonico's, by Professor George M. Lefferts, at which a large number of representative men were present. On Friday evening Dr. R. P. Lincoln tendered him a reception, and Professor Louis Elsberg, also of this city, gives a dinner to him this, Saturday, evening.

MR. HENRY C. BURDETT, of London, the author of "Cottage Hospitals" and other well-known works, sailed for his home on Saturday last.

RUPTURE OF THE STOMACH CAUSED BY LOBELIA.—A man of intemperate habits in England took a powder containing lobelia, capsicum, etc., by advice of an irregular practitioner. The patient died without vomiting. At the autopsy there was found a rent in the stomach, through which the contents had escaped into the peritoneal cavity. In a stomach weakened by disease, an emetic like lobelia may, therefore, produce a fatal rupture.

THE UNIVERSITY OF PRAGUE is no longer to be a German University. By Government vote the lectures will be delivered hereafter in the Czechic tongue. So says report. It is somewhat strange, however, if affairs are so bad, that a man like Gussembauer refuses to leave for a good position in Wurzberg. The lectures have, heretofore, been given in German and Czechic.

THE STATE OF MAINE affects medical Governors. It recently elected Dr. Frederick Robie to the gubernatorial chair. This gentleman has not, we understand, been engaged in practice of late years.

PROFESSOR DU BOIS REYMOND has been made Rector of the Friedrich-Wilhelms University, Berlin.

A WORD TO A YOUNG CONTEMPORARY.—Our esteemed and juvenile contemporary, the *Medical News*, of London, persists in copying from our item column without acknowledgment. We beg to say that this may be the English way, but it is not thought well of here.

A NEW MEDICAL WORK.—The Inner Life of Abram Lincoln. N. Y., 1883, etc.

SHOULD BABIES' MILK BE BOILED, asks the *College and Clinical Record*. Now this shows how much the subject of infant dietetics is being overstudied. We cling to the old-fashioned view, that babies should not be milked any way, much less have their milk boiled.

ASTRONOMICAL PATHOLOGY.—We would inform our correspondent, Dr. S——, regarding the new comet, now only fifteen million miles away, that the coma which affects it is not due to Bright's disease, nor has the New York Pathological Society arranged for the specimen.

TESTING THE ABSORBABILITY OF THE STOMACH.—Drs. F. Penzoldt and A. Faber, of Erlangen, have devised an ingenious way of testing the absorbability of the stomach. About three hours after a meal the patient is given gr. ijss. of potassium iodide in a thin gelatine capsule. This is swallowed with a certain definite amount of water. The gelatine capsule must be such as will dissolve in one to two minutes. The patient then, from minute to minute, spits upon a piece of paper, and a drop of fuming nitric acid is added. In the normal absorbability of the stomach a red coloring appears in from six and a half to eleven minutes, and a blue coloring in seven and a half to fifteen minutes. If the stomach does not absorb well, as in dilatation, the reaction is delayed sometimes from one-half to three-quarters of an hour.

THE TEMPERATURE OF THE STOMACH has been measured by Dr. Rodsajewsky in a case of artificial gastric fistula. It varies with the general body temperature, and with that of the ingested food. When digestion is going on the stomach temperature is lower than that of the rectum, and higher than that of the axilla. Hot food raises the stomach temperature, and also the general body temperature.

LUNACY IN ENGLAND.—The thirty-sixth report of the Commissioners in Lunacy states that the total number of lunatics, idiots, and persons of unsound mind in England and Wales, who were registered on

the 1st of January last, was 74,842, an increase upon the number recorded in the previous year of 1,729. These figures, as usual, do not include the lunatics (230 in number) residing in private houses under the personal supervision of their committees. The increase was almost entirely (1,717) among the pauper insane.

A Hint for the Treatment of Phthisis.—Mr. H. Osborn Bayfield suggests (*British Medical Journal*) that the use of inhalations of volatilized palm oil may be useful in the treatment of phthisis. He bases his opinion upon the fact that workmen engaged in tinning where palm oil is used as a flux inhale the volatilized oil and get fat. Those previously emaciated or weak rapidly improve. The idea is worth a trial.

Massage is very useful in joint diseases. That it has a notable mechanical effect here is shown by an experiment of Mosengeil's. He took rabbits and injected India ink into various joints. Some of the joints he massaged, others not. He then opened the injected joints. Those that had been rubbed were almost free from ink, which could be seen coloring the outgoing lymphatics for some distance. In the other joints the ink was found in abundance. Pure glycerine is recommended as an agent to be used in massage, rather than sweet oil, which soon gets rancid. As a rule, massage should be done twice daily for from five to twenty, or in chronic troubles, thirty minutes each time. After the rubbing it is sometimes well to lead the animal about quietly for five or ten minutes, then cover the parts with warm and moist applications.

Massage is one of those forms of treatment which will give good or no results, according as it is carefully and conscientiously used.—*Journal of Comparative Medicine.*

Notes in Comparative Pathology.—Some curious and interesting cases of diseases in various lower animals are reported in the *Journal of Comparative Medicine.* A Spitz bitch is described as suffering from an obstructed cervix uteri, with resulting hæmato-pyo-metra. Over twelve ounces of fluid were taken from the distended womb.

A llama at the Central Park Menagerie died from what might be termed galloping consumption. The superior (or anterior) lobes, as in man, were most affected. There was a fibrous tumor with a calcareous shell attached to the perineal muscles.

The eagles at the same institution are said to suffer from cystic tumors developing in the eyelids.

An iguana which kept company with a python was embraced with such excessive tenderness as to produce a bloody tumor in its left flank. The animal died from its effects.

The Cook County Hospital, at Chicago, Ill., has undergone a change of administration. At a meeting of the Board on September 3d, the whole medical and surgical staff was declared vacant and a new staff appointed, without reference to the wants of the medical colleges. It is expected that a chief medical officer with a salary will be put in charge. All this is said to be the result of politics. Between politics and homœopathy our Chicago brethren seem to have a hard time.

Trouble in the Medical College of Virginia.—Gov. Cameron a few days ago appointed a new Board of Visitors for the Medical College of Virginia, in Richmond, thereby summarily displacing the old board. This action created much excitement in medical circles, and was much criticised by the press and public. The old board, acting under legal advice, determined to hold on, claiming that the Governor, under the law, had no right to remove them; that he could only fill vacancies, and that no vacancies existed. The new board were refused admission to the Medical College by the old Faculty, which had taken possession.

An Insane Asylum Abolished.—The New Orleans City Insane Asylum has been abolished, and one hundred and thirty-five of its inmates, in charge of a large number of attendants, have been taken to the insane asylum at Jackson, La. This action is due largely, it is said, to the exposures of the ill-conduct of the institution, made by the novelist, Mr. George W. Cable, who has been a sort of American Charles Reade in the matter.

A Remedy for Corns.—Dr. Traill Green, in the Philadelphia *Reporter*, commends, from his experience, Mr. Gezou's remedy for corns. The formula is as follows: ℞. Salicylic acid, 30 parts; ext. cannabis indicæ, 5 parts; collodion, 240 parts. The remedy is applied with a camel's-hair brush. In four or five days the corn comes off, and the patient should then take a warm foot-bath. A second application may be needed.

A Conscientious Doctor.—The St. Louis *Courier of Medicine* publishes and the *Detroit Lancet* quotes the following anecdote of the late Dr. Geo. B. Winston, of St. Louis. We commend it as an illustration of the fact that there still exists a genuine nobility and heroism among medical men, though it is much the fashion just now to pooh-pooh those who hold such a view: "A friend once remarked to him, 'Doctor, what necessity is there for this ceaseless labor and study at your time of life?' With a look of astonishment, never to be forgotten, he replied: 'My dear sir, I am under bonds to do it. When I offered my professional services to this community, there was an implied covenant on my part that, so far as God gave me strength and ability, I would use them for gathering up and digesting all that has been said or written in regard to the diseases to which human flesh is heir, and if I should lose a patient because of my ignorance of the latest and best experience of others in the treatment of a given case, a just God would hold me responsible for the loss, through inexcusable ignorance, of a precious human life, and punish me accordingly; and whenever I get my consent to be content with present professional attainments and trust my own personal experience for success, I will withdraw from practice and step from under a weight of honorable obligations which, with my best endeavors to meet them honestly and conscientiously, still sometimes is almost heavier than I can bear.'"

The Last Thing in Incubation.—M. Tarnier, says *The Lancet*, the surgeon of the Maternity Hospital in Paris, struck by the great mortality among infants prematurely born and those which are very sickly after birth, has conceived the ingenious idea of constructing a box which is almost exactly similar to the incubators used for poultry. This box is divided into two compartments—the lower one being used as a reservoir for hot water, while the infant is placed in the upper one, which is well stuffed at the sides and fitted with a sliding glass cover. The temperature is maintained at 86 degrees Fahrenheit, and M. Tarnier has found that by keeping infants in the incubator for a period varying from

two days to six weeks their vitality is enormously improved. He has made experiments upon five six-months children, six seven-months, and thirteen eight-months children, and he has only lost two of them, whereas, according to his statement, three-fourths of them would have died but for this adventitious aid to vitality.

THE LATE DR. JAMES B. REYNOLDS.—*Whereas*, the Medical Board of the Nursery and Child's Hospital receive with deep sorrow the announcement of the death of Dr. James B. Reynolds, who for the past sixteen years has been a member of the attending staff of this institution, contributing so much to its welfare and success;

Resolved, That we, his former associates, desire to record our admiration for his manly qualities, and our warm appreciation of his faithful service and superior counsel so generously bestowed upon this and similar institutions. We would express our high regard for his learning and distinguished skill as a physician, and for his honorable and attractive personal characteristics.

Resolved, That we deeply deplore the loss to the community and to the profession of which he was an honored member; that we shall ever cherish the memory of our associate as an example of professional rectitude and private virtue worthy of imitation; and that we tender to his bereaved family our warmest sympathy in their great loss.

Resolved, That a copy of these resolutions be communicated to the family, and that they be published in the medical journals of this city.

J. J. HULL,
E. L. PARTRIDGE, } *Committee.*

COST OF BRITISH ARMY AND NAVY MEDICAL DEPARTMENT.—The salaries of the Directors-General of the British Army and Navy Medical Departments are put down at £1,500 and £1,300 per annum respectively. A Deputy Inspector-General in the Navy receives £720. The cost of naval medical establishments at home and abroad amounts to £63,445. The expense of carrying out the Contagious Diseases Act is £14,800 per annum, whereas in the army it is only £6,360.

LOCOMOTOR ATAXIA WITH WELL-MARKED TENDON-REFLEX.—Dr. James Leslie, of Hamilton, Canada, sends us an account of a case of locomotor ataxia in a shoemaker, aged forty-five years. The symptoms of inco-ordination without loss of muscular power were well marked. There were no lightning-like pains, however, and the tendon-reflex at the knee was very distinct. The patient had not had syphilis. He received the most benefit from daily forcible flexion of the thighs upon the abdomen.

A NIGHT MEDICAL SERVICE will be established in Brooklyn next January. A service has been established in Washington, D. C. In this city the night medical service has an average of one or two calls every night.

THE GARFIELD MEMORIAL HOSPITAL BOARD has received a deed of the valuable real estate of the National Soldiers' and Sailors' Orphans' Home. The Board will at once sell the land and purchase a site in the city for the proposed hospital.

SURGICAL OUTFITS FOR RAILWAYS.—The Pennsylvania Railroad Company has purchased two thousand tin boxes containing a few simple surgical materials likely to be used in case of accident. The boxes are kept on the locomotives. Each one contains 1 rubber compress, 1 package of absorbent cotton, 6 rolls of bandages, 1 pyramid of pins. This outfit must always be kept up, and when anything is needed requisition should be made at once.

With the box are the following simple directions: When an arm or leg is crushed, causing hemorrhage, pass compress around limb immediately below the injured part. In case of rupture, if a vein, tying it lightly until arrival of surgeon. The rupture of an artery can be distinguished by the color of the blood, which is red, and spurts out, while a vein has black blood and flows continuously. For wounds on the head or face apply absorbent cotton, and bind with a bandage. The company deserves great credit for the humanity and forethought shown in the adoption of this scheme.

THE SMALL-POX is making great ravages at Cape Town. There have been 2,000 cases thus far, mostly natives, of which 600 proved fatal. The disease has reached the military. Cape Town has been declared infected, and all vessels sailing thence for other ports in the colony will be quarantined. The greatest excitement prevails in the diamond fields.

DR. J. W. HOLLAND, who has for eighteen months edited with much ability and success the *Louisville Medical News*, has resigned. The *News* will now be conducted under the editorial care of Drs. L. P. Yandell and L. S. McMurtry.

THE YELLOW FEVER EPIDEMIC.—The yellow fever has almost disappeared from Brownsville, Texas, only 12 cases and 2 deaths being reported in the week ending October 7th. This makes a total of 1,912 cases and 109 deaths. The disease is now limited to a few mild cases inside Chi Arroyo cordon, but is reported to continue with great severity in the Mexican towns and ranches bordering on the Rio Grande. The infected districts are prevented from spreading the disease into Texas by a cordon of guards extending from Brownsville to Laredo.

Official reports by mail from Pensacola, Fla., have been received to include the 4th of October, 1882, as follows:

Date.	*Cases.*	*Deaths.*	*Date.*	*Cases.*	*Deaths.*
September 30	44	3	October 3	55	5
October 1	45	4	October 4	55	5
October 2	45	5			
Total				244	22
Previously reported				725	76
Total during epidemic				969	98

Later reports show that the fever continues without abatement. On October 9th, the forty-first day of the scourge, there were 48 new cases and 5 deaths, making a total of 1,300 cases and 112 deaths.

SEX AND RACE.—In most European nations the proportion of male births to female is as 105 to 100. Among the Jews, however, the proportion rises to 110 or 120 to 100. This is thought to be due to the fact that marriage is earlier among the Jews.

THIRTY-FIVE YOUNG DOCTORS have recently arrived in this city from Russia.

THE SANITARY COUNCIL OF THE MISSISSIPPI VALLEY will hold a special session on October 17th at Indianapolis, Ind.

FIRST RESECTION OF THE STOMACH IN AMERICA.—Dr. F. W. Koehler, of Louisville, performed resection of the stomach for cancer, September 2, 1882. We will give particulars in our next issue.

Original Lectures.

ON DIPHTHERIA AND PARALYSIS OF THE VOCAL CORDS.

By MORELL MACKENZIE, M.D.,
LONDON, ENGLAND.

I. DIPHTHERIA.[1]

Professor Bosworth introduced Dr. Mackenzie, who spoke as follows:

Gentlemen—When I found that Professor Bosworth had been kind enough to put my name down for a lecture, I hesitated about accepting the great honor he proposed to confer upon me, and for two reasons—first, I myself object to all lectures, with but few exceptions; and, second, on account of the subject which he had chosen for me.

For myself, and perhaps many of you think the same, I believe the days of lectures have gone by. Lectures were all very well in the middle ages, before works were written, or at least scattered very widely, and I still think they are well enough for clinical purposes, and also in cases where you have some instrument to describe, or some mode of investigation to exhibit, such as is seen in experimental physiology; but I believe students will learn much more from the studying of books than from listening to lectures.

I also hesitated on account of the subject which had been selected for me. It was not of my own choosing, and, as some of my friends present well know, it is impossible to do justice to it in the course of the comparatively few minutes which we can now occupy. However, without consuming your time with excuses, I will make a running commentary on the disease to be considered.

In the first place, I shall not trouble you with historical details to show that the disease existed in the earliest time. It will interest you, perhaps, to remark that the first accurate description of it was written by an American, Dr. Samuel Bard, of this city. Previously to that time, diphtheria had been described in a somewhat casual manner. As you may know, an accurate description of croup, which, after all, is a form of diphtheria, was written by Dr. Home and several English writers, but all these writers only took a local view of the disease; they did not understand the various intricacies of the complete disease. It was Dr. Samuel Bard who first pointed out that the epidemics of the middle ages and the disease described in Scotland as croup, and afterward described in Boston, were simply varieties of one disease known now as diphtheria.

Nor will I endeavor to give you a minute definition of the disease. I once tried to define it, and published my definition, and I thought it was a very good one until the reviewers said that it was not a definition at all, but merely a description, and since that I have not attempted to define it. It is sometimes considered to be an inflammatory disease of the mucous membrane of the throat, and there is a certain amount of inflammation produced by a definite cause; it generally occurs epidemically, sometimes endemically, and the great peculiarity of it is that there is a false membrane formed in the throat, and that false membrane is adherent. These are the general characteristics of the disease. Now we have to consider what is the specific nature of the disease. Here we meet with difficulties. Is it the result of certain germs, or is it not? One of the best writers on this subject, Professor Jacobi, who is with us to-day, does not, I think, believe in the germ theory. At least that was his opinion two years ago; but we change our views so often in these days that I should like to be informed if I am incorrect on this point. Many of you are well aware that certain minute bodies, generally round, and microscopic in size, are found in the false membrane of diphtheria. I myself was rather guarded in my book in giving my opinion upon this part of the subject. I did not like to express myself positively. I ventured, however, to say that if germs will not cause the disease, at any rate they have much to do with it, and if not actually the origin of the disease they carry it. That is my opinion still. I do not consider the question yet settled whether or not bacteria are the specific cause of the disease. Some interesting experiments have been performed by Professor Wood, of Philadelphia, the most important and conclusive, as it seems to me, ever performed in connection with diphtheria, and he has shown that bacteria are exceedingly abundant, increase in proportion with the violence of the disease, and are found in the blood in all cases of malignant diphtheria. By a series of most interesting experiments he demonstrated that these germs actually attack the white blood-corpuscles, and the disease seems to produce its main effect upon the constitution by this process of killing the blood at its very origin.

Well, gentlemen, my opinion is that these bacteria are most important, and Dr. Wood also has shown that they are present in every case of severe inflammation of the throat even, that is not diphtheritic in character. An important feature of his experiments was that bacteria abounded in proportion to the severity of the disease. He also showed that while fresh mucous membrane was capable of producing the disease by contiguity, when the action of the bacteria was destroyed—the bacteria were dried, so that they no longer had any activity—diphtheria no longer could be produced by infection or contagion. This is a very important point, but it does not settle the question completely, for the drying of the membrane may have destroyed some other element which produces the disease.

So we are in the position we were four years ago, and as Professor Jacobi has very properly said, the question is still *sub judice*. But I must say that it is of great importance to thoroughly determine, as far as possible, the truthfulness of this question, because, if germs have nothing to do with it, I should consider that the disease is less infectious than it is really.

Of course this question brings up the question of the identity of croup and diphtheria. Is croup a separate disease from diphtheria? That is an important point. I hold that the two diseases are quite identical. The chief reason why there is so great confusion concerning these two diseases is because the word croup has been applied in a vague way to different conditions. You all know that there are three kinds of croup: (1) diphtheritic croup; (2) catarrhal croup; and (3) nervous croup. I think that a term which can be applied so loosely is a rather unsatisfactory one to be used in medicine. I consider true croup, that is, the disease in which there is false membrane in the larynx, as really diphtheria. Then we have catarrhal croup, which is a slight inflammation of the lining membrane of the larynx. Besides, we have in young children a

[1] Delivered at the Bellevue Hospital Medical College, New York.

peculiar spasmodic affection which produces a peculiar crowing noise, technically called laryngismus stridulus, and is called nervous croup. All this has made great confusion, and I recommend to you to give up the word croup entirely. The term is used so vaguely that it only confuses. I believe, after all, that it is a mere theoretical distinction. We do not treat a disease according to its name; we study the symptoms and character of the attack, judge of the patient's whole appearance, and see whether he is vigorous or feeble, and then treat him accordingly, and not according to whether a disease is known by this term or that. It has always seemed to me that this discussion of the identity or non-identity of croup and diphtheria is very much like the discussion which once occurred as to how many angels could sit upon the point of a needle. The most violent controversy took place upon that question, and it was about as important as the question of the identity of croup and diphtheria.

We will now pass on to what is more important, and that is the

PROGNOSIS.

I leave out of our consideration the symptoms and the pathology, for either one of these is too extended to be considered at this time. These parts of the subject have been treated in detail in the text-books. As I wish to make the few remarks I offer as practical as possible, I will at once proceed to speak of prognosis, and one thing I wish to urge upon you is not to be guided by statistics. The fact is, according to the present system of getting evidence upon this point, we are not able to determine accurately what the rate of mortality is. We can only determine the actual number of fatal cases, and we do not know the number of slight cases. I have known of some of my friends saying that they had treated two hundred cases of diphtheria without a single death, but I have always thought that many of them could not have been cases of true diphtheria. Diphtheria is such a fatal disease that when a thick false membrane is deposited in the lower part of the pharynx, still more in the larynx, you must consider your patient as being in the greatest possible danger. It is one of the most fatal diseases you will have to deal with when you are asked to treat a case in which the false membrane is thickly deposited in the throat, and especially if it has extended into the larynx. Your prognosis, therefore, should be very guarded.

As a rule, the temperature is not very much raised in ordinary cases of diphtheria, not so much so as in some milder diseases, perhaps in a simple tonsillitis it may be higher, but in severe cases the temperature is often excessive, and this will point to an unfavorable prognosis. Or if in the beginning there is high temperature with great depression and disposition to vomit, you may give a very unfavorable prognosis. I think these conditions have not been sufficiently dwelt upon, and therefore I wish especially to impress them upon your minds at this time.

DIPHTHERIA A LOCAL DISEASE.

I think that, at the beginning, diphtheria is a local disease. This view was ably put forward by my friend Dr. Elsberg more than ten years ago. He showed in an article published in the *Medical Gazette*, that although the disease apparently was constitutional from the first, it was in almost all cases primarily local. That is the view I believe in. I believe that the effect of the poison may sometimes be so great that the disease appears to be constitutional from the commencement. I believe that such cases are analogous to those of scarlet fever or small-pox, where the patient is struck down at the very moment of the invasion of the disease. The poison must enter through some part of the system, and I believe that it is local at the beginning. These points bear upon prognosis, and are of great importance. From prognosis we will now pass to

TREATMENT.

Here, again, remedies of the most varied character possible have been recommended. I recollect reading a paper written by a French physician, in which he said he bled every patient, and that he had treated fifty or sixty, and every one recovered. All I can say is that if we should treat diphtheria in London in this way, I think we would almost be prosecuted. It is exceedingly bad treatment. It only shows that it is possible to make a bad diagnosis, or else it is possible for some people to stand depletion in a most extraordinary manner.

The first great point in the treatment of this disease is to attend to constitutional measures and then to local treatment. The constitutional treatment is of no less importance than the local. It is necessary to support the patient from the beginning, and stimulants are of the utmost importance. Do not wait until the patient becomes depressed, but give stimulants from the very commencement. This is an exception to all diseases, and you must begin with stimulants at the commencement, and give them in the more solid form, such as brandy diluted with water, or port wine; such as furnish nutriment as well as alcohol. When the patient is beginning to recover, the light wines, especially champagne, are useful; but, in the early stages, port wine with water is one of the most useful you can give.

Stimulants must be given during the night as well as during the day in a very large number of cases. I have seen many cases where patients have died through want of having stimulants administered during the night. In young children it is very frequently necessary to awaken the patient and give stimulants. As a general rule, it is bad to wake a patient out of a refreshing sleep to give medicines; but here is an exception, and I would say that if the child sleeps more than four hours, it must be awakened and stimulants and nourishment administered.

We now pass on from the use of stimulants to the use of medicines. Here, again, we meet with a very great variety, but the most useful, perhaps, of all is the perchloride of iron. In this matter I am entirely in accord with Professor Jacobi, who has found the remedy more useful than any other. Professor Jacobi has laid it down that this medicine should be given in full doses. It is also important to give a per salt of iron, which can be assimilated with comparative ease, and probably the perchloride is the best you can use, and of it at least a drachm a day, diluted with water, should be administered; fifteen drops, well diluted with water, four times a day. The only time when I have not given the perchloride of iron has been when I have been trying the local effects of some agent that has been employed. Quinine is a very useful medicine. When the temperature is high it has a very great effect in bringing it down nearly or quite to the normal.

These are, perhaps, the most important of the constitutional remedies.

All sorts of specifics have been recommended, but I have not had much success with them. Chlorate of potash has been very much praised both as a constitutional and a local medicine. You may give it, because it cannot, in proper doses, do much harm, and it may do some good. There is one remedy which has been recommended by a gentleman whom I see before me, Dr. Beverly Robinson, and that is copaiba, which has an important effect upon mucous membranes, as possibly some of you may have had occasion to observe. But its effects are not confined to the mucous membrane of the urethra. It also produces a marked effect upon the mucous membrane of the pharynx and larynx, and that of the whole bronchial tract. I have tried Dr. Robinson's recommendation, giving the medicine in the form of pearls, which the French make, and which children take very easily, and I have administered them with great success. But I must mention that I have used it in the catarrhal form of diphtheria—the milder cases, where the exudation is not very adhesive. When the more serious cases of diphtheria are about, you get a large number of cases of catarrhal diphtheria, and in those you will find great benefit following the administration of copaiba.

We will next pass to local remedies, and here again we have a very wide field. A great many doctors may go through a lifetime and see only a few cases of diphtheria. Some meet with severe epidemics, and others with epidemics mild in character. The consequence is that an immense number of remedies are not only recommended, but the doctors say that they have not lost a case since they began to use such and such remedies. You must look upon such statements with great suspicion, and it is safe to consider that the doctors who have treated so large a number of cases with such uniform success have, at least, treated a mild type of diphtheria.

The local remedies in most common vogue are lime-water and lactic acid. Both of these remedies have one great advantage; they do not do any harm. And here I may say, gentlemen, that it is a great thing, when you are trying a remedy, to use one that does no harm. In earlier days severe caustics were used, such as hydrochloric acid, nitrate of silver, and, if the patient recovered, it was always thought that event was due to the acid or the silver. But all that has been changed. We now know that if strong caustics are used the effect is almost always to cause extension of the disease. The remedy inflames and irritates, and a false membrane is formed in close contiguity to that which previously existed. When we were suddenly told by German physicians that lactic acid was used with great benefit, and also lime-water, the news was so gratifying that we all used these remedies, which were not injurious or painful to the patient. Both have been found useful.

I ought to say here that certain solutions have been said to be useful because of the effect they produce upon the false membrane, causing it to gradually dissolve and disappear in a short time. But, unfortunately, when we have to deal with the living subject we have a totally different condition of things from that which is present in making experiments, and I have found that when using substances locally sufficient to have any effect upon the false membrane, they had an irritating effect on the mucous membrane which I was treating. Hence I returned to the use of such remedies as do not irritate, and have given up those which had a reputation for dissolving false membrane. With regard to lactic acid and lime-water, they do not have much effect upon the false membrane in the test-tube, but they certainly do seem to have considerable effect when applied to false membrane growing upon mucous membrane. It is very difficult to make accurate observations with regard to the progress of the disease from hour to hour in children; but I have had opportunity to try both remedies upon false membrane inside of the lip and upon the tongue, where I could watch the effect. I recollect three cases in which I tried the experiment with lime-water where false membrane was growing upon the inside of the lip. I treated one side with lime-water and left the other to nature, and the side treated rapidly improved, while the other remained stationary. So I believe that lime-water is useful as a local application, and in this respect I differ with my friend Dr. Jacobi, who believes that both lactic acid and lime-water have been overestimated. I strongly recommend that you should use them in every case.

We now pass on to another class of remedies, which I wish to bring to your notice, namely, those which shut out the air. This class of remedies I have introduced, and they have been employed in England to some extent. I refer to what may be called varnishing the mucous membrane with benzoin, or tolu dissolved in ether or chloroform or alcohol, and also used in various mixtures. I found as the result of considerable experiment that tolu dissolved in ether, in the proportion of 1 to 5, made an excellent varnish, and that when applied to the mucous membrane it did not cause pain or inconvenience, was sufficiently strong to hold, and did not require to be repeated. Many of these local remedies have been recommended on the ground that they destroy germs. Just here it occurs to me that I have omitted to speak of carbolic acid and salicylic acid, etc. Carbolic acid is an excellent remedy, and it has the effect, as has been demonstrated, of destroying germs, and if used sufficiently diluted it will do no harm.

All this class of remedies have been recommended upon the scientific ground that they destroy germs.

The principle upon which I have introduced the remedies which varnish the mucous membrane is, that whatever the poisonous element may be, whether a vegetable growth or some other germ, or something else, this living matter that causes false membrane to be formed, requires the presence of air. Directly you exclude the air you prevent the growth of germs which require air for their existence. As soon as possible, therefore, I apply this varnish over the false membrane; not only over the false membrane, but all around it. It is of itself to a certain extent a germ destroyer, but everything depends upon the coating of varnish being air-tight. Some of my friends, at first, found considerable difficulty in applying it, and I also had the same experience. At first I wiped the surface, to which it was to be applied, with blotting-paper. I carefully applied this absorbing material to different parts of the throat, and then immediately afterward applied this varnish. This plan answers perfectly well when you can do it; but every now and then you will find a patient who will retch a little just after the blotting-paper has touched the surface, and the mucous membrane becomes wet before you can apply the varnish. I then adopted the plan of putting a piece of lint around my finger and drying the throat with

this, and then quickly applying the varnish with a brush. This does not hurt the child, and I speak of children because nine-tenths of our cases occur among children, and it answers perfectly well; but if you should have difficulty with this, I should advise you to apply the varnish all the same. I have had several patients treated entirely by the use of the varnish, without constitutional remedies, and with good results.

I shall feel exceedingly proud if, as the result of this lecture, gentlemen shall try the effect of this varnish.

I will now say a few words with reference to the use of steam and the use of ice. Both these remedies are useful, but they should be applied in different classes of cases. In the early stages it is very useful to employ ice. It affords the greatest comfort to the patient. Let them have ice, and take as much as possible. Many young children are pleased to have pieces of ice put into their mouths. There is no doubt that it restricts the associated inflammation so often present. In the early stages it is most desirable to use ice, and you can use any amount of it without doing harm. It is only in exceptional cases, where the patient is very much depressed, and in the very advanced degrees of poisoning, where there is gangrene, that ice does harm. In many cases it diminishes the violence of the attack.

With reference to steam, it was first recommended, I think, by Mr. Prosser James, of London. Afterward it was pointed out by Oertel that steam must cure almost every case, and that it was the only remedy of any value at all, because the effect is to separate the false membrane from the mucous membrane. The fact is that when a certain point in the disease has been reached, when the false membrane is beginning to separate, steam is useful. At that time its effect is admirable. In the early stages I do not think it does any good. I think it lowers the vitality of the tissues, and that its effect is most prejudicial; but when the false membrane shows evidences of separating from the mucous membrane its effect is most beneficial. So you need have no fear of clashing heat and cold, for you use ice at first and steam afterward, when the disease has reached a certain stage. One great advantage of steam is that you can use some antiseptic with it, such as carbolic acid, salicylic acid, or any other substance you may choose. And I should advise you to use some mild antiseptic at this stage of the disease, because a certain amount of gangrene is usually present.

TRACHEOTOMY.

These, gentlemen, are the important points which I have to bring before you, and in closing I will make a few remarks only with regard to tracheotomy. The question often arises whether or not you will perform tracheotomy. I may say here that my friend J. Solis Cohen, of Philadelphia, who is with us to-day, has published one of the most complete essays on tracheotomy ever published in the English language. I think the conclusion which may be drawn from his paper is that the operation should be performed at a comparatively early stage. That is the conviction which I have. My advice is that when once there is considerable false membrane in the larynx, when inspiration is so difficult that you see falling in of the sternum each time the patient breathes, and each supra-clavicular space deepened with every inspiration, the time has arrived for tracheotomy. But you will examine the whole of the patient's thorax, and most carefully the posterior part of the chest, to see if air enters both lungs. If you find one lung seriously obstructed, I myself should advise against tracheotomy. If you find that air does not enter the lung beyond the bifurcation of the bronchus, tracheotomy will be useless. Still there are cases in which we have everything to hope if a cure can be effected. But at the same time we should consider the interests of surgery, and when I say the interests of surgery I mean the interests of the entire public, as well as those of the surgeon. If we perform the operation in a case almost entirely hopeless, we have to consider the effect produced upon the feelings of friends when a similar operation is to be performed in a similar case. The point which I wish to insist upon is, that if you perform tracheotomy you should do it directly it becomes necessary. You must not wait until the case becomes hopeless. If you do this, you will find that a large number of cases which appear hopeless will terminate in recovery. On the other hand, if you perform tracheotomy too early, you will perform it in a large number of cases which will recover without it. I think the very favorable statistics with regard to the operation, especially those furnished us from Parisian hospitals, are partly the result of the operation being performed where it should not have been performed; that is, in cases of catarrhal laryngitis, slight cases of diphtheria. In this manner you can get the most favorable statistics, but it is not a fair procedure to perform tracheotomy before there are distinct signs of laryngeal dyspnœa.

Now, gentlemen, if you observe the directions which I have recommended, I do not think you will cure all cases of diphtheria, but I think you will meet with a certain amount of success, and I also think that you will be able to rescue many patients from imminent death.

II. PARALYSIS OF THE MUSCLES OF THE LARYNX.[1]

Professor Lefferts introduced Dr. Mackenzie, who spoke as follows:

Gentlemen—I thank you for the kind reception you have given me, and am very grateful to Professor Lefferts for the opportunity of addressing so many students who are preparing for future work in laryngology. I cannot help being struck with the immense progress which has been made in this department in America, and I feel sure that you are getting ahead of us in England when I see the great number of workers and the excellent work they are doing.

Professor Lefferts, when he invited me to address you, gave me the privilege of speaking on whatever subject I might choose, and I have selected one that is regarded by many as among the most difficult in laryngology, namely, *paralysis of the muscles of the larynx*. This is a subject which can be made exceedingly complicated, and it is one which can be made exceedingly simple. A most excellent paper has been written recently by Professor Lefferts, in which he has given a system of classification that he calls excessively simple. I can only say with reference to it that it is an exceedingly difficult one. I may be allowed to say this because I am in the position of a minister who goes into his pulpit with the assurance that at present there is no one to reply. In

[1] Abstract of a lecture delivered at the College of Physicians and Surgeons, New York.

the meantime, in his excellent system he has endeavored to distinguish between every form of paralysis which may affect the human larynx. I can only say that the system reminds me of the old and somewhat primitive method of catching birds. It is beautiful and clear, but it is so difficult of application that the bird must first be caught and the salt used afterward. He claims for it that it will be the classification of the future, and so it may be, like Wagner's music, not at present fully appreciated.

Another system has been introduced by my friend Professor Elsberg, who is with us to-day. I will not say so much against his classification, because I am not occupying his chair, and can only say that I advise you not to look at it. It provides for every contingency, and Dr. Elsberg has taken into consideration every affection of the larynx. Perhaps in the remote future you may take pleasure in investigating his system.

There is another gentleman who has written upon this subject, Dr. ——. I can only say that he has introduced a system which I brought forward some fifteen years ago, most of which I have abandoned. He has written a very nice paper supporting me entirely, and it is unnecessary, therefore, for me to make any adverse criticism of his writing.

Now, having disposed of the classifications worthy of mention, I wish to direct your attention especially to *three* important functions of the muscles of the larynx.

The *first* of these, and the most important, is to guard the entrance to the larynx.

The *second* function is that of producing the ordinary voice. Of course, articulation is effected by the tongue and lips.

The *third* function is vocalization in its higher sense, perhaps not higher, as in singing, a most useful and important function.

To recapitulate, there are these three important functions of the muscles of the larynx: (1) To guard the entrance to the larynx; (2) to produce the ordinary speaking voice; and (3) to produce the singing voice.

Some of my friends will be astonished, no doubt, because I am so particular in making these divisions; but I do so for the reason that I do not wish to trouble you very much with the singing voice, for it is, after all, of only secondary importance.

What I wish to bring especially to your notice are the functions of guarding the orifice of the larynx, and thus protecting the life of the patient, and the function of producing the ordinary voice.

When a patient is brought to you supposed to have paralysis of the larynx, you are at once to consider whether he has paralysis interfering with life, or whether it is simply a question of affection of the voice. Of course the two may be combined; but the question is, What form of paralysis is this patient suffering from? If the patient has difficulty of breathing, you examine his larynx, and find that one or both vocal cords are not drawn aside in inspiration.

Many of you will recognize what the difficulty with the patient is as he enters your consulting-room. The patient who has his vocal cords paralyzed in such a manner that they are not drawn backward in inspiration, will have this peculiar difficulty of breathing. This is the most important form of paralysis with which we have to deal, and it s produced by paralysis of the posterior crico-arytenoidean muscles, or, as I have ventured to call them, the abductors of the vocal cords, because they draw the vocal cords apart in inspiration. When a patient has paralysis of these muscles, he has considerable dyspnœa. It is a curious fact that these muscles may be completely paralyzed, and when the patient is very quiet he breathes quite easily, so much so that you may think there is nothing the matter with him; but if he walks into the room you at once see that he has slight *stridor*, and cannot breathe without making a noise in inspiration. Another marked peculiarity is that when he is asleep he makes a great noise in breathing.

This form is called paralysis of the abductors of the vocal cords, and when you look into the larynx you will see a narrow chink between the vocal cords. It may look so narrow as to prevent the insertion of any substance of the thickness of an ordinary visiting card, perhaps a little wider, and it may be a little wider still.

What I have particularly to urge upon you is, that it is the most important form of paralysis with which you will have to deal. Directly upon seeing a patient in this condition tracheotomy should be performed. Patients have come to me with this form of paralysis. I have advised them to have tracheotomy performed at once, but they have gone away without it, and have died suddenly as a direct result of this condition.

On the other hand, I had tracheotomy performed upon one of my patients nearly twenty years ago. It was among the first cases recognized, and the patient is still living and wearing the tracheotomy tube.

If the paralysis is slight, you may try some other treatment, such as the use of the iodide of potassium or galvanism; but, as a rule, you must not waste time by useless treatment, and should put the patient in a condition of safety by tracheotomy. Of course this does not cure, but it is a palliative measure which preserves life indefinitely.

Now, briefly with regard to the cause of this condition. This is exceedingly difficult to determine. It may be, or it may not be, that both muscles are paralyzed. Where both muscles are affected, the condition may be produced by lesion in the brain. For example, a small clot in the fourth ventricle, injuring some of the nuclei of the pneumogastric nerve, may be followed by this form of paralysis. In that way the affection may be of central origin. Or both branches of the pneumogastric may be injured by pressure upon the neck; this is rare. It may be due to some disease of the œsophagus pressing upon both recurrent laryngeal nerves, or to some disease outside of the œsophagus producing the same effect. In the same manner, it may be caused by an enlarged thyroid gland.

I think I have now given all the conditions which may give rise to paralysis of the abductors of the vocal cords. But I must tell you that there are cases, not frequent, in which there is no apparent external cause. There are cases of myopathic origin —that is, the muscles are primarily implicated, and atrophy, the same as occurs in other parts of the body. We feel convinced that there are certain cases which originate in the muscles themselves.

I have now told you that in most cases you can determine what the cause is, and you know what the treatment is; but there are cases in which we do not know what the cause is, and until we can determine the cause we shall not be able to apply Professor Lefferts' excellent classification.

Affection of one of these muscles is less important.

It generally occurs upon the left side, and usually depends upon some disease of the aorta, such as an enlargement pressing upon the left recurrent laryngeal nerve. This is probably true in six out of ten cases, and in this way we are able to make a diagnosis in cases in which it has been overlooked by the general practitioner.

I pass now from paralysis of the abductors to *paralysis of the adductors of the vocal cords.* Paralysis of the abductors causes difficulty of inspiration; paralysis of the adductors causes loss of voice. If a patient comes to me—generally a young, hysterical woman, not always hysterical, however—complaining that she cannot speak loud, and has not done so for two or three years, I always suspect this condition. It is a curious thing to notice that if you can get such a patient to cough she will make a noise, and she will sneeze naturally, and all this she will admit. Her friends will usually say that she laughs out loud, occasionally at least, and then you will know at once that it is a case of nervous paralysis of the adductors, and that the reflex functions are properly performed. Perhaps the patient is somewhat anæmic, and as you look into the throat you may see a slight amount of congestion of the fauces; but being of a nervous temperament, she does not like to part with her aphonia, and keeps it because she regards it as a part of herself.

These cases are exceedingly easy of cure. Almost any shock will cure them. I recollect a case which I think I published many years ago in my book. A lady who had not spoken loud for many years was sitting by a window in Vienna, when, as she chanced to look at a house on the opposite side of the street, she saw a baby fall from the third or fourth story window, whereupon she gave a tremendous scream, and was at once cured. Of course it is not necessary to drop a baby out of a window every time you wish to restore the voice in these patients, but you can do it very well by applying electricity to the vocal cords. A good shock will almost always restore the voice, and if it does not restore it you may be quite certain that there is something else the matter. If you once begin with the use of electricity, never leave the patient until she speaks. You must make the current stronger and stronger until your purpose is accomplished. It may seem brutal, but never let them go until they speak.

Some of these patients lose their voice a second time, but you may be sure that if they return they never like to have the second application made quite so strong as was the first. They will say that they 'think a little weaker application will answer this time." You do not always cure these patients the first time, but it is a great point to impress upon them, not only that you have restored their voice, but that when they lose it again it can be restored. It is also very desirable to have some friend present when you restore the voice. I never restore the voice in one of these cases unless some friend is present as a witness that the voice has been restored. The object of this precaution is easy to understand.

If you do not have the convenience for applying electricity, you can use nitrate of silver, the effect of which is to cause temporary spasm. In the same way any other strong remedy which you may choose may be applied. Another plan recommended is to administer chloroform, but this is a rather dangerous method. Sometimes, however, it is not a bad measure, and the plan is to gradually put the patient into a semi-unconscious state, when she will probably speak as well as ever, and then allow her to become conscious gradually, when she discovers that she is speaking loud, and is satisfied that she has regained her voice. I hope, gentlemen, that I have succeeded in making myself understood in these few remarks to which you have listened so attentively. What I wished to bring out particularly was the two important forms of paralysis of the muscles of the larynx; that which threatens life, and that which threatens the voice. At some future time you may have opportunity to study the paralysis which threatens singing, or affects the tension of the vocal cords. When the cords are very much affected in this manner, it is seldom that you can do much good by treatment. If these muscles, the thyro-arytenoidean, are out of order, the only important thing to do is to put them at rest. I usually, however, in addition, give some mild remedies and soothing inhalations.

Original Communications.

ON CULTIVATION AS A TEST FOR MICROCOCCI.

By D. E. SALMON, D.V.M.,

ASHEVILLE, N. C.

The article of Dr. Rollin R. Gregg, on page 202 of the current volume of The Medical Record, contains a number of statements which I, as one of the humbler believers of the germ theory, cannot allow to pass uncontested. With the relation of the micrococci found, or supposed to have been found, in various parts of the body in cases of diphtheria, to the essential cause of this disease, I shall have nothing to say, since no one recognizes more clearly than myself the necessity for more extended and more satisfactory investigation of this question. To throw doubt upon our ability to recognize micrococci and other forms of bacteria by suitable cultivation, however, is a blow so plainly aimed at the most important results of all the recent researches into the nature of disease-germs, that it cannot be considered otherwise than as a direct challenge to those who have been engaged in such investigations to defend the tests which they have employed. Being, though unnamed, one of the fortunate or unfortunate few who have given practical attention to this subject, and who believe that they have isolated and cultivated disease germs, and that these, in certain cases, were micrococci, I accept that part of this challenge relating to the test by cultivation. And I do this, not because I think Dr. Sternberg unequal to the emergency, but in the hope that he will treat the question from a somewhat different standpoint—at all events, the number of investigators in this department is not so great but that all can be heard to advantage on a contested point of such importance.

In his rather remarkable article, considering the present position of science, Dr. Gregg says: "Of that 'most reliable test,' as 'conceded by all authorities,' namely, the 'cultivation' of micrococci 'in a sterilized liquid,' there is also something to be said. Here, too, we find the source of a great error, if I mistake not, when applied to diphtheria, and all for the want of proper discrimination at the outset. The sterilized liquid is broth made from the meat of a healthy animal, and heated to the boiling-point,

or beyond, to destroy the germs of vegetable-cells that may have found admission into it. This broth holds in solution more or less of the fibrin that was contained in the juices and blood remaining in the meat after being dressed for cooking. And it is this fibrin in the broth, coagulated into granules by the process called 'cultivation,' and it is these granules of fibrin thus coagulated that are held up to us as the most reliable test to prove the existence of micrococci or bacteria in the blood and in the exudations of diphtheria."

To demonstrate this emphatic assertion, the very questionable axiom is laid down that "*Everything in nature begets its kind.*" Is it possible? Do the lifeless things in nature beget their kind? Does oxygen beget oxygen? does beefsteak beget beefsteak? or does gold beget gold? Well, no; not exactly. If they did, many of us would be better supplied with certain useful commodities than we are at present. But it would seem that we are expected to accept this "axiom" in a qualified sense, for he goes on to say that "many things which cannot beget their kind nevertheless induce their kind."

I beg the reader to be very careful in applying such "axioms" to the solution of contested questions, otherwise they will lead him into the wrong way, and, before he is aware of his mistake, down he goes into a pitfall. We will willingly admit that everything that can beget at all begets its kind; in other words, living things beget their kind; but when it is attempted to apply this principle to the inanimate things in nature, I challenge the assertion at once, and demand the most convincing proof in every case to which it is applied.

We have not far to go for an example. "The least particle of the coagulum of sour milk, for instance," says Dr. Gregg, "added to fresh, sweet milk, begins at once the work that soon leads to the coagulation of that. The particle of the coagulum introduced does not in and of itself grow, or multiply indefinitely, but simply induces the change in the corresponding element, casein, of the fresh milk that originally led to its own coagulation." Now, I might, with very good reason, retort in Dr. Gregg's own words, and ask "What kind of science is this?" but being generously inclined, I shall proceed in a methodical manner to show why it is impossible for us at the present day to accept such a view of this very common phenomenon. As Carpenter's "Physiology" is quoted very freely in the article we are considering, I hope our friend will not object to this authority on certain other questions. Referring to the ninth edition (1881), page 971, we find the following: "If it [milk] be kept long enough, a spontaneous change takes place in its composition; the milk, sugar, or lactose is converted into lactic acid by a process of fermentation induced by a small particular ferment, the bacterium lactis, and this coagulates the casein, precipitating it in small flakes."

If I am not mistaken this changes the aspect of the question somewhat. The coagulum is not induced by a previous bit of coagulum, but it is produced by the action of lactic acid, which in turn is produced during the multiplication of a particular bacterium; and when a particle of this coagulum is added to sweet milk, such coagulum *per se* has no effect whatever, but it carries with it a specific bacterium which multiplies, and during such multiplication produces lactic acid, which again coagulates the casein. This illustration, then, does not support the argument for which it was intended, viz.: that a particle of fibrin introduced into our sterilized cultivation-liquid would induce the coagulation of the fibrin in that broth into granules.

"That such are the facts," however, "in regard to coagulated particles of fibrin inducing other fibrin held in solution in any fluid to also coagulate" is shown by a quotation from Carpenter which states that "just as crystals will form around a nucleus of the same kind from a solution that *would not otherwise have deposited them*, so will a fibrinous coagulum often separate from a serous fluid and form around a piece of washed clot of blood, or of the buffy coat, or of muscles or some other animal tissue placed in it, although the fluid (such as that of hydrocele), *would not have otherwise shown any disposition to coagulate.*" Then follows a quotation from Virchow, which, as it only shows that coagulation may occur very slowly, we will pass over for the present, in order to connect the final illustration with the one just quoted. It is a quotation from Carpenter, to show "the power of diseased or dead animal matter to compel the coagulation of fibrin even in the living body." It is the now well-known experiment of M. Dupuy, which by the injection of cerebral substance into the veins of an animal occasions death almost as instantaneously as if prussic acid had been administered, the circulation being rapidly brought to a stand by the formation of voluminous clots in the heart and large vessels.

"The foregoing," says Dr. Gregg, "would seem to be sufficient to settle the questions of the cultivation of the assumed micrococci in animal broth, and reproducing them within the animal system by inoculation with diphtheritic blood or membrane." There is only the question of fission to be explained and this is easily disposed of: it is only fission in appearance, and is in reality the union of two or more granules of fibrin in the first phase of the formation of a fibril.

The whole argument, then, rests upon the power of fibrin to induce the coagulation of other fibrin in solution, as apparently shown by the experiments referred to above. But science is advancing; phenomena which were imperfectly understood a few years ago are plain enough now, and inferences accepted then will hardly do to try our most important investigations by to-day. We will pause, therefore, to inquire what science says at *present* as to the cause of the coagulation of the fibrin in cases like those we have been considering.

The great question is, Does the coagulation of the fibrin in hydrocele liquids and in the blood occur by and because of the direct influence of the fibrin which has been added, or is it independent of this and the result of the action of something added in these particular cases *with* the fibrin? This is a very important question for our purpose, and one which we should not have expected a scientific gentleman of Dr. Gregg's standing, one completely "familiar with the literature of the subject," to have overlooked. And yet, when we come to examine into the matter, we find that modern scientists (what unsatisfactory fellows they are, to be sure!) have reached the conclusion that the coagulation is caused by a substance, called by them fibrin-ferment, which is liberated by the disintegration of colorless corpuscles of the blood, the cells of the cerebral substance, and to a less extent by the cells of other tissues; that there is no real fibrin in these liquids, but a substance called fibrinogen, which is changed by the so-called ferment into fibrin, and this, not being soluble, of course coagulates. (See last edi-

tion of Carpenter, also Gamgee's excellent recent work on "The Physiological Chemistry of the Animal Body.")

In hydrocele and pleuritic liquids there is frequently none of the fibrin-ferment, and hence there is no coagulation; in other cases, as in the observation quoted from Virchow, there is but a small proportion of ferment, and for that reason the fibrinogen is but slowly changed into fibrin, and the coagulation may go on for days or weeks. And here is a point which I hope will be carefully noted by the reader, as it bears directly on the subject in hand. The fibrin ferment, like other formless ferments, is incapable of reproduction, it cannot even "induce its kind," and therefore, to form a given amount of fibrin in a given time, it must be present in a certain definite proportion; if it exists in a smaller proportion, the coagulation necessarily occurs more slowly, until, when reduced to a sufficient extent, its action must entirely stop.

Having gone somewhat hastily over these general principles, to give the reader the benefit of the latest scientific investigations and conclusions on phenomena so important to this inquiry, I will now attempt to apply them to the practical work of testing the vitality and nature of granules found in the body, by the process of cultivation. And I wish it distinctly understood that I am referring to a certain definite method of cultivation—not the cultivation in a drop or two of liquid on a slide, but in tubes or flasks containing two or more drachms and capable of complete sterilization and indefinite preservation; nor of the cultivation in agneous or vitreous humor or other normal animal liquids, but in broth which has been heated to the boiling-point and filtered to perfect transparency.

Suppose, now, we wish to test the vitality of certain granules or rods which we have discovered in the blood by microscopic investigation. We take, say, a fifth of a drop of such blood, with suitable precautions to prevent contamination with atmospheric germs, and transfer it to a cultivation flask containing, say, half an ounce of sterilized broth which has been in the incubator a week or more, to prove that it has been sterilized. We place this in the incubator at the temperature of the animal body, and in about twenty-four hours we see that a remarkable change has occurred in its appearance. The liquid is no longer limpid, but has become opalescent; there is no precipitation of coagulated matter at the bottom, but there is a milkiness evenly diffused throughout. We place a drop under the microscope and, behold! our granules or rods are found to have multiplied enormously. The liquid swarms with them. If the operation has been properly performed we have a pure cultivation; that is, we do not have all the forms of bacteria or fibrin, but we have either all rods or all granules as the case may be; and if we preserve the cultivation indefinitely, though the micrococci may be aggregated into clusters and chains, they will never form rods (or fibrils).

There is, then, an important difference in the actual facts and the theory of Dr. Gregg as to what ought to occur. Instead of the forms appearing invariably as granules, and the granules aggregating themselves into rods, and the rods twisting themselves into spirals, as must necessarily occur if his theory were correct, we find with certain diseases the first form is a rod, and this rod, instead of forming a spiral, increases in length and produces spores, but does not break up into granules by fission, as would occur in the disintegration of a fibril of fibrin. In other diseases, the first and only form is a micrococcus which, though it forms chains and clusters, never produces rods or spirals. Now, how explain this difference? If we have been simply producing a coagulation of fibrin in our cultivations, the forms assumed by this fibrin, since they occur under the same conditions, should be identical in every disease. The production of coagulated fibrin, as we have seen, is the result of certain chemical and physical influences, and such influences exerted in liquids of the same composition, at the same temperature and during the same length of time, must produce substantially the same result in all cases.

Let us suppose, however, in order to dispose of other objections, that in adding the particle of blood we have added sufficient fibrin-ferment to produce enough fibrin in twenty-four hours to render our liquid opalescent. To determine if this opalescence is due to bacteria or coagulated fibrin, we take, say, one-fifth of a drop and place it into a new apparatus charged with half an ounce of a similar liquid. Now, if we consider a half ounce to contain four hundred drops, each drop in our first apparatus must contain one two-thousandth part of the fibrin-ferment in a drop of the original blood; while in our second apparatus, each drop contains but one four-millionth part of the ferment in a drop of the original blood. It is, therefore, very plain, from the laws governing the action of these ferments, that if twenty-four hours were required to produce opalescence in the first case, a much longer time would be necessary in the second; while if we carry the cultivation to the third or fourth, we should fail entirely to produce any effect because of the extreme dilution of the agent causing the coagulation.

With bacteria, now, the very opposite is the case. Our broth seems more favorable to the reproduction of these organisms than the blood, and, consequently, every drop contains a much greater number. Our second cultivation-liquid usually becomes opalescent even sooner than the first, and our third certainly as soon as the second. We are not confined to the quantities of liquid I have mentioned, however, nor to so restricted a number of cultivations; we can as easily produce a quart of virus at a time, and we can carry it through a hundred cultivations.

Having gone through all this long statement of facts to show how completely Dr. Gregg is at fault in his assertions, we may now ask what is the actual result in practice of adding a drop of blood free from bacteria to the liquid in one of our cultivation-tubes? If either the fibrin of the blood or the fibrin ferment can induce a coagulation producing anything like the opalescence of bacteria it certainly is an easy matter to establish this fact. Having again and again taken my own blood, and that from healthy and sick animals which contained no germs, and cultivated it in exactly the same manner as that containing the pathogenic bacteria, I feel secure in asserting that there is scarcely a possibility for any one of experience to mistake the results, even with the microscope left out of the question. Where there are no bacteria, there is a small amount of coarsely granular or flaky matter, which settles to the bottom of the tube and never produces that diffused opalescence which is constant in the early stages of bacteria cultivations. This precipitate exists in little if any greater amount than would be formed by the quantity of blood added, and cannot

be compared to that formed in a coagulating liquid containing much fibrinous matter in solution.

Again, it is pertinent to the question to ask how is it possible for a broth, which has been heated for a considerable time to the boiling-point, to contain either soluble fibrin or fibrinogen? Solutions of fibrin in the neutral salts coagulate at 65° C., while fibrinogen coagulates at an even lower temperature. Our sterilized liquid is then in all probability free from either fibrin or fibrin-forming substances, and, if so, it would be impossible for granules of fibrin to form in the way supposed by Dr. Gregg.

It must be admitted, however, that a precipitate can be formed in such cultivation-liquids under certain conditions; thus, the addition of solutions of acetate of lead, iodine, or glyceroborate of soda may produce a marked turbidity. With the latter agent, especially, one can imitate so closely the appearance of a micrococcus cultivation that when examined, either with the naked eye or the highest powers of the microscope, the most practised observer, if not actually deceived would at least be very doubtful in regard to the nature of the granules which he sees. But is this any evidence that we cannot learn the nature of these granules by attempting a cultivation of them? Dr. Gregg would say that if we place a drop of this liquid in a new apparatus, the granules which it contains will induce the formation of similar granules in the fresh liquid until it becomes turbid in turn. On the other hand, I have attempted to show that these granules have not the power to produce any such effect. The issue between us is perfectly plain and simple—we have appealed to science, now let us appeal to experiment.

Since reading Dr. Gregg's assertion that the formation of granules might be induced in this way, I have made a considerable number of experiments to test the hypothesis; but in no case have I been able to produce any turbidity of my cultivation-liquids by adding granules which had been formed in similar liquids in various ways, even though allowed to remain in the incubator for several times the usual period.

While, therefore, I shall not attempt, in this communication, to say that this or that series of investigations are reliable, or that any disease is or is not caused by certain forms of bacteria, I do assert most emphatically that by a proper method of cultivation the experienced investigator can determine with certainty whether the granules or rods which he sees in pathological liquids are living bacteria capable of reproduction, or whether they are lifeless particles.

If I have discussed this subject at greater length than may seem necessary to some, it is because I cannot willingly permit the dissemination of doubt in regard to a method of investigation so generally relied upon, and which has been the means of accomplishing so much. The gentlemen who have been so flippantly charged with neglecting the commonest precautions for the avoidance of error in their special field of research are the foremost scientists and investigators of the age. Who, for example, has done as much as Pasteur to dispel the mystery that has so completely enveloped the contagious diseases through the whole history of medicine? And who has done more to inspire the hope that, by patient investigation, the medical profession will one day be able not only to control but to exterminate them? Such a man is not above criticism, but it is going too far to charge him with either the most inexcusable carelessness or the grossest ignorance, unless there is a better foundation for such charges than has so far been developed.

In concluding, I beg leave to assure the reader that the "so-called science of bacteria" is not "erected upon an entire misconception and wrong interpretation of a very simple question in pathology," nor is it yet "the most remarkable and the greatest pathological error of modern times." The germ theory has come to stay, and the results to which it is leading will be the crowning glory of a century remarkable for the number and magnitude of its scientific conquests.

HYSTERIA IN THE MALE SUBJECT.

By ANSON P. SMITH, M.D.,

SANDY HOOK, CONN.

Hysterical phenomena are confined almost entirely to females. Some medical authorities have even denied its existence in other than the female sex. Hippocrates believed that the source of hysteria lay in the uterus and its appendages, and many physicians of our own day, such as Landouzy, Monneret, Villermay, and others, share his opinion. John Hughes Bennett defines hysteria as "any kind of perverted nervous function connected with uterine derangement." Numerous writers admit that it may sometimes be manifested in men, but only in weakly and feminine subjects, and then to a lesser degree. Thus Rosenthal says: "We must admit that moral causes which may often lead to hysteria in the female, may also produce the same disease in *delicately constituted* members of the male sex." He takes up the opinion which has obtained with a few others, namely, that hysteria sometimes remains unrecognized in males, many cases of the disease being diagnosticated as hypochondria. I think they are seldom, if ever, confounded. Hypochondria is a mental aberration; it has a different cause and history. We know it to be often dependent on disordered digestion, and we know also that it is a disease connected with the brain. It is characterized by illusions of the senses and morbid feelings, which may simulate any disease, hysteria no more frequently than any other. Who would look at a case of hysteria, with its muscular spasm, terrific convulsions, coma, anæsthesia, hyperæsthesia, mania, paralysis, and train of minor symptoms, and call it hypochondria? Bennett makes a strong differential diagnosis, and denies their similarity. Bright considers that one-fourth of all females are affected with hysteria, and one-half show some signs of it. Among one thousand cases he noticed fifty males. This is a larger proportion than any other author allows, as far as I have observed. Watson says: "Hysteria is almost exclusively confined to women in its paroxysmal form." Cullen wrote, nearly a century ago: "Hysteria sometimes, though rarely, attacks the male sex, never, that I have observed, in the same exquisite degree." I have questioned numerous physicians, who never saw a case in the male. I might go on and quote numberless authorities, all to the same effect as the few I have noted, but this is not a compilation, but simply the notes of a case which has interested all who have seen it as well as myself.

The patient is J—— C——, of Irish parentage, born in the United States, aged twenty-two; height, 5 ft. 3 in.; weight, 168 pounds; very stout, robust,

and healthy-looking. Is of active disposition, and very jovial, laughing, and good-humored. Occupation was freight-handling. Often worked at shovelling coal, and would do a large amount of work without suffering any physical inconvenience. Was noted for feats of strength, as in lifting heavy weights, etc. Was temperate in his habits, and very industrious. Family history good. Father, killed by boiler explosion, was very healthy. Mother living, health good. One brother, who has always been well and strong. No nervous symptoms in any branch of family, and no history of syphilis.

Patient has enjoyed excellent health until within a few months. About one year ago, while standing on the brakeman's platform near the top of the freight car he fell backward suddenly to the ground, striking upon his head. Was rendered insensible, but soon regained consciousness and went to work. Does not know what made him fall as he did not slip or stumble. Thinks he grew dizzy and then lost himself. No injury was perceptible, and no trouble of any kind resulted. About four months ago he had an attack of rheumatism. Think it was not inflammatory, as he says he had no redness or swelling of joints. Did not see him at the time. He recovered entirely in about five weeks and went to work as usual. No cardiac murmur or disturbance in circulation left after disease. Patient enjoyed his usual health for three or four months.

September 6th.—I was called to his boarding-place and was told by his friends that he had been having fits, which seemed to be fainting or sinking turns. Learned that he had been on an excursion in a steamer the day previous. He had acted strangely and became unconscious at times. Had also been violent and made an attempt to throw himself overboard. His companions thought he had been drinking, but patient denied having drank to any excess, and said he felt badly before he started away. Said his head felt very bad all day and the night before. Had several of the fits after reaching home. Slept through the night and had another of the attacks in the morning. I found patient sitting up; looked rather pale and anxious. Was not low-spirited but joked about his condition, although he talked coolly and sensibly. Complained of a severe pain in the top of his head and a numbness in his left arm and leg. Pulse 68, intermittent, temperature normal, bowels had been regular and digestion perfect. Pupils were normal and active. Found muscular power equal on both sides. Pinched the skin on his left hand, and, to my surprise, found he could feel nothing. I then took a needle and thrust it into the skin at various points, and found an entire loss of sensation at the left of median line. This was sharply defined, even to the tongue. Patient was not conscious of having any paroxysms except as informed by his friends. He simply "felt a dizziness and then something shut down over his eyes."

Gait staggering; could only walk by holding something to steady himself. When walking he would plunge forward, and on standing still would tend to fall backward. Mind clear at all times. My diagnosis was given rather guardedly, but I told him that he had some form of epilepsy, or else a tumor growing in the brain. Prescribed potass. brom. in 40 gr. doses every four hours, and a pill of ferri strych. and quinine.

September 7th.—Found his condition much the same.

September 8th.—Pain somewhat less, and convulsions less frequent. Condition gradually improved until September 12th, when I met him on the street. Said he felt nearly as well as ever.

I was called in the evening of the same day, but being out did not see him until morning. Found him in much the same condition as at first. Pain in head worse, more discouraged about his condition, and power of co-ordination less. Learned that he had been around town all the day before, sitting most of the time, talking with his friends at stores, hotels, etc. On reaching home complained of feeling tired, and soon after went off into a succession of his old attacks. Denied having drank any kind of stimulant, which statement was verified by his brother, who went to the different saloons and inquired if any had been sold him. Ordered doses of bromide to be given every two or three hours till attacks grew less frequent, and added small doses of morphia to relieve pain.

Saw patient twice daily until September 18th, at which time I called Dr. Robert Hubbard, of Bridgeport, in consultation. While examining patient, he was observed to fix his eyes and fall suddenly backward on the sofa where he had been sitting. Muscles became rigid, so that no amount of force could flex arm or leg. Was entirely insensible to pain. Occasionally gave a deep sighing respiration. Eyes closed; no opisthotonos. Body was raised once almost to a sitting posture by involuntary muscular contraction. Otherwise complete tonic spasm. No outcry at beginning of attack; no frothing at the mouth. Spasm lasted nearly five minutes, when muscles began to relax; eyes opened and patient rose up suddenly, and asked why his mother was holding him, and what we were all around him for. No disposition to sleep manifested. Dr. Hubbard, after carefully considering the facts in the case, gave it as his opinion that the patient was suffering from Jacksonian epilepsy. He had had a somewhat similar case in his practice, in which the same diagnosis had been made, and which Professor Hammond, with whom he consulted, had sustained.

In the present case, owing to hearty appearance of patient, lack of any emotional tendencies, imaginative disposition, or any of the characteristics which might be supposed to obtain in a case of hysteria, combined with his good common sense, which enabled him to discuss his condition and chances of recovery coolly and intelligently, hysteria was at once dismissed from the mind as being a probable cause of his trouble. In the form of epilepsy described by Dr. Hughlings Jackson, we have the petit mal with paralytic manifestations.

Todd describes it (the paralysis) as partly motor, partly sentient, and partly sensorial, with lasting paralysis after epileptic convulsions. He says: "We can assume no epilepsy proper but the convulsions are the symptomatic expression of a cerebral lesion. Usually there are tumors, embolisms, or hemorrhages in the artery of the fossa of Sylvius." Reynolds treats of the disease in Ziemssen at some length. I quote: "The presumption is, that with the severe spasm there is palsy. In many cases the palsy is trifling, such as numbness." He thinks the cause of fits is in the abnormal condition of gray matter.

September 19th.—Dr. J. O. Tousley, of the Manhattan Eye and Ear Infirmary, made an ophthalmoscopic examination of patient. Found a slight hyperæmia of disc on right side, left being normal. Dr. Webster afterward examined patient with same result.

September 20th.—At solicitation of patient and his friends I procured his admission into the Manhattan Hospital, under charge of Professor E. C. Seguin. It being the day on which Dr. Seguin held his clinic I accompanied patient to the city. He was seen by several physicians at the hospital before the arrival of Dr. Seguin, and the general opinion given was that he had a cerebral tumor which caused the epileptiform convulsions. Dr. Seguin, on his arrival, made a careful examination of patient after obtaining his history. Finding him unable to stand alone, he directed him to look at the wall over his head. While his eyes were fixed there he stood perfectly still. After noting this significant fact, the Professor tested the sensation thoroughly, and found hemianæsthesia complete. Thrust the needle of his instrument deeply into the tissues, drawing blood each time, without causing the slightest pain. Taking two twenty-dollar gold pieces from his pocket, Dr. Seguin pressed them firmly on the back of patient's hand within a half inch of one another. After holding them in position for three or four minutes he removed them and pressed the needle into the skin where the gold had been applied. Patient winced and withdrew his hand. Same experiments tried on different parts of arm with same results.

One coin was held on the tongue for a few minutes, and sensation found to be restored upon its removal. Dr. Seguin, after concluding his examination, pronounced the disease hysteria, and mentioned sexual excess as being the probable cause. Ordered ferri strych., and twenty grains of quinine per day, also the application of gold plates and the electric wire brush to anæsthetic side of body. Patient remained in hospital three days, when he walked out early in the morning and came home. Saw him September 24th. Pain almost entirely gone; could walk perfectly well. Sensation was restored; had no seizure since his departure from home; has steadily improved, and at present date, October 7th, is apparently in perfect health and at work.

This manifestation of hysteria is described by Dr. W. J. Morton in THE RECORD of October 2, 1880, as seen by him in the wards of the great Salpêtrière at Paris, of course in female subjects only. I refer more particularly to the symptom of hemianæsthesia and its treatment by use of metals, magnets, diapason, and static electricity, as adopted by Professor Charcot. No attempt has been made, as far as I can determine, to account for the curious influence exerted by contact of metals upon an anæsthetic surface. Dr. Seguin declares that it is not a moral effect, as he has often made the trial when the patient was unconscious of his designs and produced the same return of sensation. It cannot be the result of galvanic action, as one plate alone applied to a dry surface is followed by the same result. In reference to etiology of case in question, I would say that patient denied any abuse of sexual function. If we may believe him, why may not his disease be attributed to the effects of malarial poison? This disease takes all forms in this section of the country, where it is rife, and as quinine seemed to control the spasm at once in this case, why may not this be another instance where the drug, by its prompt action where other medicines have failed, makes the diagnosis for us?

THE FLUID EXTRACT OF TOMATO is recommended in nursing sore mouth and cancrum oris.

CASES OF CARDIAC, PULMONARY, AND AORTIC THROMBOSIS OCCURRING IN THE STATE ASYLUM, MORRIS PLAINS, N. J.

BY T. M. LLOYD, M.D.,

MORRIS PLAINS, N. J.

CASE I.—*Subacute mania—Pneumonia—Cardiac and pulmonary thrombosis.*—W. S. H——, male, aged sixty-three, admitted November 11, 1881, a very raw, cold day. Patient much exposed during journey.

November 3d.—Pneumonia both lungs; respiration rapid; pulse frequent.

November 4th.—Stimulants given through the night; respiration less frequent; pulse very intermittent and irregular.

November 5th.—Whiskey and carbonate of ammonia given freely with milk; pulse rapid, but less intermittent and irregular.

November 6th.—Took stimulants and milk very well through the night; at 7 A.M. partially unconscious and unable to swallow; pulse very weak, rapid, and intermittent; unconsciousness continued until death, at 1.10 P.M.

Autopsy, nineteen hours after death. Lower lobe of right and upper lobe of left lung hepatized; other lobes much congested. Heart: a white, tenacious, fibrinous clot was found extending from right ventricle into pulmonary artery and some of its branches. Pulmonary portion cylindrical, and about one-half the diameter of vessel. No coagula in left cavities. Calcareous deposit on one of the aortic semilunar valves. Blood very dark.

CASE II.—*Acute mania—Cardiac and pulmonary thrombosis.*—Z. O——, male, aged fifty-eight, admitted May 19, 1882. First symptoms noticed three days before; unusual silence, quickly succeeded by great restlessness and want of sleep; soon became very boisterous. Cathartic given; free action yesterday. Slept two hours last night.

May 20th.—Chloral hydrat., gr. x.; ext. hyos., fl. ℥xx.; morph. sulph., gr. ⅛, at bedtime, and repeated once during night; no sleep; very maniacal. 10.45 A.M.—Hypodermic injection morph. sulph., gr. ⅛; repeated at 11.10; fifteen minutes' sleep between 12 and 1 o'clock. 2.40 P.M.—Pulse, 156, noisy and restless; hyp. morph. sulph., gr. ⅛; twenty minutes later pulse 150. 4 P.M.—Asleep; pulse 118; respirations 13, and irregular; one deep inspiration, followed by three or four superficial ones. Respiration peculiar while patient was awake, but his extreme maniacal state made definite observation impossible. Slept one hour and a half, very much disturbed; ext. hyos., fl. ℥xx. 7.30 P.M.—Asleep; pulse, 140; respiration, 14. 10.15 P.M.—Asleep; pulse, 138; respiration, 18, with quick, sudden, rather superficial inspiratory act, but equal in duration and unvarying in character.

May 21st.—Slept most of the night. 5.45 A.M.—Respiration more frequent, but of same general character. Died suddenly at 6 A.M.

Post-mortem examination three hours later. Heart: right auricle much dilated; walls thin. A white, tough clot found clinging closely to tricuspid valve and wall of right ventricle. A cylindrical clot, same character, about one-half diameter of vessel, in pulmonary artery, with two large branches eight to ten inches long. Vessels on surface much congested. Valves normal.

CASE III.—*Paralytic dementia—Chronic suppura-*

tive pericarditis—Cardiac and pulmonary thrombosis.—C. P——, mariner, aged sixty-two, admitted June 3, 1882. History very imperfect. Right hemiplegia for over three years and cough for some time. Attempted to jump out of high window three days before admission. Two days in bed; appetite poor; restless at night. Brought forty miles by rail and stage; walked upstairs with assistance on entering building. Very weak; complains of pain in cardiac region; pulse rapid, feeble, irregular, and intermittent; respiration labored. Put in bed at once; stimulants administered.

June 4th.—Very feeble; taking nourishment and stimulants; condition unimproved.

June 5th.—Died at 5 A.M.

Post-mortem examination, five hours later. Pericardial sac greatly distended with thin, purulent fluid, containing numerous white, flaky particles floating through it. Surface of heart closely covered with granulations, in places aggregated into raspberry-like elevations. White, fibrinous clots in right cavities of heart, and cylindrical clot, same character, about one-half diameter of vessel, in pulmonary artery, and prolonged into several of its branches. Smaller branches of more recent coagulation.

CASE IV.—*Acute mania—Cardiac thrombosis.*—C. E. P——, male, aged thirty-two, admitted August 1, 1882. On Saturday, three days ago, went to circus; afterward lectured on religion on the street; next day climbed into a church steeple because St. Peter and God had told him to ring the bell; made extreme exertion, was taken down with difficulty. Has eaten nothing for two days, talks incessantly and incoherently. Placed in bed, liquid food, stimulants and hypnotics administered per œsophageal tube. During two days following admission vomited several times a very dark, thin fluid, resembling coffee-grounds, but afterward retained everything administered. Had good action of bowels; slept fairly well; talked constantly when awake, but made little muscular exertion.

August 7th, 8 A.M.—Has great pallor of skin; pulse very small and frequent, but regular. Whiskey and ammonia were increased, but condition was not improved during day.

August 8th, 7 A.M.—Pulse scarcely perceptible at radial and temporal arteries. Died at 12.30 P.M.

Post-mortem.—Large, white, fibrinous clots closely adherent to walls of both cavities of right side of heart. Size of heart and valves normal. Lungs blanched and exsanguine.

CASE V.—*Chronic mania, with increased maniacal excitement—Pulmonary thrombosis.*—W. A——, male, aged thirty-five, admitted July 14, 1882. Insane for ten years, more disturbed for a fortnight.

August 18th.—Had severe maniacal attack, succeeded by a week of tranquillity and much mental appreciation. Another exacerbation, more marked than before, very restless, and more continuously excited. Conduct evidently influenced by delusions, but expresses few of them; asserts that he is dead; at times becomes suddenly violent toward others. Recently he made a sudden spring and butted his head with great force against the wall. Temperature is increased, face dusky, pulse quick, small, and frequent. Heart clot suspected, placed in bed, liberal and frequent doses of carbonate of ammonia ordered.

August 21st.—Has continued very restless, failing in strength. Pulse, same general character. Had short syncopal attack this afternoon. Pulse at temple almost imperceptible during the evening; still able to swallow.

August 22d.—Died at 8.15 A.M.

Post-mortem.—Heart: right auricle dilated, recent coagulum in right ventricle; a small quantity of dark, thin blood in left auricle, left ventricle strongly contracted, valves normal; a markedly fibrinous clot *filled* the pulmonary artery, extending from heart to lobes of right lung. The distal ends were of more recent formation.

CASE VI.—*Chronic mania—Cardiac hypertrophy—Aortic thrombosis.*—J. McC——, mariner, aged forty-eight, admitted December 30, 1880; duration of disease and history unknown. Had hypertrophy of heart; pulse large and full, carotid and temporal pulsations visible; respiration embarrassed. Occasional excitement strongly affected the circulation and made heart's action and respiration very labored. Was not violent, and never made much muscular exertion. In December, 1881, became very feeble, and remained in bed four weeks; capillary circulation much impaired, and marked tendency to bedsores. Rallied, and was about the ward daily until August 19, 1882. Condition of mind much demented.

September 1st.—In bed and failing in strength since last date; unable to take food this morning; afterward became unconscious. Temperature high, perspiration profuse, pulse feeble and very rapid.

September 2d.—Unconsciousness, with symptoms noted above, continued until death at 9 P.M.

Post-mortem examination, eleven hours later.—Heart: left ventricle greatly hypertrophied; gelatinous clot filled right auricle, a smaller clot of same character in right ventricle. The aorta, which was exceedingly dilated, had marked concretions above semilunar valves, and contained a white, fibrinous cylindrical clot, one-fourth of an inch in diameter and nine inches long, with branches extending into right subclavian and right common carotid arteries.

These imperfectly reported cases are offered to call attention to a mode, if not often a direct cause, of death in diseases of the brain. We believe that central thrombosis, as a *cause* of death, especially in acute mania, is not sufficiently recognized. These cases occurring in our practice within a year indicate that this accident or condition cannot be very rare. Cases I., II., IV., and V. exhibit central thrombosis complicating acute disease. Cases III. and VI. exhibit the same in chronic disease.

We believe that in Cases V. and VI. the clots in the pulmonary artery and aorta, respectively, were formed where found, and that the initial point of coagulation must have been very near the heart. In the former, the clot entirely filled the vessel at its beginning, and was most highly organized in that portion; the distal branches were most recently formed. There was no clot of corresponding character in the right cavities of heart. In the latter, the diameter of the clot was small compared with the dilated vessel, and it must have been carried further into the circulation except for its attachment to the aortic wall. There was no coagulum in the left ventricle.

In the cases of associated cardiac and pulmonary thrombosis the primary coagulation probably took place in one of the right cavities of the heart.

Symptoms referable to this complication were manifested: in Case I., more than forty-eight hours; Case II., fifteen hours; Case III., two days; Case IV., twenty-eight hours; Case V., four days; and Case VI., two days before death.

The most prominent symptoms were: disturbance of the heart's action, as shown by increased fre-

quency and feebleness of the pulse in all the cases, irregularity and intermittency in two cases; inequality of respiration and interrupted rhythm in one case, where the different effects on the respiration, produced by morphia and hyoscyamus, made an interesting study.

Intercurrent syncope in one case, extreme pallor in another.

Sudden death was attributed to heart clot in two cases of acute mania where autopsies were not obtained. The first had decided embarrassment of heart's action, with rapid, very feeble pulse; pallor and cold extremities occur some days before death.

Kept in bed, alcoholic and ammoniacal stimulants given. Died suddenly a few minutes after the ingestion of food. The other, under care less than five days, very violent and maniacal, died a few minutes after making severe muscular exertion. Another sudden death occurred in a patient with chronic mania and Bright's disease, who was about the ward daily, but went to bed complaining of abdominal pain only a few hours before death.

Autopsy revealed firm, decolorized clot in right side of heart, and small abscess in kidney.

THE ELECTRIC BATH.

By WILLIAM F. HUTCHINSON, M.D.,

PROVIDENCE, R. I.

In 1874, incited by the example of Dr. Schweig, of New York, and by the work which was being done about that time in Europe in the direction of passing electric currents through the human body immersed in water, I fitted up a room in my office for that purpose. The bath-tub was made of heavy wood, entirely free from metal fastenings, and was cased in lead to prevent leakage. Into its upper and lower ends, about six inches from the bottom, were recessed carbon plates eight by twelve inches, covered with wash leather and made flush with the inner surface, which acted as electrodes, and these were connected with brass screw posts set at convenient points upon the rim of the tub. The constant current used was from a permanent series of forty two-gallon Weiss elements, which produced an even and steady flow capable of minute division by selectors and a wire rheostal. Faradism was supplied by a DuBois Reymond coil, driven by two five-gallon Smee cells (carbon-zinc). Extra carbon plates were provided for application to different parts of the body, and thus equipped I took the field.

During the four years succeeding, the number of cases treated in this manner was 87, the number of baths given 462. The majority of patients were sufferers from chronic rheumatism in an advanced stage, or from such a neurasthenic condition as precluded the usual localized applications of electricity or its more general use by sponges. In one case confidence in the bath was so great that the patient, an exceedingly intelligent old lady, went to the considerable expense of having a tub erected at her residence, where she was treated fruitlessly forty-two times before the disease gave way.

An analysis of the results was so unfavorable, as compared with those obtained from treatment out of water, as to lead to a total abandonment of the method and the removal of the apparatus from my rooms.

Chief among the difficulties encountered was the frequent systemic depression following immersion of the entire body in water for the usual time allowed for a bath, say fifteen minutes, from which enfeebled persons would sometimes not rally in hours, although the temperature of the bath was carefully maintained at such a height as was perfectly comfortable, usually about 80° F. The fatigue from completely undressing and dressing was often considerable and often objected to. When the patient left the office I discovered that a sensation of chilliness was common, followed by a stroke of cold, and the same result was noticed by myself while engaged in proving the current when the batteries were being arranged, although it was several hours before I went out.

So, finding that better results were obtained out of the bath than in it, and that patients grew heartily tired of the extra amount of trouble and fatigue attending its use, I abandoned it as a failure.

It has since been a matter of regret that my experience in the matter was so unfortunate when I have read of the success of others, and it is quite possible that some details of operating may have been neglected which longer perseverance would have taught; but I entirely agree with the editor of The Record in the value of making public failures as well as triumphs.

Progress of Medical Science.

Amyloid Kidney.—Dr. E. Wagner has investigated 265 cases of amyloid degeneration of the kidneys, and published the results of his researches in the *Deutsches Archiv fur Klinisch Medicinisch*, xxxiii. p. 416.

The causes which in these 265 cases led to the amyloid degeneration of the kidneys were as follows: Phthisis, 136; diseases of the bone, not syphilitic, 56; syphilis, 36; diverse rarer diseases (bronchiectasis, chronic ulcerative skin affections, chronic diseases of the mucous membranes, of the same nature, empyema, pyelitis, pyelocystitis, parametritis, psoas abscess, cancer, sarcoma), 36; without detectable cause (no dyspepsia, based upon amyloid degeneration? Ref.), 7. Regarding their morbid anatomy, four different varieties may, according to Wagner, be recognized, possessing also some clinical importance.

a. Amyloid kidney without alteration of the epithelium and the stroma.

b. With fatty degeneration of the epithelium, but uninjured stroma.

c. With fatty degeneration of the epithelium and fresh interstitial alterations.

d. Amyloid-atrophic kidney. This form happens mostly in syphilitic persons, and is caused by amyloid degeneration of a previously atrophic kidney.

In twenty cases, in which the urine had been more or less frequently examined, the latter was as follows: Quantity mostly decreased, rarely normal or increased at the beginning of the disease. Specific gravity generally 1.012–1.020. Color usually light and clear. Percentage of albumen medium. Sediment sparingly or absent; if present, pale. Tube-casts often for days absent, broad forms very rare. Only twice amyloid reaction demonstrable on the tube-casts. The latter hyaline or fatty degeneration, and frequently covered with white corpuscles. Twice casts with myelin drops; once epithelial casts. In one-fourth of the cases red, in

half of them white blood-corpuscles. Mostly sparingly granular detritus.

Dropsy was not an extraordinarily frequent symptom, but when present remarkably obstinate. Several times uræmic vomiting. Ten times hypertrophy of the left ventricle, but, we suppose, then with atrophy of the kidneys.

Recovery of Nine Cases of Hydrophobia.—At a recent meeting of the Paris Academy of Medicine a memorandum was read by M. Decroix, reporting nine cases of cure of hydrophobia. The Committee on Rabies made, during the year 1874, a series of experiments with medicines said to be useful for curing rabies, in which they made use of pilocarpin three times, and in every case the remedies hastened death by the violent fits they brought on. In the course of his experience M. Decroix met with two cases of rabies which did not end fatally. The conclusions arrived at by the Committee are as follows:

First.—It has been experimentally demonstrated that rabies may recover spontaneously.

Second.—Up to the present no treatment has proved to be anti-hydrophobic, and cases of cure by this or that means may be attributed to the efforts of nature.

Third.—All the means used by the Committee since 1874, comprising principally injections of pilocarpin, have hastened rather than retarded the death of the subject.

Fourth.—Those dogs usually recovered which were left without treatment, as the medicines brought on violent fits, and there is an inclination among medical men to leave men thus attacked in perfect quiet, and only practise experiments on animals. The filing down of dogs' teeth—an easy and almost painless operation—is still the most efficacious preventive of madness.

Fifth.—Rabid people left in the dark and kept quiet are not subject to fits, unless they are brought on by excitement or by ordinary medicines, and "as far as I am concerned," says M. Decroix, "I would rather be attacked by this kind of madness than many other diseases, particularly than that red chancre of smokers."—*Medical Press.*

Effects of Irritating the Encephalon.—At a recent meeting of the Paris Biological Society, M. Brown-Séquard communicated some facts to show that the movements produced by irritating different parts of the encephalon are unlike those which ought to occur, in accordance with the accepted theories concerning the cerebro-spinal motor and sensitive apparatuses. In 1879, Dr. Brown-Sequard published, in the *Archives de Physiologie*, the results of experiments which demonstrated that irritating the base of the encephalon determined movements of the limbs on the side corresponding to that on which the encephalon was irritated. If the medulla oblongata be irritated, the above result is repeated nine times out of ten; but its frequency gradually lessens when the irritation is applied higher, that is to say, beginning at the medulla oblongata, and continued toward the corpus striatum. Dr. Brown-Séquard now adds further facts. Irritating the anterior pyramid determines movements of the limbs on the side of the body which corresponds to that irritated. Sometimes the movements are limited to one limb, the arm, or the leg. He concludes that the nerve-elements, after passing to the opposite side of the spinal cord, return again, and thus produce the movements observed. Irritating the two surfaces presented by a transverse section of a lateral half of the base of the encephalon, results most generally in the occurrence of movements of one or both limbs on the corresponding side of the body.

Jaundice in Pregnancy.—Dr. Underhill, of Cincinnati, in volume vi. of the *Gynæcological Transactions*, asserts that pregnancy is a predisposing cause of certain varieties of jaundice. Icterus gravidarum is often followed by abortion, sometimes even by the death of both mother and offspring. Among the conditions which may give rise to jaundice, and which affect pregnancy especially, he names:

a, Disease of the liver and biliary ducts; *b*, constriction of the ductus choledochus and hepaticus; *c*, stenosis of same ducts; *d*, mental emotion; *e*, pyæmia; *f*, typhus; *g*, the epidemic form; *h*, malarial fevers.

These, he thinks, are the principal conditions giving rise to jaundice that are more likely to be followed by grave results in the pregnant than in the non-pregnant state. Formerly jaundice from pyæmic infection of the blood was explained by the disintegrating action of the poison on the red corpuscles of the blood. Andral, and still others, noting that pyæmic jaundice was often too intense to be accounted for in this way, claimed that there was an inflammation of the common membrane lining the duct and duodenum which would account for the tinging. Virchow is nearer right in his view that the cause of icterus in metastatic pyæmia is due to a condition of the liver similar to that existing in acute atrophy, rather than to catarrh of the mucous membrane or to the action of the poison on the red corpuscles. Catarrhal jaundice, or what is believed to be such, may shortly become malignant by reason of blood changes and by degeneration of hepatic tissue. Of this a fair illustration is given in a case reported by Dr. W. H. Parish. At the outset it seemed to be a case of ordinary catarrhal jaundice, but soon assumed a malignant type, and at the autopsy were found unmistakable evidences of acute atrophy. Indeed, Davidson, as quoted by Playfair, states that "yellow atrophy originates in catarrhal icterus, the excretion of the bile-products being impeded in consequence of pressure."

Accepting as true this theory, we have a clew explaining the fact that this disease is not only much more prevalent, but also more fatal, in the pregnant than in the non-pregnant state.

Bleeding in Heart Diseases.—Judging from recent publications, bleeding is to be restored to favor as applicable to a goodly proportion of cases in which so violent a measure has been quite successfully tabooed for many years.

In *The Lancet* Dr. Fenwick gives vent to his faith in bleeding for various cardiac affections. He states, however, that since loss of blood is a common cause of fatty degeneration, therefore it would not be wise to bleed where we have or fear this condition. He only uses leeches or cupping to remove blood directly from the cardiac region in cases where stenosis exists. He imagines that we obtain thereby more certain and more rapid results with a more accurate loss of blood than when venesection from the arm is resorted to. Still, this is a matter of such great practical importance to the patient's welfare and to our own success, that he feels bound to state distinctly some reasons for his judgment: 1. The patient and the patient's friends usually object less when leeching or cupping is suggested than when "bleeding" is proposed, and they are less

alarmed at a local application to the seat of disease than at the procedure necessary to open a vein and keep it bleeding. 2. The quantity of blood to be abstracted can be more accurately measured and controlled, and is generally much more easily obtained in cases of advanced stenosis by local than by brachial venesection. 3. Even as, like all practical men, he gives a hypodermic injection of morphia at the seat of pain, although he cannot explain why its insertion there should give so much greater and more rapid relief than when introduced into the same blood at a distance, so he cannot explain why a little blood removed from the cardiac region should afford greater and quicker relief than is derived by the abstraction of even a somewhat larger quantity from the arm. He does the former, and leaves the latter undone in these cases, because he is convinced of the great practical truth that thereby greater good is gained.

He has been astonished to find how drugs which had been given for days or weeks without apparent benefit, as soon as even a little blood has been removed, seem at once to assert their power again. Next, with regard to acute pericarditis and endocarditis, he has not had the opportunity of using venesection in many such cases, but where he has done so he has invariably bled by cupping the cardiac region, and always with good results; so successfully indeed as to make him believe that if this measure be taken at the onset of the disease, it will very often, if not always, cut the attack short, or, at least. greatly mitigate its severity.

Finally, with regard to pain, more or less severe and more or less persistent in the cardiac region, he has found nothing give such rapid and complete relief as local abstraction of blood. In conclusion he summarizes thus:

1. In cases of valvular stenosis, if dyspnœa, or pain, or urgent symptoms be present, bleeding is generally useful. It appears to be better to bleed often, if necessary, but to take only a small quantity each time, and this, by means of leeches or the cupping-glass, direct from the cardiac region.

2. In cases of valvular incompetency, if urgent dyspnœa, or cyanosis, or stupor be present, it appears best to bleed freely from the arm to about sixteen or twenty ounces, if necessary, and, if possible, once for all.

3. In cases of acute pericarditis and endocarditis the attack may possibly be cut short by freely cupping the cardiac region at once.

4. In cases of cardialgia, without any evident cause, leeching or cupping over the heart's area will probably give relief.

HEMERALOPIA IN JAUNDICE.—M. Cornillon, of Vichy (*Le Progrès Médicale*, 1882, No. 23), having referred to a paper of his own in the same journal for last year, and one by Dr. Parinaud in the *Archives Générales de Médecine* at about the same time, and to the inaugural thesis of M. Mouly, all describing cases of hemeralopia in diseases of the liver, adds three more cases, one of hypertrophy of the liver from gall-stones, one of hypertrophic cirrhosis, and one of atrophic cirrhosis. In the first case only was an ophthalmoscopic examination made; in that case the appearances in the fundus were, distention of the veins with black blood, not like venous blood, varicose dilatations on veins, slenderness of arteries, with peri-arterial and peri-papillary œdema, no pigmentation or hemorrhages. He states the hemeralopia varies with the jaundice, and is not found in liver diseases apart from jaundice. He thinks it is not uncommon, and is of grave significance. It is subject to variations and remissions. It is incurable, though in one case temporary benefit was obtained by eating raw bullock's liver.

TREATMENT OF DIABETES BY BROMIDE OF POTASSIUM.—Before the meeting of the Académie de Médecine a member read a paper on the treatment of diabetes by bromide of potassium. For the last six years the author has made this disease the object of his researches, and during that period he treated fifteen cases. He ignored entirely the classic *régime* of gluten bread, etc., being of the opinion that the disease consisted, not in the presence of sugar in the urine, but in the disorder of the organism, which produced the sugar in excess. Having had a patient who was diabetic, but who consulted him for certain nervous affections, he observed that under the influence of the bromide of potassium, of which he prescribed a drachm a day, the former disease yielded. This case gave him the idea to make experiments on rabbits, in which he produced artificially diabetes in touching the floor of the fourth ventricle, according to the method of Claude Bernard. Four grains of the drug injected into the veins caused the sugar to disappear in each case. Consequently, ever since, the author has entirely adopted this drug in the treatment of the disease in question, and always with good results. The author further insisted on the necessity of employing muscular exercise of every kind. The use of alkalies, and of iron, arsenic, quinine, according to their several indications, form part of the general treatment. There is one point worthy of remark in the above communication, and that is, the complete disregard as to *régime*, which must be beneficial to the patient in that he is relieved from the irksomeness of observing a certain imposed diet, which soon disgusts him, and what is more grave, keeps him continually dwelling on the affection from which he suffers, a fact which often leads to another malady, which, though less formidable, is not without producing a deleterious effect on the constitution, already weakened by the primitive disease, hypochondria. If further researches verify the efficacy of the observations of the learned author, the treatment of this grave affection will have made a *pas en avant*.—*Medical Press*, August 30, 1882.

TREATMENT OF BUBO.—The *Revista de Ciencias Medicas* gives the following account of a case of bubo treated according to an Italian method: The chancroid at the end of several days had almost cicatrized, and the bubo presented fluctuation. The patient was placed in the dorsal decubitus, with the extremities semiflexed. The tumor was grasped at its base and pressure exercised. With a straight bistoury of narrow blade a puncture was practised at the highest point. The instrument being withdrawn and the pressure still kept up, the contents of the abscess were evacuated *ad maximum*. A solution of cupric sulphate (30 ctgrs. to 30 grammes) was then injected in sufficient quantity to cause the abscess to regain its primitive size. After two minutes the liquid was allowed to escape and a graduated compress applied. An inguinal bandage was adjusted to keep up moderate compressure. On the following day there was slight tumefaction without pain, and the edges of the incision had united. Four days later the small wound had cicatrized without pain or increase of volume. Compression was then suspended and the patient discharged.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THE NEW CORPUSCLE OF THE BLOOD.

THE appearance of Dr. Richard Norris's work upon the physiology and pathology of the blood[1] seems likely to create a new epoch in this branch of the medical sciences. For some years past the profession has seen frequent references to new elements observed in the blood. Thus Pouchet described certain free nuclei which he found in the blood of ovipara. He called them *noyau de origine*, and thought them the source of the red corpuscles. Hayem, in 1877, described the hæmatoblasts in mammalian blood, and assigned to them an independent rôle in producing the colored discs. Dr. E. C. Wendt, of this city, gave an ingenious and plausible explanation of their origin. In 1878 Dr. Norris announced the discovery of an invisible corpuscle in the blood, which he said played a chief part in coagulation, and was the forerunner of the red corpuscle. Last January, Bizzozero, of Turin, also announced that he had seen in the blood of chloralized animals pale corpuscles hitherto undescribed, which corpuscles were the chief factors in the process of coagulation. Hayem has but recently read a communication before the Academy of Medicine, of Paris, in which he claims that his hæmatoblasts, not the white corpuscles, are the sources of fibrin and the morphological factors in coagulation.

At this juncture the work of Dr. Norris appears. It is a most elaborate and exhaustive one, representing the result of his five years' study of the subject in hand. He brings fresh evidence to establish the existence of his invisible corpuscle, claims that Bizzozero's discovery is no discovery at all, but a confirmation or a theft of English work, and that Hayem's hæmatoblasts are only modified forms of his own spectre corpuscle.

It is impossible here to furnish any adequate description of all the methods and arguments used by Dr. Norris to demonstrate his discovery or support the inferences which he draws from it. We must content ourselves with giving a somewhat bald description of his views.

Let one place a drop of a saturated saline solution upon the finger; then prick the finger, mix the blood thoroughly, and let it run under a cover strapped down upon the slide. There will then be seen among the red corpuscles, round, transparent spaces, which indicate the existence of the invisible corpuscles. These corpuscles, although transparent and of the same refractive index as the plasma, have a sufficient color to affect sensitive plates, and may be photographed. Dr. Norris presents numerous photographic pictures of them. He demonstrates their presence in various ways; among others, by packing, by altering the refractive index of the plasma (as in the method just described), by isolation, by osmic acid, vapor and cold, by tinting the plasma, and by staining with aniline blue.

The chief objection made to his method and to the reality of his discovery by Hart, Hayem, Bizzozero, and others is that the alleged new corpuscle is only the red corpuscle decolorized. To this objection Dr. Norris replies with a series of arguments which, we confess, it is hard to answer. In addition, he fortifies his position with many beautifully taken photographs, illustrating the results of every one of his procedures.

The general characters of this new corpuscle are as follows: They are biconcave discs, having the same size and shape as the red corpuscles. They are perfectly colorless, have the same refractive index as the plasma, are lighter in weight than the red corpuscles, and very easily diffuse and break down into granular or fibrillar fibrin. They exist in the proportion of about one to sixty red corpuscles.

In order to determine their origin and function, Dr. Norris made some new studies of the lymph-fluid and the blood-glands. Most physiologists and histologists content themselves with the statement that the lymph-corpuscles are identical with the white corpuscles of the blood. Dr. Norris gives measurements, photographs, and various other tests to show that this is not the case. The lymphatics and the blood-glands contain, he says, two kinds of corpuscles. One is a small, rough, flattened disc, a little thicker and smaller than the red blood-cells, measuring about $\frac{1}{2000}$ inch in diameter. This has no nuclei, but has a closely applied capsule, owing to which it does not stain. It contains a little dark greenish coloring matter, which it gives up when in liquor sanguinis. It corresponds to the free nuclei ordinarily described. Dr. Norris calls it the *primary*

[1] The Physiology and Pathology of the Blood, comprising the Origin, Mode of Development, Pathological and Post-mortem Changes of its Morphological Elements in Mammalian and Oviparous Blood. By Richard Norris, M.D. London: Smith, Elder & Co., 1882.

lymph-corpuscle. The second element is a larger, smooth, very delicate, non-nucleated, flattened disc, of about the same diameter as the red blood-corpuscle. It is very plastic, and easily breaks down into fibrin forms, or it may swell to a larger size ($\frac{8}{7000}$ inch). It stains very readily, and can thus be distinguished from its fellow. It is called the *advanced lymph-corpuscle.* It has been seen and described before by Hughes, Bennett, and Gulliver.

Now, Dr. Norris adduces reasons for the belief that most of the primary lymph-corpuscles in the passage to the blood lose their capsules and become the larger, soft, *advanced corpuscle,* that this latter passes into the blood and speedily becomes the invisible corpuscle. As it sweeps through the circulation it takes up hæmaglobin, and becomes finally the red blood-cell. If the blood is shed the invisible corpuscles rapidly melt down, giving up the factors which form fibrin, and being thus the essential agents in coagulation.

The primary lymph-corpuscles, for the most part, take the course above outlined. A minor number, however, are carried into the blood without losing their capsules. They are then soon developed into the white blood-cells, giving up their pigment to the plasma. The white blood-cells are uninuclear and multinuclear, the latter being simply developed from the former. In the circulation they lose their granular envelope; the nuclei thus set free enlarge, become invisible blood-discs, then red blood-corpuscles. This is the second and minor way in which the process of red disc manufacture takes place.

The "hæmatoblasts" of Hayem and the "blood-discs" of Bizzozero are, in part, the decapsulated lymph-cells before they have become invisible, and in part the developing nuclei of the white cells, or perhaps fragments, incompletely colored, of the invisible cells.

In the fœtus the process of forming primary lymph-cells, and of their development into red blood-cells is localized, being confined to the blood-glandular tissues. Even in the adult there may still remain a slight activity in this method of manufacture. It is very probable that the pigment brought into the blood by the primary lymph-cells may be one of the sources of the blood-pigment.

Dr. Norris advances so many new and radical views that he will necessarily encounter much criticism. He has, however, undoubtedly established sufficient facts to oblige a modification in the present ideas regarding the blood and the lymph.

THE FIRST RESECTION OF THE STOMACH IN AMERICA. To homœopathy belongs the, perhaps, doubtful honor of performing the first reported operation in this country for resection of the stomach. The gentleman who thus abandoned the 'transcendental globule for the knife is Dr. F. W. Koehler, of Louisville, Kentucky.

The patient was a woman, sixty-five years of age, whose health had been good until about seven months previous to the operation. She then began to suffer from various gastric symptoms indicating the presence of a cancerous growth.

The disease progressed rapidly. A tumor appeared; the patient could retain nothing on the stomach, and began to emaciate. During the last few days she was nourished by enemata. The patient was evidently in a hopeless condition and consented to have an operation performed. The only contra-indication, in the opinion of the surgeons, was the age of the patient, her strength being still quite good.

The operation was performed upon September 2d, and is thus described in the *New York Medical Times:*

"The patient being etherized was placed upon the operating table, and the abdomen having been well sponged off with pure tepid water the operation was begun. An incision through the abdominal wall, commencing a short distance below the ensiform cartilage and terminating just below the umbilicus, was made. The peritoneum was not incised until all bleeding from the abdominal incision had been arrested. This having been accomplished, the abdominal cavity was opened and we had the pleasure of seeing the tumor before us. The stomach was partially drawn from the abdominal cavity, and it was then found that the tumor involved the anterior wall of the greater curvature, extending from near the pylorus toward the cardiac extremity.

"I now made an incision through the stomach wall, when it was discovered that the cavity of the organ was occupied by an offensive material, seemingly a mixture of decomposed food and cancer tissue. Before proceeding with the excision of the tumor this material was all carefully sponged out, especial care being taken to prevent any of it getting into the abdominal cavity. Having thoroughly sponged out the stomach, the incision was rapidly extended all around the growth. During this part of the operation three arteries of considerable size were cut, but the parts were so manipulated by Dr. v. Donhoff that all the blood flowed into the cavity of the stomach, and as ligatures were at once thrown around the vessels they gave but little trouble. All hemorrhage having been arrested, the cut edges of the stomach were brought in apposition and united by about forty points of suture, silk soaked in melted beeswax and *carbolic acid* being used for the purpose. This part of the operation was very tedious, great care being exercised to get the edges accurately united. Having satisfied ourselves that all the parts were absolutely clean and that all hemorrhage, even the slightest oozing, had been arrested, we proceeded to close the external wound. For this purpose the same variety of suture that had been used in the stomach incision was made use of."

The line of sutures in the abdomen was hermetically sealed with oiled silk and collodion.

The Lister method was not employed.

The operation lasted about one hour. The patient became quite weak at times during its progress, and at the close stimulants had to be given. These revived her temporarily, but her strength failed again, and she died five and a half hours later.

A post-mortem examination showed no hemorrhage.

While we have no doubt that the operation was skilfully done, yet, considering the age and weakened condition of the patient, it does not seem to us to have been judicious surgery.

THE MICRO-ORGANISMS OF GONORRHŒA AND THEIR REMOVAL.

At a recent session of the "Gesellschaft de Charité Aertze" in Berlin, Dr. Leistikow reported the results of his experiments in regard to the above subject—micrococci found in gonorrhœal pus. These organisms were first described by Neisser in 1879, and occur, as he states, in all gonorrhœal affections of the urethra and conjunctiva without exception, as 200 cases of gonorrhœa, 6 of urethritis in females, 2 of gonorrhœal blennorrhœa and blennorrhœa neonatorum demonstrated. For the most part they are situated in the pus cells, and this intra-cellular life differentiates them from all other species. They are not present in urethral secretions of another nature, and not in the conjunctival secretions of trachoma, blepharitis, or dacrocystitis. The physician, he thinks, is therefore justified in regarding the nature of the disease as gonorrhœal only when these organisms are detected. The micrococci decrease in number in the later stage of the disease, but are found even in gleet, thus contradicting, so far as it goes, the assertion sometimes made that gleet is not infectious. Remedies, such as sulphate of zinc, acetate of lead, carbolic acid, tannic acid, so effective in gonorrhœa, destroy the micrococci after a few injections. Balsam of copaiva taken internally acts in the same way.

Corrosive sublimate, so warmly recommended by Prof. Koch as a disinfectant, arrests the development of the organisms of gonorrhœa, and is therefore advised as an excellent remedy to combat the disease. It is injected in very weak dilutions (1 to 20,000 or 1 to 30,000), and used a few days after the complete cessation of the secretion, in order to prevent a relapse.

Inoculation of gonorrhœal pus upon the urethra and conjunctiva of other animals, even the monkey, have so far, we are told, given a negative result. That gonorrhœa is a disease caused by invasion of micrococci will be only then proven by cultivating and successfully inoculating these organisms in individuals. Such cultivations are claimed to be possible, because the micrococci found in gonorrhœal secretions are so characteristic that they may be distinguished from all other kinds, because they appear in very large quantity, and lastly because all effective gonorrhœal remedies occasion the disappearance of the bacteria.

Prof. Hirschberg, in conjunction with Dr. Krause, undertook experiments in regard to the possibility of infection of the secretion of acute blennorrhœa, and they have published their results, in part (*Centralbl. f. Augenheilk.*). This secretion, without any exception, infected man without any previous injury, while pus from a lachrymal blennorrhœa only caused disease when the cornea was injured. The common pus of an abscess never injured the conjunctiva. The experimenters could always detect the Neisser gonorrhœa-micrococci in the pus of an acute blennorrhœa, but they were always missing in conjunctivitis simplex. In blennorrhœa of the new-born Hirschberg also found these micrococci. He could not inoculate the urethra and conjunctiva of other animals with these secretions, but he could produce gonorrhœa in man by inoculation with blennorrhœal secretions. He regarded, therefore, acute blennorrhœa of the eyes identical with gonorrhœa.

In the discussion following Leistikow's report Prof. Lewin emphasized the importance of the gonorrhœa-micrococci in a practical direction, to decide the question whether a soft chancre or a gonorrhœa exists, and if an existing urethritis is infectious or not. He confirmed the existence of micrococci in acute gonorrhœa. In six old-standing cases he found them only once. He had also found it impossible to inoculate animals. Injections of corrosive sublimate (1 to 20,000) he found successful, though even in this dilution they are still painful.

Dr. Gueterbook remarked that Belgian physicians used pure water as an injection, and asked whether it was the water in the weak dilution of the corrosive sublimate which acts so serviceably.

To this Dr. Leistikow replied that in his department cases of gonorrhœa had healed within four to six weeks without any injection. He had, however, tried injections of water, and thought their action to be a purely mechanical one.

Since the debate which brought out the above facts the gonorrhœal organisms have been discovered by several other investigators. It is rather the opinion, however, that they simply accompany septic pus, and have no other specific character. To those who believe that gonorrhœa is not a specific disease, this would not weaken the argument that it always has a micrococcus which carries the infection.

THE WORK OF VACCINATION IN ILLINOIS.

In the fall of 1881, small-pox being in several parts of Illinois, and steadily spreading, the State Board of Health promulgated an order requiring all school children to be vaccinated.

A circular is now issued showing the good effects of this order and requiring its enforcement for 1883. We are told that since January, 1882, over one million three hundred thousand vaccinations have been made in Illinois as the result of the Board's action, and that small-pox has nearly ceased to exist in the State. Furthermore, public schools have not been broken up by the presence of the disease in any locality where vaccination was performed, while before the systematic vaccination this frequently happened.

The Board also states that among the thousands of cases of small-pox which occurred in the State in the past year, not one is reported of a public scholar who had been properly or recently vaccinated. Several cases, however, with a large proportion of deaths, did occur among scholars who had not been vaccinated at all or not since infancy.

Regarding the statement frequently made that vaccination sometimes causes loss of arms, or even death, the secretary states that after a careful investigation he has been unable to find any such cases.

The facts thus cited are additional proofs of the value not only of vaccination, but of the good that may be done by proper sanitary supervision of our schools.

PASTEUR'S FURTHER EXPERIMENTS IN THE ATTENUATION OF VIRUS.

One of the most notable features of the recent International Congress of Hygiene, at Geneva, was an address by M. Pasteur on the attenuation of virus. Despite adverse criticism and contradictory experience, this eminent savant persists in his researches and periodically announces new proofs of the correctness of his views. His last address was listened to with the greater interest because Dr. Robert Koch, of bacillus fame, and who has announced his disbelief in Pasteur's theory, was present.

M. Pasteur gave an account of new experiments with the virus of rabies, which he had been conducting in connection with M. Thullier. Nearly a year ago he had inoculated rabbits with the saliva of a child who had died from rabies. He found that the animals took the disease and that there was always present in their blood a microbe, which, when inoculated, caused rabies in other animals. The cultivation of this organism, however, did not become attenuated, but were just as virulent, no matter how far they were carried.

M. Pasteur then discovered, what was announced some time ago in this country by Sternberg, that human saliva may prove fatal to rabbits even if it has none of these specific microbes of rabies.

Death in this latter case is due to a septic poison, which poison, Pasteur avers, resides in another microbe. This organism was cultivated by M. Thullier and himself. The former gentleman had the patience to carry the cultivation to as far as the eightieth generation. If then injected into rabbits it killed these animals, with a septic fever, as quickly as ever. In order to attenuate the virus, therefore, the experimenters submitted the cultures to the action of oxygen, as in the case of the chicken-cholera virus. The cultures were also made in a special fluid composed of two parts veal-broth and one part rabbit's blood. For it seems that these salivary organisms are dainty in their tastes and soon die in simpler mixtures. Thus fed, however, the microbes live, exposed to the action of oxygen, for forty or fifty days. During this time they gradually weaken in virulence. If taken during the last ten days and inoculated into rabbits, these animals do not die, and become protected against other inoculations of the active virus.

To the above M. Pasteur adds the results of his experiments with secretions taken from the nostrils of horses suffering with typhoid. These secretions, he claims, produce true typhoid fever when inoculated into rabbits. By treating them in a similar way to that just described he was able to attenuate the virus and thus secure immunity to the rabbits. Whether there is a promise here of typhoid vaccine the experimenter does not say.

In closing his address, he defended himself and his views against some of the attacks which had been made. When he had finished, Dr. Koch arose and said that he was disappointed in the paper, and that the facts lacked novelty. He proposed to criticise the views expressed at length in the scientific journals. The sympathies of the audience, however, were manifestly with Pasteur, who claimed that already his discovery had achieved a great amount of practical good. There had been, he said, no less than 400,000 sheep and 40,000 bullocks vaccinated against anthrax. The deaths from this disease had been reduced to 1 to 300 among sheep and 1 to 2,000 among cattle. The only unfavorable results had been in Italy, and these were due to mismanagement and the hot climate.

In this connection, we should state that Dr. E. Klein, of London, has recently made an unfavorable report upon the anthrax vaccine sold in France for use abroad. This vaccine is obtained of M. Boutroux, Pasteur's agent, and comes in tubes, each containing enough to vaccinate one hundred sheep or fifty cattle. There are two kinds: the "premier vaccin," which is used first, and the "deuxième vaccin," which is inoculated twelve or fifteen days later. Dr. Klein states that animals inoculated with this "vaccin" are not made immune against anthrax, while either the "premier" or the "deuxième" may cause fatal infection.

It seems that there are likely to be serious obstacles against the practical use of attenuated virus, however thorough its action may be proved in the laboratory.

THE GENEVA CONGRESS.

THE International Congress of Hygiene recently held at Geneva has attracted much more attention in professional circles than did any of its preceding meetings. In a five days' session there were over fifty papers read, many of which embodied the results of laborious scientific work. The substance of these papers will be duly presented to the public. Meanwhile, we will indicate here some of the more important topics discussed.

M. Pasteur's contribution to the subject of attenuated virus has been noticed elsewhere. It was regarded by the Germans as a failure, by the Frenchmen as a glorious ornament to French science.

The subject of mountain altitudes was introduced by the President, M. Lombard. M. Paul Bert stated the interesting fact that the blood of animals living in low countries absorbed from ten to twelve per cent. its weight of oxygen; while in animals acclimatized at twelve thousand feet above the sea it absorbed from eighteen to twenty per cent. its weight. High altitudes have a tendency, therefore, to enrich the blood in hæmaglobin. The prophylactic and therapeutical value of high altitudes in phthisis was conceded.

The subject of the contagion of phthisis was discussed by several members. The drift of opinion was against the view that phthisis is a contagious disease, to any such extent as to require the disinfection and isolation of its victims. M. Leudet, of Rouen, said that among fifteen widows of phthisical husbands, only two had subsequently died of a phthisis that could be considered as originating from the husbands. Among forty-one widowers of phthisical wives only three died of phthisis.

The subject of alcohol as a cause of death and disease was brought up by MM. Roulet, Challand, and others. It was stated that in Switzerland the deaths from alcohol were five out of every thousand. The annual consumption of alcohol per country was given as follows: Danes, 23 litres; Russians, 16 litres; Swedes, Germans, and Belgians, 9 to 10 litres; Swiss, English, and North Americans, 6 to 8 litres; Frenchmen, 3 litres.

The prevention of blindness is a question now exciting especial interest, and Dr. Haltenhoff, of Geneva, gave some statistics regarding it. He calculated that there was one blind person out of every thousand of the European population. This gave about three hundred and thirty thousand blind persons in Europe. The larger half of these cases might have been prevented. Dr. Roth calculated that the blind in Europe cost society 100,000,000 francs annually.

Cremation and the proper soil for cemeteries furnished topics which awakened much discussion. The Congress unanimously reaffirmed its view that cremation was a mode of disposal of the dead, the adoption of which was often needed on hygienic grounds. The proper choice of soil for cemeteries received elucidation at several hands.

No subject attracted more interest than that of the hygiene of schools. There were many reports showing the progress made in this important department of sanitary science, and the deficiencies that still existed. It was the universal opinion that sanitary and medical supervision should be constantly exercised over public and private schools.

The Congress, of whose work we have thus given a brief indication, was unquestionably a most successful one, and its influence upon public medicine can hardly fail to be widely felt.

Reviews and Notices of Books.

A TREATISE ON THE SCIENCE AND PRACTICE OF MEDICINE; OR, THE PATHOLOGY AND THERAPEUTICS OF INTERNAL DISEASES. By ALONZO B. PALMER, M.D., LL.D. Vol. II. New York: G. P. Putnam's Sons. 1882.

IN this volume, containing 856 pages, Prof. Palmer writes on "Diseases of the Respiratory System," "Diseases of the Heart," "Diseases of the Urinary Apparatus and Urinary Diseases," "Diseases of the Male Sexual System," "Diseases of the Brain and Nervous System," and "Parasitic Diseases." The first forty-five pages are devoted to physical diagnosis and "general vital symptoms of respiratory diseases," and contain a fair statement of what has for a long time been accepted and taught. The pathology, diagnosis, and treatment of particular diseases of the respiratory system follow, and, beginning with nasal catarrh, the author leads the reader into the larynx and trachea and points out the different diseases to which these organs are liable. He regards membranous croup as distinctly different from diphtheria. On these pages also the reader will find a moderately fair synopsis of the present knowledge upon these diseases. The reviewer fails, however, to discover anything which has not heretofore been published, and at the same time inclines to the opinion that a better compilation could have been made. That the author is not a systematic writer is as apparent as it was in his first volume, and the general criticism might as well be introduced here as elsewhere, that the work of a competent editor would have added very much to the value of the volume.

Naturally, the next topic is bronchitis. Here an innovation seems to have been made, and a number of pages on the microscopic anatomy of the bronchial tubes have been introduced, for which the author acknowledges his indebtedness to D. J. Hamilton, M.B., Demonstrator of Pathology in the University of Edinburgh. Bronchitis has been presented under the headings acute, chronic, and capillary. No mention has been made of fibrinous bronchitis, a disease of sufficiently frequent occurrence to find a place in a "Treatise on the Science and Practice of Medicine."

The bacillus, for some reason, has been kept out of the author's pathology, and yet the "filaria sanguinis hominis" appears prominently in the eti-

ology of "chylous urine." It is right to say, however, that the latter carries with it a qualifying sentence.

Prof. Palmer believes that "hyperæmia of the brain" has been completely demonstrated, and therefore the affection in both of its forms, active and passive, receives a full description. The space allotted us will not permit a detailed criticism of this part of the volume, or indeed of any other, and we must be content with the general statement that while it is made apparent that the author has read extensively upon the subjects therein contained, the analysis and conclusions fall short of what the general practitioner has a right to expect in a work of this character. There is an unpleasant lack of precision, which leaves the reader in doubt in many instances. As might be expected, Prof. Palmer, who has passed through several decades in therapeutics, refers to the old-fashioned measures, blood-letting and tartar emetic and blisters, but we find his recommendations guarded by a commendable degree of caution in the use of these potent agents; but it is evident that he either has considerable faith—perhaps more than the average amount—in the efficacy of drugs in the treatment of disease, or else he wishes to give the practitioner a fund of resources upon which to draw when called to treat the affections of which he speaks.

He has great faith in the power of iodide of potassium, and, consequently, it appears on the field whenever a formidable enemy is to be encountered; but we fear that his positive affection for the drug has led him to reach some questionable conclusions. For example, he agrees with Lebert in the statement that "the preparations of iodine hold the first rank" in counteracting the tuberculous process, and at the same time he seems to have overlooked the significant word contained in the following sentence, quoted from that writer: "I have for a long time used the iodide of potassium in cases with a syphilitic complication, and have been struck with its good effects and perfect tolerance." Probably no one would oppose this statement made with reference to a certain class of cases, but to apply it, without qualification, to the general subject of tuberculosis or phthisis seems to ignore the possible answer to two questions: First, Does syphilis give rise to phthisis? and, second, Does phthisis, as a rule, depend upon syphilis?

He also has great faith in the efficacy of quinine in the treatment of pneumonia. We can easily understand why this should be so, as doubtless can all practitioners who pursue their calling in certain parts of our country. But aside from the power which the drug possesses in overcoming "malarial influences," he believes that it has an almost specific effect in the treatment of this disease, and, in imagination, we can go back to the days when we heard "the old man wax eloquent" on the subject now under consideration. The work will be read with pleasure, and doubtless with profit, by a large percentage of those who help to swell the great multitude to whom Prof. Palmer has lectured during the last forty years.

Electrization of the Larynx.—Rossbach claims that the intrinsic muscles of the larynx can be feebly excited and the vocal cords moved by the percutaneous use of faradic and galvanic currents. The active electrode is placed deeply in front of the sterno-cleido-mastoid, between the larynx and sternum.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, September 27, 1882.

Dr. E. C. Seguin, President, in the Chair.

FIBRO-MYOMA OF THE UTERUS—MISCARRIAGE AT SIX AND A HALF MONTHS.

Dr. N. Bozeman presented a specimen expelled by regular labor pains twenty-nine days after a miscarriage, occurring in a woman six and a half months advanced in pregnancy. The tumor was probably the cause of the miscarriage. The patient, thirty-three years of age, the wife of a physician in this city, was attended by a midwife, and delivered of a fœtus six and a half months old on August 21st. Dr. Bozeman was called to see the case on September 15th, and found that the woman was suffering unquestionably from septicæmia, concerning which he learned the following history: The midwife asserted that the after-birth was thrown off in the usual manner. The case progressed satisfactorily for ten or fifteen days, but the patient not getting on well, a physician was called, who found a mass in the cavity of the uterus, which he supposed to be a retained placenta. This was on the seventeenth day after confinement. He introduced a vulsellum forceps into the lower portion of the mass and used very violent efforts for its extraction, but the instrument tore out and nothing further was done toward its removal. After a few days, fever supervened, symptoms of septicæmia developed, and the patient went on from bad to worse, until the time when Dr. Bozeman saw her in consultation. He then found that the mouth of the uterus was slightly dilated, that the end of the tumor was in a ragged condition, that the patient's temperature was 102.5° F., and the pulse 130. The uterus was quite large, there was a sanious discharge and considerable abdominal tenderness, with tympanites. On the following day ether was administered, and he introduced two fingers into the cavity of the uterus; was able to explore the tumor to the extent of three or four inches, and found it perfectly free, except at its front portion, where it was attached to the anterior wall of the uterus down to within one inch of the internal os. Not succeeding in effecting manual dilatation a large Barnes dilator was introduced and allowed to remain from four to six hours. By this, the os was considerably more dilated, yet nothing in addition was learned by exploration. The prostration of the patient was very great, and Dr. Bozeman determined to discontinue any further operative procedure until her strength could be somewhat improved. She was then removed to the woman's hospital, and it was ordered that she receive vaginal injections of a two per cent. solution of carbolic acid and rectal alimentation. This treatment was continued for three days. Soon after beginning the disinfectant injections labor pains came on. The patient seemed to be gaining in strength, and the treatment was continued, no unfavorable symptoms developing until twenty-nine days after the miscarriage, when violent labor pains set in and the tumor was expelled, presenting a ragged surface of attachment. The specimen was about six inches in length and three inches in diameter, and exhibited at one point the surface where it had been attached to the anterior wall of

the uterus. It had been examined by Dr. Welch, Pathologist to the Woman's Hospital, who reported that it was a fibro-myoma of the uterus. After the expulsion of the mass the patient's condition became more favorable and improvement had gone on, and at the present time the temperature was 99° F., and her pulse 98.

Dr. Ripley asked Dr. Bozeman if he delayed interference on account of the weakness of the patient.

Dr. Bozeman replied that he did, and also on account of the difficulty of dilating the os. Besides, there were no symptoms, such as hemorrhage, which indicated immediate interference.

Dr. Ripley thought it would be a fair question to raise as to whether the danger from septicæmia was not greater than from operative interference. In regard to dilating, as a general rule, in these cases, the hand alone is sufficient to dilate the cervix for all the manipulation necessary. In quite a number of cases, although the patient was very much prostrated, he had dilated the cervix with the hand, washed out the uterus, and recovery had been rapid and satisfactory. The question was, therefore, whether the delay in Dr. Bozeman's case was justifiable.

Dr. Bozeman replied that Dr. Ripley's suggestion was a very good one, and that his views also were quite correct. He had the same view himself, and thought it would be possible under chloroform to dilate sufficiently to permit the removal of the mass in the uterine cavity, but after making sufficiently violent efforts to do so, he was only able to get two fingers into the uterus, and then, having in addition tried the Barnes dilator, it seemed to him that further interference at that time was not justifiable. In addition, there was the fact that strong traction had previously been made upon the tumor by means of the vulsellum forceps without any effect. He therefore thought it more advisable to wash out the necrosed tissue with an antiseptic solution and build up the patient preparatory to subsequent dilatation and removal of the mass, and the result undoubtedly justified the plan of treatment. For septicæmia began to disappear immediately after antiseptic injections were begun, and the patient's general condition began to improve after the use of these injections and rectal alimentation. If hemorrhage had resulted after his first examination, under these circumstances, the question would have come up as to the best mode of removing the mass, and he thought the only chance would have been in the performance of hysterectomy.

ORIGIN OF CYSTS OF THE KIDNEY.

Dr. Heitzmann presented microscopical slides illustrating the development of renal cysts, accompanied by the following remarks:

"Dr. Jeannette B. Green, a student for several months in his laboratory, had devoted special attention to chronic nephritis, and had succeeded in proving how cysts in the kidneys, such as seen with both catarrhal and croupous (parenchymatous) nephritis, are formed.

"Neither of the former views, that cysts arise from tufts or from uriniferous tubules, is satisfactory. Cysts are often found on the surface of the kidneys where there are no tufts, the same as in the pyramidal substance. In cirrhotic kidneys we not infrequently meet with capsules containing a shrivelled or compressed tuft and an albuminous liquid, but in no instance has dilatation of the capsule been observed sufficiently marked to allow the diagnosis of a cyst. Neither could we understand how, by simple dilatation, uriniferous tubules could reach the size that we observe in cysts. The way in which cysts are formed is as follows: first, the interstitial as well as the epithelial tissue of the tubules breaks down into inflammatory or medullary corpuscles, and thus an embryonal tissue is produced, sometimes occupying large territories of both the cortical and the pyramidal substance. Next, a transformation of the medullary into myxomatous tissue takes place, marked by the presence of a light, nearly homogeneous basis substance, which is traversed by nucleated bioplasson strings. In further growth these delicate strings perish, and a cavity is formed filled with an albuminous liquid. Around the cavity delicate fibrous connective tissue is developed, the inner surface of the wall of the cyst being lined with flat endothelia. From all evidence those medullary corpuscles that have sprung from former epithelia of the uriniferous tubules are the only ones fit for a transformation into first, a myxomatous tissue, and later, by liquefaction, into cysts. From what I have seen in kidneys, ovaries, and in the skin, I would consider this manner of formation of cysts as the only one which occurs. As to cysts of the liver, my experience is too limited for a positive statement; there are good authorities claiming that from bile-ducts, by simple dilatation, cysts may originate."

SARCOMA OF THE UTERUS AND LIVER—DOUBLE HYDRONEPHROSIS.

Dr. R. W. Amidon presented specimens accompanied by the following history: The patient was a woman sixty-two years of age, a widow, mother of five or six children, who first consulted him in September, 1881, for œdema of the right leg. She had always been very healthy up to a short time previously, when she began to suffer from swelling of the feet and ankles, chiefly upon the right side, accompanied by dull pain and irregular discharges of dark fluid from the vagina. She had never had headache or backache, or any urinary trouble. There was no evidence of an abdominal tumor. There was slight abdominal tenderness, especially in the right iliac region and along the course of the iliac and femoral veins. The entire right lower extremity was œdematous. The urine was high-colored, but contained no casts, and was otherwise normal.

September 12th, three days after her first visit, Dr. Amidon made a vaginal examination. Found the uterus low down, firmly fixed, the cervix having a rigid, cartilaginous feel. There was also an indurated mass above Poupart's ligament, but there was no induration of the femoral (?) glands. He diagnosed cancer of the uterus. The patient lived until July 10, 1882. At the autopsy he found the pelvis filled with a morbid growth, which had been submitted to a microscopical examination and found to be sarcomatous in character. There was, besides, sarcoma of the uterus and of the pelvic organs in general, sarcomatous nodules in the liver, and abscesses. In addition, there was induration and enlargement of the mesenteric glands. The spleen was riddled with small abscesses. He also found double hydro-nephrosis which had not given rise to symptoms. Microscopical examination of the primary location of the sarcomatous growth, which was in the uterus, showed that it possessed no special peculiarity; but the formation of abscess in the liver showed how the epithelium of the liver breaks down and makes pus, which had already been re-

ferred to by Dr. Davis in an article published in the *Archives of Medicine.*

This condition Dr. Amidon illustrated by means of microscopical slides, and also exhibited microscopical specimens of the sarcomatous growth.

Dr. Heitzmann asked Dr. Amidon what his experience had been concerning cancer changing into sarcoma. He said he was first struck by this appearance in primary cancer of the uterus, where an enormous sarcomatous growth had followed cancer, and he had since been able to trace, in quite a number of cases, this same transition, so much so that when he met with large sarcomatous tumors he sought to determine, if possible, whether the original growth was not cancerous in character.

Dr. Amidon replied that he was unable to trace any such transition, although at the time he made his second examination of the patient he diagnosed cancer of the uterus.

Dr. Ripley asked if he understood Dr. Amidon correctly in the statement that the hydro-nephrosis was not attended by symptoms?

Dr. Amidon replied that no urinary symptoms were present until the patient became so weak that she ingested scarcely any fluid. He examined the urine several times and never found any pathological condition. He thought it was the general rule for hydro-nephrosis, particularly when unilateral, to go without recognition until at the autopsy.

Dr. Ripley remarked that there were cases upon record where both ureters had been occluded without producing symptoms. There was a case in this city in which the patient did not pass any urine for twelve days. Ebstein mentioned a case where no urine was passed for two weeks. In the case which occurred in this city there were no urinary symptoms until nearly the close of life, which, he thought, was rather remarkable; whereas, in anuria from nephritis severe symptoms set in early. As a rule, an obstruction of this kind may exist for a long time without giving rise to any grave symptoms.

Dr. Amidon remarked that the only symptom which pointed toward uræmia was somewhat persistent vomiting, but he had attributed that to the use of morphine, of which the patient was obliged to take large quantities.

Dr. Ripley suggested that it would be a fair question, then, as to whether the vomiting was uræmic or due to the influence of morphine.

Dr. Amidon said that it would.

DIASTASIS OF THE UPPER EPIPHYSIS OF BOTH HUMERI.

Dr. Van Santvoord presented specimens removed from the body of an idiot boy, six years of age, and accompanied by the following history: He had been treated on two or three occasions for bronchial trouble. He was able to move his limbs, but had never been able to walk; had always been confined to the bed. About six weeks before death one of the attendants directed the attention of the house-physician to a swelling on the child's arm. The house-physician on examination found that the entire right shoulder and arm were much swollen, and that there was a slight amount of ecchymosis in the axilla. The limb remained œdematous and continued in about that condition until the child died. The swelling was fluctuating in character and the child had moderate fever, the temperature, however, never exceeding 100° F. The house-physician suspected the existence of an abscess, but did not feel prepared to open the swelling because there had never been any redness or heat, and he was rather doubtful concerning diagnosis. He therefore contented himself with making an attempt at aspiration, but the aspirator withdrew nothing except a small quantity of blood, and as the child was evidently soon to die no further attempt was made. The patient died of exhaustion. At the autopsy the right arm presented the appearance already described, and cutting into the swelling Dr. Van Santvoord opened into a sac filled with clotted blood. In the midst of the clot he found embedded the upper extremity of the humerus. The head of the bone was in the socket and perfectly healthy, except upon the under surface, where it was somewhat eroded. There had been no history of traumatism. The under surface of the humerus was covered with badly developed granulations. He was unable to detect injury of any blood-vessels. He found that the head of the opposite humerus was loose, and on cutting into that joint, found about an inch and one-half of the bone eroded, but the joint contained only a small quantity of blood. In the absence of any evidence of inflammatory process he concluded that there had been injury which had not been reported. There was separation of the upper epiphysis of both humeri, and the amount of hemorrhage was probably six or seven ounces. He examined the other joints of the body but did not open them, as these two were the only ones which seemed to be affected.

Dr. Ripley asked if the child was syphilitic.

Dr. Van Santvoord replied that he was unable to answer the question. The condition of the brain, however, was somewhat interesting. There was no external malformation of the head, but on the left side there was total loss of a large number of convulsions, and the space which the convolutions should occupy was occupied by a sac that communicated with the lateral ventricle.

Dr. Jacobi said he had seen a number of such cases, but in the cases which he had observed the spontaneous separation had been attended with acute osteitis, and always attended with suppuration. In this instance there was no evidence of suppuration, but on the contrary there was a great deal of hemorrhage, and therefore the specimen looked as if it were of traumatic origin, and probably the case was one of murder.

Dr. Ripley thought the case was very similar to two which he had seen and in which there was separation of the shaft of the bone from the epiphysis, due to syphilis, and in these cases by keeping the bones in apposition they finally united firmly. One of these cases was seen by Dr. Keyes, who regarded the lesion as syphilitic. He thought the hemorrhage might have been simply a coincidence or accidental, resulting from the rupture of some small vessel, but in other respects the case corresponded very closely with the syphilitic cases to which he had already referred. Besides, the malformation in the head to which Dr. Van Santvoord referred also pointed to syphilis.

Dr. Jacobi suggested that the condition of the brain pointed to arrest of development rather than to syphilis.

Dr. Ripley thought it possible that the arrest of development might be due to syphilis.

Dr. Briddon was inclined to regard the case as one of traumatism, and of old date, but probably associated with a recent accident which caused loss of blood. To him there seemed to be no evidence of epiphysitis. He thought the most frequent manifestation of hereditary syphilis was overgrowth of bone.

Dr. Ripley thought that the argument presented by Dr. Briddon had no special weight, that is, that such cases are not very common, for it was sufficient to know that they do occur; and inasmuch as they might occur, this might have been one of those cases of which there are several upon record. He himself had already seen two cases, so that they were not so very rare after all.

Dr. Briddon said he was willing to admit disease of the epiphysis caused by syphilis, but he believed they were rarely, if ever, associated with diastasis.

Dr. Ripley said that was the very point which he wished to make, that there was no pain, as only slight inflammation attended the condition. This was also a peculiarity of syphilitic dactylitis, which might occur without giving rise to only very slight pain.

Dr. Briddon remarked that pus was scarcely ever found in connection with dactylitis.

The President asked if the cerebral malformation was bilateral.

Dr. Van Santvoord replied that it was unilateral. The child had not been examined carefully, and the ante-mortem history was so defective that it was almost worthless. He further remarked that in looking up the literature of the subject, he found a single case reported in the "Transactions of the London Pathological Society for 1876," by Mr. Thomas Smith, as a case of "Hemorrhagic Periostitis." In that case there was complete separation of the femoral epiphysis, the tibial, and partial separation of the fibular epiphysis upon both sides, and also separation of the epiphysis of some of the other joints, especially the shoulders, which were not opened. The periosteum was much injected. There was some hemorrhage in the muscles attached to the shaft of the femora, and there was a layer of blood between the shaft of the bone and the periosteum, but there was no suppuration whatever. The child died of exhaustion. In that case also the patient complained of but little pain on being handled. Although the disease had lasted two months, the shafts of the bone were smooth, differing from the appearance of the humerus in his case, where there was considerable erosion.

PERFORATION OF THE INTESTINE.

Dr. Van Gieson presented a specimen of perforated intestine which was removed from the body of a man aged sixy-two, who, until the symptoms immediately preceding his death, had been in the enjoyment of very fair health. He had had for many years upon the right side a reducible inguinal hernia, which had been readily controlled by means of a truss, and, so far as he was able to learn, had not given rise to special trouble during life. He had occasionally had attacks of rheumatism, not sufficiently severe to confine him to bed, but simply much interfered with locomotion. He had not been under the attendance of a physician for some years. His occupation was that of a waiter, but during the last four or five years he had lived a life of inactivity. On the previous morning he arose and said he felt better than usual, and he thought he would make himself somewhat useful by visiting his son's grocery store and doing some light work. He accordingly walked to the store, went down into the cellar to arrange some empty barrels, none of which had any very great weight, and while rolling an empty kerosene barrel he was suddenly seized with acute pain in the bowels. His cries attracted the attention of his children in the store above, and when they reached the stairs they found that he had nearly gotten to the top of them, and was complaining of intense pain. There was a marked tendency to syncope, which was overcome by a small dose of brandy, and the pain soon left him. He sat down for a little time, and then went home. After mounting the stairs at the house he was again taken with extremely acute pain. Meanwhile Dr. J. A. Jenkins had been called, and when he arrived he examined both sides to ascertain with reference to hernia, for he supposed that the case was one of some form of strangulation; but the old hernia was so reducible, and there was no evidence of hernia upon the opposite side, that he was at a loss to account for the symptoms. Morphine was administered according to circumstances, and under the influence of opium the pain disappeared to a considerable extent. About five o'clock in the afternoon there was a slight natural movement from the bowels. About six o'clock the doctor saw him again, and found that the pain was recurring at intervals, but was not severe. He was sent for at nine o'clock, at which time the patient had been taken with vomiting for the first time, and there was slight evidence of tympanites. The vomiting went on; the material ejected had a foul smell and a suspicious color, and Dr. Van Gieson thought it was probably stercoraceous. At ten o'clock the pain was very severe. Up to this time there had been no elevation of temperature, but now the thermometer stood at 99° F. On the supposition that there might be some irritating matter in the bowels, an injection of warm water was given in the course of the night, but not very much fecal matter was passed. On the following morning the vomiting, which had continued throughout the night, still remained incessant, and a few hours afterward the patient died. At the autopsy the body was found well nourished and muscular. Upon opening the abdomen the lesion was reached at once. About a pint and a half of serum was found in the abdominal cavity, and a small portion of the ileum immediately presented itself at the opening, and in this presenting portion there was an opening in the gut, which extended entirely through the intestinal walls. The gut was not agglutinated to other coils of the intestine, nor adherent anywhere by adhesive inflammatory deposit, but all over the peritoneal surface there was abundant evidence of recent inflammation. The gut in the neighborhood of the lesion was strongly congested, and here and there there was an effusion of recent lymph. When the edges of the opening were examined they were found to be cleanly cut. The question was as to the origin of the opening, and this to some extent was explained by the beginning of a process which would terminate probably in the same result if the man had lived. A little to one side of the complete perforation there appeared to be a solitary follicle, which had taken on a low grade of inflammatory action characteristic of follicular inflammation of the intestine. In the one instance the inflammatory process had been completed and perforation had taken place, and in the other it was incomplete, but probably would in time have produced the same result. Dr. Van Gieson was of the opinion that Nature had made an attempt to seal the opening, which had existed for a long time, and that it had been kept partly plugged up by adhesive material. The minute opening had probably permitted a slight escape of the contents of the intestine, and the exercise in the cellar may possibly have opened

the gut and allowed a sudden escape of intestinal material, and thus gave rise to the shock, collapse, and death.

Dr. Wendt thought if the intestine could have been examined throughout its entire length there would probably have been found evidence of follicular inflammation at different points.

The President asked if there was any evidence of cardiac disease, as the lesion was suggestive of those which come from plugging of an artery, and not unlike that which occurs in the stomach as a result of embolism and thrombosis of the smaller vessels.

Dr. Van Gieson replied that there was no evidence during life of the existence of cardiac disease. They were not permitted to make an autopsy with reference to any of the organs of the chest.

Dr. Jacobi remarked that there were two places in which there was superficial erosion in the neighborhood of the place in which perforation existed.

Dr. Briddon asked Dr. Van Gieson if he supposed the perforation had taken place before the man had made the exertion in the cellar.

Dr. Van Gieson said that he could not account for the inflammatory condition, which was evidently quite recent, upon any other hypothesis. That such an amount of inflammation as this could be developed within twenty-two hours he thought was quite impossible.

Dr. Ripley referred to a case which probably Dr. Jacobi would recollect, in which a boy died of peritonitis without any symptoms at all except those of parotiditis, or ordinary mumps. But in cases of perforation the rule is that the inflammation is limited as compared with the gravity and rapidity of the symptoms which follow. In cases of typhlitis a fatal result follows pretty rapidly, although the area of the inflammation is quite limited.

AMYLOID LIVER.

Dr. E. C. Wendt presented a specimen accompanied by the following history:

Wm. A——, aged thirty-eight, a native of England, blacksmith, was admitted to the St. Francis Hospital in July, 1882. No hereditary taint. Some two years before admission, he developed several abscesses over the region of the sacrum, which healed poorly, leaving five fistulous openings. Syphilis was not present. About a year later two new abscesses formed in the lumbar region on the right side. On admission he presented an appearance of marked cachexia, with great emaciation and feebleness. The previously mentioned fistulæ were still discharging large quantities of thick pus. The liver was prominently enlarged, extending to the umbilicus. During his stay in the hospital it continued to grow quite rapidly. The other organs were found to be normal, barring some enlargement of the spleen. Examination of urine negative. Its specific gravity was 1,010. No ascites occurred in the course of his illness. Three weeks before his death an intractable diarrhœa set in, and he died of exhaustion on September 25th. The post-mortem examination, made seven hours after death, revealed the usual atrophy and anæmia of long-continued wasting disease. The liver was found to be enormously enlarged, owing to the presence of extensive amyloid degeneration. Its weight was *fifteen pounds*, that of the patient being only about seventy. It had pushed the diaphragm up to the third rib, the right lobe extending down into the pelvis. The left lobe reached below the anterior superior spine of that side. In the spleen incipient amyloid changes were visible, but the kidneys showed only the usual yellowish gray appearance of the cortex, due to granulo-fatty alterations.

Dr. Wendt further remarked that in cases of this kind it was the rule to find the liver presenting a pale grayish hue, but in this instance it was of a brownish color, showing that all the lobules were not completely infiltrated, and that there was still a moderate amount of blood in the organ. The bile-forming function of the liver had not suffered, and the gall-bladder was seen to be well filled with the normal secretion. The case was a somewhat unusual one, on account of the very rapid hepatic infiltration, leading to such enormous dimensions of the organ, while the spleen was only slightly implicated, and the kidneys not at all.

Dr. Heitzmann asked concerning the original cause of the suppuration.

Dr. Wendt said he was unable to ascertain the cause, as there was no history of injury or of syphilis. No caries had been developed. It was presumable, however, that there was caries, although it had not been detected.

The President asked if the spleen and the kidneys had been examined by tests for waxy degeneration.

Dr. Wendt replied that they had. There was but slight involvement of the spleen, and none of the kidney.

Dr. Jacobi suggested the possible existence of interstitial hepatitis, and asked if there was any ascites.

Dr. Wendt answered that the specimens had not been examined microscopically, but there was no ascites.

CARCINOMATOUS PEDUNCULATED TUMOR ATTACHED TO THE INNER WALL OF THE UTERUS.

Dr. Ferguson presented a specimen, removed from the body of a woman sixty-five years of age, consisting of the uterus, which contained a tumor that involved nearly its entire fundus, projecting into the cavity, dilating the os, and forming a kind of polypoid mass. A microscopical examination had revealed epithelium upon its surface, such as lines the uterine cavity, and the tumor itself was made up of very large alveoli, packed with small cuboidal cells, and surrounded by a small amount of stroma. There were no carcinomatous growths in the other organs of the body, and none of the mesenteric glands were enlarged. There was a moderate amount of interstitial parenchymatous nephritis. So far as the history could be obtained the tumor in the uterus had not given rise to hemorrhage.

Dr. W. M. Carpenter asked Dr. Bozeman if intra-uterine polypoid growths, carcinomatous in character, were of frequent occurrence.

Dr. Bozeman replied that he had not seen such a case.

In answer to the same question Dr. Heitzmann replied that he had not met with such a tumor.

The President asked Dr. Bozeman whether it was customary to make a microscopical examination of uterine polypoid growths before their removal.

Dr. Bozeman thought it was not the general custom unless there was a strong suspicion of the existence of carcinoma.

Dr. Heitzmann asked if it was out of the question that this tumor was cancerous.

Dr. Ferguson replied that it might not be cancer, but it was a tumor which consisted of quite small cuboidal cells, which filled up alveoli that were sep-

arated from each other by thin partitions made up of connective tissue, and from a somewhat rapid examination he reached the conclusion that it was carcinoma, because of the large alveoli separated from each other by distinct walls of connective tissue and filled with cuboidal cells.

Dr. Heitzmann remarked that in making microscopical examination of myoma and fibro-myoma of the uterus, cross sections exhibited an appearance which very closely resembled small cuboidal epithelial cells.

Dr. Ferguson thought that a gross examination of the tumor would exclude fibro-myoma, because it was entirely too soft for that form of neoplasm.

The specimen was referred to the microscopical committee.

VESICAL CALCULUS.

Dr. J. Lewis Smith presented a specimen removed from a boy eight years of age, with the following history: The patient had been perfectly well up to a few days previously, when he began to complain of some pain in passing urine. On September 16th he had not been able, although he had attempted several times, to pass urine, and on the evening of the same day he succeeded in passing a small quantity, and it was stated that he was entirely relieved. The case being one of considerable interest he thought it well to make an examination, and the result showed that it was well that he did, because he discovered a calculus lying in the meatus within the glans-penis, and as he pressed upon it it protruded from the meatus. But it was so tightly fixed that in order to remove it he was obliged to use a proper pair of forceps, and then succeeded only with considerable difficulty. The case possessed additional interest for him, because it was the second one which he had encountered within the last six months in which obstruction to urination had been caused by a calculus that had lodged in the urethra in the glans-penis. In the first case the calculus was not as large as was the specimen presented, and at his visit it was protruding somewhat so that he could see it. In the second instance, however, the calculus protruded only after making slight pressure upon the glans penis, and by so doing he was enabled to get hold of the stone with the forceps.

The specimen was referred to the microscopical committee.

Dr. Briddon remarked that several years ago he was called to see a child under similar circumstances, suffering with retention of urine. He introduced a catheter and felt a calculus in the perineum, and with great difficulty he got a small instrument beyond the obstruction and emptied the bladder. He arranged for its removal by operation on the following day, and Dr. Gurdon Buck was invited to be present. On their arrival, and after drawing the foreskin back, they found the calculus impacted in the meatus. This was removed and then a sound was introduced into the bladder and another calculus was felt, which he proceeded to remove by lateral lithotomy, and found it to be an inch in diameter. He thought it was proper in all these cases to explore the bladder with the sound to see whether there were any more calculi present.

UNDESCRIBED ERUPTION OCCURRING DURING THE USE OF BROMIDE OF POTASSIUM [ULCUS ELEVATUM].

The President presented microscopic sections with the following history: Annie L——, aged twelve, was brought to him at the Manhattan Eye and Ear Hospital on February 24, 1882, to be treated for peculiar attacks which he considered epileptic.

The child's health seemed good; she was fairly well-colored, and her skin was everywhere normal.

She was put upon regular bromide treatment, taking from three to four grammes a day at various times. The indications of coarse cerebral disease was so strong that he also gave her .75 grammes of iodide of potassium three times a day, and applied a few blisters behind the ears.

The epileptic attacks were at once controlled, and the child seemed to bear the medicines well. Owing to some annoyance at having to wait very long one day, the mother ceased bringing the child to the hospital; this was some time in March, and there was then no bromism or eruption.

Rather accidentally, Annie again came under his care in June, and upon inquiry he found that she had had private treatment since leaving the hospital, and had taken bromide of potassium only (no iodide). She was somewhat stupid from the bromide, but the amount given was impossible to ascertain. There was almost no facial acne; the child's color was clear and healthy. The mother, however, stated that since leaving the hospital clinic the child's legs had become the seat of very painful sores. The bandages were removed from both the child's legs, and he saw ulcers distinctly elevated above the surrounding healthy skin. The outlines of the sores were very irregular, varying in vertical width from three to eight centimetres; the largest surface of each sore being on the fibular side of the leg. The edges were sharply defined and nearly vertical. The surface of the sores, raised two or three millimetres above the healthy skin, was covered with brownish black scabs and a most offensive sanies. On removing some of these scabs a rough granulating surface, easily bleeding, was revealed. He used the word granulating, but the appearance was that of a firmer, more villous, in places almost papillomatous formation, than the delicate translucent and uniform surface of ordinary granulations.

The mother stated that this local trouble began in April, while using the bromide prescribed by the physician she consulted after giving up the hospital. At first the right leg was affected with large pimples or boils, which "broke," ulcerated, and coalesced into an open sore. In about a fortnight the left leg was similarly affected. Dr. Seguin directed that the ulcers be gradually cleaned of scabs by frequent washing, and that a strongly carbolized ointment be used twice a day. The dose of bromide of potassium was fixed at two grammes night and morning. The treatment was not carried out well, and on July 28th he gave her ether, and after removing nearly all the scabs from the left ulcer, applied to it Paquelin's cautery quite freely, and ordered a carbolized lotion for a few days, to be followed by applications of balsam of Peru ointment. At the same time he cut out a strip of the ulcer and adjacent sound skin for histological study; this was pinned on a cork and placed in bichromate of potassium solution. In cutting away this little flap he demonstrated that there was no appreciable lesion of the subcutaneous connective tissue; the derma seemed hypertrophied, but the whole piece was easily dissected away with the scalpel. He reduced the bromide to gr. xv. night and morning, and gave five drops of Fowler's solution after each meal.

Sections of the piece of tissue removed from the ulcer showed great increase in the thickness of the

rete Malpighii, with hypertrophy of the whole skin in places. In several places villosities visible to the naked eye occurred, made up of all the elements of the skin thrown up and out into a minute mushroom-like or polypoid mass. In other places proliferation of young cells had taken place in the cutis, with atrophy and rupture of the epidermal layer, and partial escape of the newly formed tissue, constituting a sort of abscess, opening externally. In other localities the patches of inflammation were wholly circumscribed and subepithelial. The deeper layers of the skin, and to a certain extent the subjacent connective tissue, were infiltrated with young cells. The papillæ, hair-follicles, and sweat-glands did not appear to be the seat of any primary or important inflammatory change. In no part of the section was its surface (edge) covered by granulation tissue, as in a common ulcer. From these appearances he concluded that the ulcer resulted from a dermatitis, which was partly suppurative but largely hypertrophic.

Dr. Heitzmann said that the form of disease described by Dr. Seguin was very rare indeed. Dr. Ripley may have remembered a case seen in his office of a girl twelve years of age, who was taking large doses of bromide of potassium for epilepsy, and the result was visible upon the legs. It was not until he found single pustules of acne (with regular gradations toward the condition upon the legs) that he reached the conclusion that the condition was due to the effect of the bromide. In his case, as in Dr. Seguin's, the local treatment cured the eruption without ceasing the use of the bromide. It was a form of dermatitis in which it was perfectly surprising to see what degree of hypertrophy of certain portions of the skin might take place. It was really a papillomatous dermatitis, as the part most always affected was the derma, and it was sometimes raised to a degree rarely seen in warty growths. The epithelium of the mucosum was not materially changed. It was entirely of the nature of papillomatous dermatitis.

Dr. Ripley remarked that he remembered the case, and also remembered that the bromide was discontinued, and the child got better. But the bromide treatment was renewed because of a return of the epileptic seizures, and he would like to know whether the eruption upon the leg returned also.

Dr. Heitzmann replied that it did not; also that the bromides were not discontinued entirely; that the size of the doses was simply diminished, but as the child had another epileptic attack the dose which had heretofore been taken was again prescribed. The local treatment which he adopted was that which he ordinarily employed in the treatment of eczema, such as the use of diachylon ointment, tar ointment, etc.

Dr. Jacobi asked the President if the naked eye appearance of the ulcer in any way reminded him of some forms of lupus.

The President replied, not so much the appearance of lupus as that of epithelioma.

The Society then went into executive session.

Malt Extracts are stated by Dr. A. B. Prescott, (*Physician and Surgeon*) to contain about ten per cent. of albuminoids, which are mostly in a soluble form, twenty to forty per cent. of malt sugar, and about five to eleven per cent. of dextrine. The amount of diastase appears to be small in amount and feeble in effect.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, October 6, 1882.

Dr. E. C. Spitzka, President, in the Chair.

Dr. E. C. Spitzka presented a case of

INSANITY FOLLOWING SCARLET FEVER.

The patient was a girl aged about twelve, who had had an attack of scarlet fever at the beginning of the year. Symptoms of insanity, with attacks of mania and epilepsy, supervened. The child at present was partially demented.

LARYNGEAL EPILEPSY.

Dr. L. C. Gray read a paper on laryngeal epi epsy, the laryngeal vertigo of Charcot. After narrating a case of his own, Dr. Gray gave the histories in full of four cases of Professor Charcot's, one by Dr. Gasquet, and a very remarkable one of Dr. Sommerbrodt's. In all of these the essential symptoms were: a spasmodic cough, accompanied by a tickling or burning sensation at about the level of the larynx, then a sudden loss of consciousness, occasionally with slight convulsive movements. In Sommerbrodt's case the symptoms were seemingly due to a large intra-laryngeal growth, which was removed, when the patient recovered.

Dr. Gray contended that epilepsy was a more fitting name for this group of symptoms than vertigo. He suggested the possibility of epileptic, convulsive, or neurotic tendencies, either personal or hereditary, in patients manifesting these symptoms, but of the six cases only two were stated to be non-epileptic, while a third (Sommerbrodt's) had been subject to convulsions in early youth; even in these two non-epileptic ones the hereditary and the merely convulsive or neurotic tendencies do not seem to have been inquired into.

The fact that the attacks ceased promptly under treatment by counter-irritation to the skin over the larynx and the internal use of the bromides, the author of the paper did not regard as a valid argument against the epileptic basis of this disease; for in many of the cases the duration of treatment is not mentioned, and in Sommerbrodt's patient, who was unquestionably of convulsive tendency, there was no return of symptoms during nine months' observation. Dr. Gray then gave an account of the violent spasmodic cough occasionally seen in locomotor ataxia, as described by MM. Féréol and Jean, and also an autopsy made by the latter author, when atrophy of laryngeal muscles and of the pneumogastric and recurrent laryngeal nerves was found; he claimed that this went to show that organic alterations leading to violent cough did not necessitate unconsciousness. Dr. Gray then completed his paper by alluding to the researches of Dr. S. Weir Mitchell during the civil war, as showing how great a direct injury of a nerve was needed to produce unconsciousness. Of fifty-six cases of gunshot wound of the brachial plexus, ten fell unconscious, seventeen fell without losing consciousness, and twenty-nine walked away.

Echinococcus Disease in America.—Dr. Wm. Osler, of Montreal, read a paper upon this subject at the recent meeting of the Canadian Medical Association, and said that he had been able to find the histories of only nine cases in Canada and sixty-one in North America.

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending October 14, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Oct. 7, 1882.	0	27	30	1	12	31	1	0

Medical Policlinic of the North-Eastern Dispensary.—We have received a circular announcing that the managers of the North-Eastern Dispensary have arranged to utilize the large mass of clinical material at this dispensary. Five clinics a week are to be held in one of the rooms of the main building. The clinics cover the subjects of Gynecology, by Dr. J. H. Gunning; Eye, Ear, and Throat Diseases by Dr. Simon Baruch; Skin Diseases by Dr. Wooster Beach; Nervous Diseases by Dr. Charles L. Dana; Heart and Lung Diseases by Dr. D. M. Camman. We are informed that the North-Eastern Policlinic does not aim to give a post-graduate course, but simply to furnish opportunities for personal study and diagnosis to limited classes. The terms begin October 27th. This attempt to make the material of our largest dispensaries available for study is a step in the right direction.

The Amount of Sulphur in organic combination in the urine is found by E. J. Stimson, Ph. C., to average .0031 gramme to 200 c.c. of urine. In a case of cancer of the liver this proportion was increased sixty fold, being .195 gramme to 200 c.c. of urine.

The New York Policlinic is another post-graduate school which will be opened in this city the present fall. It has been organized with the special view of teaching only clinical medicine and surgery. Didactic lectures will form no part of the plan of instruction at this institution.

A portion of the college building, situated in Thirty-fourth Street, is occupied by the Free Dispensary, under the management of the faculty, for the gratuitous treatment of the poor, and, in addition to the large number of patients treated, the matriculants of the Polyclinic receive bedside and operating-room instruction in the various hospitals and eleemosynary institutions of this city, with one or more of which every member of the faculty is connected.

There will be five sessions of six weeks each, commencing on Tuesday, November 7th. Thirty-six clinical lessons will be given on each subject during each session.

The Clinic will be open from 11 to 12 A.M., and from 1 to 5 P.M. daily (Sundays excepted), and both lecture-rooms of the college will be occupied at the same hour by different sections of the class.

The faculty is as follows: James R. Leaming, M.D., President of the Faculty, Professor of Diseases of the Chest; John H. Ripley, M.D., Visiting Surgeon to Charity Hospital and Visiting Physician to St. Francis Hospital, Professor of the Diseases of Children; E. Darwin Hudson, M.D., Professor of General Medicine; Louis Elsberg, M.D., Professor of Laryngology at Dartmouth College, Visiting Physician to Charity Hospital, Professor of Laryngology; Langdon C. Gray, M.D., Lecturer on Diseases of the Nervous System at Long Island College Hospital, Professor of Diseases of the Mind and Nervous System and Electro-Therapy; Richard C. Brandeis, M.D., Assistant-Surgeon to the New York Ophthalmic and Aural Institute, Professor of Laryngology and Otology; Andrew R. Robinson, M.D., Visiting Dermatologist to the Demilt Dispensary, Professor of Normal Histology in the Women's Medical College, Professor of Dermatology; Edward B. Bronson, M.D., Dermatology; George B. Fowler, Adjunct, Dermatology; John A. Wyeth, M.D., Surgeon to Mount Sinai Hospital, A. P. Gerster, M.D., Surgeon to Mount Sinai and German Hospitals, Professors of General and Genito-Urinary Surgery; Paul F. Mundé, M.D., Gynecologist to Mount Sinai Hospital (Outdoor Department), Visiting Physician to the Maternity Hospital, Professor of Gynecology and Obstetrics; W. Gill Wylie, M.D., Visiting Gynecologist to Bellevue Hospital, Surgeon to St. Elizabeth Hospital, Professor of Gynecology and Obstetrics; Emil Gruening, M.D., Visiting Ophthalmologist to Mount Sinai Hospital, to the German Hospital, Surgeon to the New York Eye and Ear Infirmary, Professor of Ophthalmology; David Webster, M.D., Assistant Surgeon to the Manhattan Eye and Ear Hospital, Professor of Ophthalmology; V. P. Gibney, M.D., Assistant-Surgeon to the Hospital for the Ruptured and Crippled, Professor of Orthopedic Surgery; Charles F. Stillman, M.D., Adjunct Professor of Orthopedic Surgery.

That Young Architect to whom our esteemed colleague, Dr. J. S. Billings, has been writing sanitary letters for so long, recently died at the ripe age of ninety-three. He reports the sanitary arrangements of his present quarters not up with the science of the day.

The Yellow Fever Epidemic.—During the week ending October 14th, 24 cases of yellow fever and 3 deaths were reported from Brownsville to the Surgeon-General of the Marine Hospital Service, making a total during the epidemic of 1,936 cases and 112 deaths. The disease is diminishing in the ranches. There are no cases outside the cordon. Since the 14th very few cases have occurred, and the epidemic is practically at an end.

At Pensacola, during the week ending October 11th, there were 420 cases and 27 deaths. Since that date the daily number of new cases has continued to be between 60 and 70, with from 2 to 4 deaths.

The mortality has been very light among the colored population. Three of the physicians have been taken sick, but are at present writing all doing well.

Some sensation has been occasioned by the appearance here of an Italian professor or doctor, who claims to be able to cure yellow fever effectually in the course of a few hours, without restricting the patient in drink, diet, or locomotion. In consequence, as is supposed, of a repetition of the same old scandal that generally occurs in epidemics, Major Walthall, Superintendent of Nurses for the Board of Health, has issued an order positively prohibiting nurses from accepting presents from patients under their care.

Nitrite of Amyl is said to stimulate the menstrual flow.

Original Communications.

CONSIDERATIONS ON THE ORIGIN AND NATURAL HISTORY OF TUBERCULOSIS.

By THOMAS E. SATTERTHWAITE, M.D.,

PROFESSOR OF HISTOLOGICAL AND PATHOLOGICAL ANATOMY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; PATHOLOGIST TO THE ST. LUKE'S AND PRESBYTERIAN HOSPITALS, ETC.

THE study of tubercle, as we understand the term in its broadest significance and under its most varying manifestations, has always attracted profound interest among practitioners of medicine; and chiefly because of the close relations it holds to pulmonary consumption. But it is proper to say, that the present century enjoys the credit of having made the most notable advances in its study, the names of Bayle,[1] Baillie,[2] Laennec,[3] Louis,[4] and Rokitansky[5] being associated with a number of established facts that belong to the history of the disease; while on the other hand, a more numerous body, representing the work of the last fifteen years, appears even to have surpassed the men of the earlier half of the century, if we found our comparison upon the thoroughness, exactitude, and practical utility of their studies.

Nor is this astonishing when we remember that the older work was based almost exclusively on morbid anatomy, while the modern has utilized not only pathological histology, but its necessary ally, experimental pathology.

If, therefore, in the first place, we compare the present sphere claimed for tubercle in the animal economy with that given by Rokitansky,[6] in his manual, we find that the joints (Koester[7]), iris (Gradenigo[8]), skin (Lang,[9]), bones (under certain conditions, Friedländer[10]), the blood (Baumgarten[11]), and even the female breast (Le Dentu[12]) and synovial sheaths (Terrier[13]) are parts of the system that may at times be invaded, some even asserting that any tissue or organ can be the seat of the disease.

Whether or not we are prepared to accept these dicta, or any considerable part of them, it must be confessed that we have at our disposal a vast mass of accumulated facts that are calculated to greatly simplify our conception of the disease. Let us now examine them, with the view of determining the vital questions that are at issue, and which centre about (1) the histology of phthisis; (2) its unitarian, dual, or plural nature; (3) its so-called infective qualities; (4) the mode in which it originates; and (5) the intimate nature of the presumed infecting agent.

It is my purpose, in the limited time at my disposal, to give a review, necessarily hasty, of the experiments and observations of these later years, so as to deduce from them such conclusions as they seem to justly warrant.

The word *tubercle* is here defined to mean miliary tubercle, the pearly or gray granulation of Bayle,[1] or of Laennec,[2] which, by the way, appears to have been first described by Mangetus, who, in 1700, edited Bonet's[3] Sepulchretum.

And since the conclusions that are held by many to-day carry us back toward the doctrines of the great French school, it will be necessary to recall to our minds the tenets of Laennec and Louis. Before doing so, however, it is well to premise by stating that Bayle described tubercular phthisis in 1809, clearly distinguishing it in his descriptions from other forms of phthisis that he called *melanotic, ulcerous, calculous, cancerous,* and *granular.*

Laennec, however, was the first to give a clear delineation of the morbid appearances. In 1819, he stated that tuberculous matter occurred either under the form of *insulated bodies,* or of an *infiltrated substance.* Of the former the chief varieties were the *miliary,* the *crude,* the *granular,* and the *encysted,* while the infiltrated substance was *irregular, gray,* or *yellow.* For him tuberculosis (pulmonary) was not inflammatory, and pneumonia was not transformed into phthisis. These views of Laennec were subsequently sustained by Louis, who, after having examined the records in M. Chomel's service at the Charité, where sixty-seven phthisical patients died during a period of three years, was enabled to say: "Nos observations confirment celles de M. Laennec, et que, pour nous comme pour lui, l'existence des tubercules dans les poumons est la cause et constitue le caractère propre de la phthisie." It is interesting for us now, after analyzing all the vast amount of work that has been done on this topic during the succeeding years, and before the microscope had become a power in medical pathology, to weigh well these remarkable words. Afterward Lebert,[4] who brought the microscope to bear upon the matter, further corroborated the teachings of Laennec and Louis, asserting confidently that both forms of tubercle already mentioned were of the same nature, containing the peculiar bodies that he called "tubercle corpuscles." Somewhat earlier, however, Rokitansky had given in his adhesion to this view, but called attention to the multi-nucleated corpuscles (mutterzellen), which he had observed in the tubercle granulum.

But these statements were not to remain long unchallenged, and Rheinhardt[5] had little difficulty in demonstrating that the so-called infiltrated tubercle had properties which would naturally belong to an inflammatory deposit undergoing cheesy transformation. It was now the merit of Virchow to step in, and accepting Rheinhardt's discovery, to ask for the repudiation of any so-called tubercle that was not of the miliary variety. This move in the direction of simplicity was the more acceptable when he demonstrated conclusively that the *yellow, infiltrated,* or *crude* tubercle (for it possessed these names in common) might originate from inspissated pus or encysted parasites.

These rigid requirements, however, seemed to raise an insuperable barrier before the adherents of the unitarian theory, for it was often impossible to

trace any genetical relation between the miliary disease and certain forms of phthisis.

It was natural enough, therefore, that some other cause should be sought for, and accordingly an opportunity was afforded for the doctrines of Niemeyer,[1] who endeavored to connect phthisis with pneumonia, of which he claimed it might be a natural sequel.

But Buhl,[2] of Munich, soon succeeded in turning the tide of opinion back to the direction in which it had formerly flowed under the influence of the French school, for he succeeded in showing that bodies resembling tubercles in their gross and microscopic appearance might be produced in animals by the presence in the body of certain centres of infection—cheesy foci. These views had been hinted at by Virchow, but loudly proclaimed by Villemin,[3] some years before, on the strength of elaborate and thoughtful experiments.

Villemin, who was a Professeur Agrégé at the École Imperiale of Val de Grace, had inoculated animals with the caseous matter of human phthisis, and found not only that his subjects soon gave evidence of infection, but upon being examined after death exhibited well-marked tuberculosis of internal organs. He accordingly adopted the view that phthisis is a specific disease and contagious, or, which is practically the same thing, communicable by inoculation.

Villemin's doctrines were neither favorably received by the French Academy, to a committee of which they were referred, nor by the pathologists of England and Germany, who repeated his experiments. For Wilson Fox[4] and Burdon Sanderson[5] argued that though the lesions were in reality produced they were not due to a specific virus, but rather to a *mechanical irritant*. Fraenkel and Cohnheim,[6] from their earlier observations, further sustained this view. The experiments of Waldenburg[7] also now assumed a proper prominence, for he showed that inoculation of alcoholic specimens and boiled tissues, which are inert as poisons, and aniline dyes, will also set up a tuberculosis. This experimental disease, therefore, received, and justly, the name *artificial tuberculosis*. But it was not without a struggle, for as each successive observer studied this artificial disease and compared it with the miliary lesions of tuberculosis, so it came to be discovered that the histological constitution of the tubercle is not a perfectly simple matter. The adenoid tissue, compared by Virchow to that which forms an important element in the structure of the lymphatic glands, was not always present, nor was the giant cell, first described and delineated by Rokitansky.[8] In fact the epithelioid corpuscles of Schneppel, which Rindfleisch thought so characteristic, were not always present, nor was there the central caseation which is now so much spoken of, though one or the other would usually be present; and yet the miliary body might also have developed into a fibrous nodule or simply a mass of plastic material containing the lymph-corpuscular elements. It was no wonder, then, that observers were in doubt as to the genuineness of either the real or the artificial disease, as the result of microscopic investigation, and it was not singular that Schottelius[1] should insist that phthisical granulations may be mistaken for minute capillary pneumonias or for occluded bronchioles. For it was thought necessary to believe that the tubercular deposit must occur at a special point in the lung, whereas we now know[2] that the infiltrations may originate in the wall of a pulmonary vessel, of a bronchiole or larger bronchial branch (Charcot), or an infundibulum, or alveolus, the intramural deposit itself, or the exudation from the contiguous surface, extending into the vessel, air-tube, alveolus, or infundibulum. Thus the histological structure has been found to be complex, and its site variable. Fortunately the gross appearances are such that no serious doubt could well be entertained of their true nature, for the early appearance of the bright, translucent granulations, often formed of aggregated spheroidal bodies, each at a later stage prone to undergo central caseation, establish conditions that are not apt to be confounded with any other deposits.

In returning to the question of the specific nature of the infection, we may now say that the conclusions of Waldenburg were offset by those of Gerlach,[3] Professor in the Veterinary College of Berlin, who claimed as the result of elaborate experimentation, that non-tuberculous matter will not produce tuberculosis. With this direct opposition of results among scientific men, it was thought best to adopt new methods, and accordingly Orth,[4] a pupil of Virchow, tried the experiment of feeding animals with tuberculous matter. He selected a number of rabbits that appeared to be healthy, and fed them with tuberculous matter from cows and human beings. The rabbits fed with the former became infected by generalized tuberculosis, but with the latter the results were negative. The microscopic characters of the lesions were the same as those found in the human species. Professor Schneppel[5] now came to the side of Villemin and Gerlach, and opposed Fox and Burdon Sanderson, for he showed that the forced inhalation of such substances as coal, cinnabar, dried pus, fecal matters, and mould fungi has no unfavorable influence upon the tissues of the air-passages. On the other hand, decomposing substances will, under similar conditions, cause processes that we should now regard as tubercular.

Tappeiner,[6] of Meran, continuing the same line of experimentation under Professor Von Buhl, subjected dogs to an atmosphere laden with phthisical sputum in a state of minute division. He compelled them to inhale it from twenty-five to fifty-one days. They were subsequently found to have developed miliary tuberculosis in every instance.

Schottelius[7] then varied the experiment by forcing dogs to inspire an atmosphere laden with various organic substances, such as bronchitic sputum, Limburger cheese, and powdered brain, in a state of fine division, and his results were the same as at first. These views were further sustained by Wargunin,[8] acting under Professor Rajewski, who subjected sixteen dogs to an atmosphere laden with

emphysematous sputa, meal, disinfected tuberculous sputa, and Schweitzer käse. The experiments were all positive, in so far as tubercles occurred in every case, the grade of the disease depending on the age of the process.

Some later experiments of Tappeiner[1] have taken away from the force of his early ones, in so far as that he could not infect dogs fed with tubercular matter from the human being, but Weichselbaum's[2] experiences of the present year sustain the theory of specificness. He performed eleven experiments on dogs, forcing them to inhale an atmosphere laden with tuberculous sputum, and infection followed uniformly, even after a single inhalation. When Limburger cheese was used, the experiments were negative in two cases, and positive in one. Of two dogs into whose bodies was injected a solution of tuberculous sputum, miliary intoxication ensued in both. Two dogs were then subjected to the same treatment, except that Limburger cheese was used, and the result was negative in both. He therefore felt justified in claiming that tuberculous matter, when inhaled or injected, uniformly produces tuberculosis, while, on the other hand, other substances either do not or only on particular occasions. The later experiments of Baumgarten gave further support to this view. Taking a few drops of blood from a tubercular animal, he succeeded in so inoculating the anterior chamber of the eye that a crop of miliary tubercles developed in the course of a few weeks. On the other hand, blood from a healthy animal produced no pathological effect. Even septicæmic blood had no other result than a chronic inflammation. This we see is directly opposed to the conclusions furnished by a case in the practice of Dr. J. R. Wolfe,[3] where a blow upon the eye was followed by a little nodule in the upper segment of the iris. After removal of the deposit the wound did not heal kindly, and finally the eye was enucleated. On microscopic examination, the iris and ciliary body were found studded with tubercles, showing in their centres giant cells. In this instance, the tubercles followed a blow, and the child was subsequently found to be cachectic, while indolent, ichorous ulcers developed on both legs. The teachings of this incident would seem to be, that the traumatism developed the tubercles, which subsequently became generalized; or, possibly, that the condition of the patient determined the inflammation to be tubercular. In either case, the traumatism seems naturally to have been the exciting cause.

Thus far, then, we have found one class of observers who claim from experiments on the lower animals that the inoculation of phthisical matter produces a specific disease—Villemin, Gerlach, Tappeiner, Weichselbaum, and Baumgarten; while it is even reported that some Greek physicians have injected tuberculous matter from a cow into the circulation of a living man doomed to death by gangrene of a limb. At the post-mortem examination numerous small and recent tubercles, without abscesses, were found.[4] On the other hand, Fox and Burdon Sanderson, Andrew Clark,[5] and Schottelius, Schneppel, and Wargunin oppose this view, while Cohnheim[1] first joined the opposition, and now appears to believe in a specific virus. The truth remains, that observers of the most respectable reputations have recorded results from the same series of experiments that are diametrically opposed to one another. Nor do clinical facts aid us materially. Thus while the contagionists refer to the often-asserted communication of phthisis to one another by cattle through *cohabitation*, by which is meant close association, as in adjacent stalls, the fact is assured, as I shall presently show, that the tuberculosis of animals is in several ways distinct from that of the human kind, and again the evidence of those who have had large experience in consumptive hospitals is by no means favorable to the contagion theory. Davies[2] and others I might cite show that there seems to be no tendency among the medical attendants or others employed in the care of the sick to contract the disease.

We therefore seem to be justified in claiming with Virchow, little more than two years ago,[3] that neither "experiments nor clinical observations, up to the present moment, have furnished any decisive facts. We should, therefore, consider the subject in a state of abeyance; for if one is desirous at present of arriving at a conclusion by comparing the positive and negative results that have been reached, especially in forgetting that the proportion of animals used for investigative purposes which became spontaneously tuberculous is considerable, he must go beyond the facts in the case. It is possible to think that hazard plays an important rôle in the results. For one, at least, who cannot recognize the similarity of the tubercles of the bovine race and the caseous products, the results obtained, so incongruous and contradictory, do not appear to me to have been yet scientifically demonstrated. Therefore, in the light in which I consider it, experimental investigation should be devoted to ascertaining if, by any alimentation, consisting of different, altered, and unwholesome substances, a formation of similar products will not occur in the organism of our domestic animals. Moreover, it is only by including in our researches a very large series of subjects, and not isolated cases, as some physicians have done lately, that we will succeed in learning in what proportions pre-existing or coincident affections force the result of the conclusions."

In the presence, then, of this opposing array of statement and counter-statement, how difficult it is to believe that we are in the presence of an infective disease, armed with a specific virus.

For even the apparently conclusive experiments of Cohnheim and Baumgarten are met and negatived by the no less striking one of Wolfe, in which he clearly shows that a simple traumatism of the eye in an apparently healthy child occasioned miliary tuberculosis that led slowly but steadily to systemic infection.

Before closing this part of our subject, it will be worth our while to advert for a moment to the experiments of Professor Siedamgotsky,[4] employed by the Chancellor of the King of Saxony to inquire "whether and how far the use of the meat and milk of cows which have the pearl disease (bovine tuberculosis) is harmful to human beings." He experimented on nineteen lambs and pigs, the latter being presumed not to have proneness for tubercle.

[4] Siedamgotsky: Arch. f. Wiss und pract. Thier-hlke., Ma 8, 1882.

Twelve lambs and pigs were fed on tuberculous milk or meat, and eleven were found, on post-mortem examination, to be tuberculous. The positive results of this experiment are met by the fact that of five lambs and pigs which were subjected to the same conditions, except that they were not fed with tuberculous matter, four were found, on post-mortem examination, to be tuberculous; so that he was justified in concluding that his experiments yielded no result giving any positive support to the statement that tuberculosis can be conveyed to mankind through the milk or meat of tuberculous (pearly) cattle.

The evidence of Law on an allied point is also important. According to him ("National Board of Health Bulletin," 40, 1882), we have no satisfactory evidence that tuberculosis has ever been conveyed by bovine lymph. How then explain that animals, especially pigs, should acquire tubercle, as Siedamgotsky's did, when not naturally prone to it? May not the answer be, as suggested by Virchow, that *under confinement* certain foods or drinks will permit of the disease being engendered?

This supposition brings us back to the tuberculosis of horned cattle, and the phthisis of animals in menageries and zoölogical gardens, which, according to many old observers, is to be credited to their captivity. According to Cruzel, quoted by Fleming,[1] of one hundred old and fat oxen, fully half were tuberculous, while cows were rarely affected. Prof. Lafosse, of the Toulouse Veterinary School, found that cattle employed in agriculture, or cows that were used for breeding purposes, escaped the disease; while, on the other hand, long-continued lactation promoted it. Still, remarkable instances are given by veterinary surgeons, where cattle apparently healthy have become tuberculous by cohabiting, *i.e.*, occupying the same or adjacent stalls.

And now it is well to observe at this point that the so-called bovine tuberculosis is, in reality, different from the human, at least in its morphological character and mode of development. We therefore should recognize, with Virchow, that this difference may impair the strength of arguments based upon the use of it in inoculation experiments. The points of difference are as follows: In man tubercle tends to become caseous; in cattle cretaceous. The cretaceous change is comparatively rare in the human being, and follows the caseous. The caseous change is a rarity in the bovine race. Ulcers and cavities (vomicæ) are characteristic of the advanced stages of human phthisis, which we have here assumed to mean tuberculosis. They occur rarely, if at all, in the animal variety.

The little centres of disease in the bovine race grow by the deposit of cretaceous matter in concentric layers until the pulmonary lobule is distended to many times its normal size, so that at length in some cases it bursts through its boundaries and unites with a similarly extending deposit in an adjacent lobule, the two forming a yellow tumor of stony hardness. Meanwhile the interlobular tissue is filled with little tumors, usually pedunculated, that vary much in size, each developing a yellow centre. (See Fig. 1.) The visceral and parietal layers of the pleura are also covered with similar tumors, which are then known by the name of "grapes," "angleberries," etc. (See Fig. 2.) Now the affected glands develop in a similar way in cattle by "concretive accretion," while in the human kind they first atrophy before the deposit of lime-salts takes place. Virchow,[1] accordingly, has been inclined to regard the latter changes as similar to those that attend the development of tumors, and prefers to consider them in the category of the lympho-sarcomata. At this point it is but proper to advert for a moment to the remarkable views of Dr. Charles Creighton,[2] of

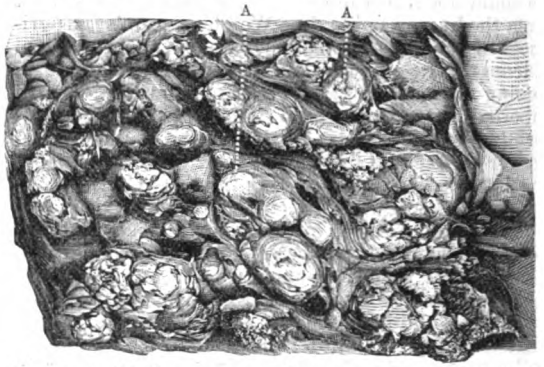

FIG. 1.—In this figure are seen the cretaceous nodules, A, A, of bovine tuberculosis. From the photograph of a specimen in the possession of the author of the paper.

Cambridge, England. This observer, in conducting post-mortem examinations on phthisical human subjects, was led to think that a certain class could be separated from the ordinary varieties, and these presented certain peculiarities similar to those described in the pearl disease (bovine tuberculosis, *Merlinsigkeit, Duckweed, Potato Disease*). In the twelve cases which serve to form the basis of his views, he lays stress upon certain (1) leaf-like or cord-like outgrowths of the pleura and peritoneum; (2) distinctly nodular formations in the lymphatic glands; and (3) the smooth-walled vomicæ or en-

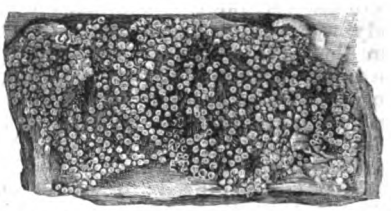

FIG. 2.—In this figure are seen the "angleberries" or "grapes" of the bovine race, this specimen having been taken from the parietal pleura of a tuberculous (pearly) cow. Each berry is usually pedunculated, and each has a cretaceous centre.

capsuled nodules. Apropos of these points, it may be said here (1) that the writer's experience in two cases of bovine tuberculosis do not lead him to believe that the "leaf like or cord-like outgrowths" are distinctive of the bovine disease, and that there is a danger of mistaking cross-sections of terminal bronchial twigs for smooth-walled vomicæ; a criticism which has already been made by one who has authority.

It is also well to observe here that it is not only in the lungs that these curious tumors are found, but also in other parts of the body, as in the peritoneum, membranes of the brain. When, therefore, Toussaint,[3] in a very recent article, claimed that tuberculosis of men and cattle is the same, he laid himself open to serious criticism, and when he, on

another occasion, detailed the results of his experiments on hogs, rabbits, and cats, it was easy to see in the first place, from the experiments of Siedamgotsky, that hogs may be improper subjects for experimentation, while we are also now aware that rabbits are wholly unsuited for the purpose, since both they and guinea-pigs are prone to tuberculosis under the ordinary conditions in which we find them.

But turning aside from this form of animal experimentation, let us glance at another method. For some years past a certain class of German and French observers has been devoting attention to the question of bacteria and their relation to various infective diseases. Tubercle has, according to various of them, been claimed to have a peculiar pathognomonic parasite, but since this claim has been so frequently made, and often upon slender grounds, pathologists have not turned very willing ears in this direction.

Quite recently, however, Dr. Robert Koch, now of Berlin, advanced a theory in support of the doctrine of a specific parasite in tubercle, and his writings and demonstrations have revived the matter and secured for him an unusually attentive hearing.

I do not propose here to give an extended description of the methods employed by Dr. Koch, suffice it to say that he finds a peculiar microphyte in every form of tuberculosis. This parasite has a length equal to half the width of a red blood-corpuscle, is staff-shaped, and has a slightly notched extremity. By a special method of his own he cultivates it in the blood serum from the ox, and having isolated it, as he claims, inoculates successive cultivations upon different animals. It is not my intention here to criticise his methods, but merely to say in passing that experiments on rabbits and guinea-pigs, which he practised extensively, are open to objections on grounds that have already been given. But so far as my personal experiments are concerned, and they have not been numerous, I have not been able to discover these bacteria by Koch's method, although I have seen the pulmonary alveoli of phthisis crowded with ordinary bacteria. I have been successful, however, in obtaining certain peculiar bacteria in phthisical sputum. Dr. Devlin, of the St. Luke's Hospital resident staff, having recently obtained for me some phthisical sputum, I subjected it to the method of Dr. Gibbes,[1] curator of King's College Museum, London.

The following are the formulæ recommended:

Take two grammes of magenta crystals, three grammes of pure anilin, twenty cubic centigrammes of alcohol, specific gravity 830, and twenty cubic centigrammes of water. Dissolve the anilin in the spirit and then rub up the color with it in a glass mortar, adding the spirit gradually until it is all dissolved, then add the water slowly while stirring, and keep in a stoppered bottle. Make a saturated solution of chrysoidin in distilled water, and add a crystal of thymol to make it keep. A dilute solution of nitric acid (com.), one part of acid and two of distilled water is then made.

Spread a thin layer on a cover-glass and let it dry; when quite dry pass it two or three times through the flame of a small Bunsen burner and let it cool. Filter two or three drops of magenta solution in a watch-glass, place the cover-glass with the sputum downward in the stain, taking care that there are no air-bubbles under it. Let it remain for fifteen or twenty minutes, then wash in the dilute acid until all color has disappeared. Remove the acid with distilled water, when a faint color will return; then place the cover-glass in the same manner as before in a few drops of chrysoidin filtered into the bottom of a watch-glass, and let it remain a few minutes until it has taken on the brown stain; wash off the superfluous color in distilled water and place the cover-glass in absolute alcohol for a few minutes; remove and dry perfectly in the air and then mount." Prepared in this way certain bacteria may be seen which, according to measurements made by myself, in conjunction with Mr. Grunow, the microscope maker, had a diameter of about $\frac{1}{21600}$ inch. They were rod-shaped, somewhat constricted at the centre, like the cakes known as lady-fingers, and had a length equal to three or four times their breadth. They stained a deep blue, and were to be distinguished from other rod bacteria in chains that did not color, and still others which appeared in groups, the so-called micrococcal colonies. The breadth of these latter was about $\frac{1}{31000}$ inch. These bodies were not as uniform in appearance and arrangement as the ordinary bacteria of the mouth that may be seen when covering an epithelial scale, but while grouped together were at somewhat varying distances apart. Though taking the color, as described by Koch, they do not precisely correspond to his description, and it is just here where there is an insufficient amount of agreement, even among those who believe with Koch that we are in the presence of the specific parasite. The inoculation experiments of Koch, however, though requiring time, are not remarkably difficult, and we may hope that within a short time sufficient light will be thrown upon the subject to enable us to estimate their proper relations to phthisis.

Should these peculiar views eventually prevail they would set at rest forever the question as to the dualistic or pluralistic character of phthisis. It is noteworthy, however, that there is a strong tendency toward the unitarian theory of consumption, not so much the result of histological study as from the standpoint of experimental pathology and morbid anatomy. For continued research has shown that while we cannot regard either adenoid tissue, the giant-cells, epithelial corpuscles (Schneppel's), or round-celled infiltrations as pathognomonic, we have turned rather toward a point in the gross appearances, viz., *central caseation*, which in most cases develops in due time. But the revelations of the microscope have not been without their good result, since they have shown that all these elements are merely the ordinary products of inflammation, which, however, instead of progressing toward organization tends toward destructive metamorphosis. And the close relation of tuberculosis with inflammation is further shown by the fact that the miliary deposits accompany or are a sequel to inflammatory processes. Indeed, *artificial tuberculosis* is uniformly produced by agents that set up inflammation.

How, then, may we explain the different aspects under which we recognize phthisis? In a simple manner. The miliary tubercles form at first either in the nooks and angles where the bronchiole meets the alveolar passages (Rindfleisch[1]) or in the walls of a vessel (Cornil and Ranvier[2]), infundibulum, or even in one of the larger divisions of the bronchus. These nodules, growing, eventually occlude the alveolar passage, vessel, or bronchiole, as the case

[1] The Lancet, Aug. 5, 1882.

[2] Cornil and Ranvier, loc. cit.

may be, and uniting to form a globular mass set up an inflammation in the surrounding tissue. It may be a pneumonia; it may be a bronchitis. The former is the *desquamative pneumonia* of Buhl, or *infiltrated tubercle* of Laennec, or it may be that the tubercles do not undergo caseous change, but the fibrous, and that the adjacent inflammation partakes of the same nature. This form of tuberculosis, the fibrous, occurred in one-third the cases of Charcot; about one-fourth, or twenty-eight per cent., is my experience, while the cheesy change occurs in about one-half, fifty-two per cent., the calcareous in thirty-seven per cent. Miliary tubercles were found in my experience in about one-third the cases that I have recorded (thirty-two per cent.), but this is doubtless a low estimate, for attention was not always specially directed to this point. Orth[1] found tubercles in about one-half the cases of phthisis he saw.

Cavities are found as the result of the separation of large cheesy masses, which are formed by the caseation of the tubercles and the contiguous tissues.

Fibrous phthisis is that form of phthisis that is undergoing spontaneous cure, a result which nature has in view, and will often accomplish, if she meets

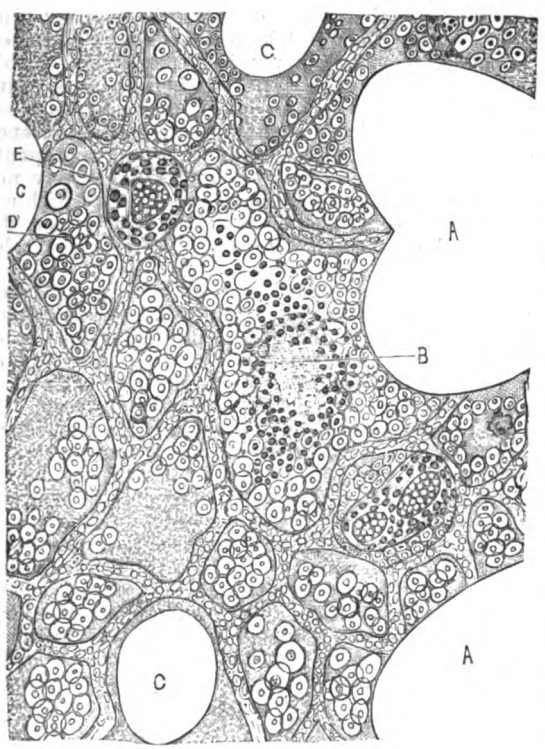

FIG. 3.

with assistance rather than obstruction to her peculiar methods. In this form of phthisis miliary bodies are hard to find, and yet Baumgarten[2] claims to have been successful in finding them by assiduous investigation. These unitarian views receive the support of Charcot,[3] Grancher,[4] Cornil and Ranvier[5] of the present French school, as well as Rindfleisch,[1] Ziegler,[2] and Koester[3] of the German school, Fox, Burdon Sanderson, Moxon, and Andrew Clark of the English, and carry us back to that remarkable phrase of Louis to which we have already alluded, and which was uttered more than sixty years ago: "L'existence des tubercules est la cause et constitue le caracter propre de la phthisie."

The illustrations of miliary tubercle employed in this article were taken from original specimens in the possession of the author, and exhibit the lesions as they were seen in the most typical examples of disease, viz., in the pulmonary tissue and serous membranes. In the one instance (Fig. 3) the miliary nodule is seen to be located in the wall of an infundibulum (A), while there is a change in and about a blood-vessel (E) that indicates it is the seat of commencing tuberculous change. The centre of the granulum (B) is cheesy, but whether or not this cheesy centre corresponds to a giant-cell is difficult to say. About this centre is a zone composed of degenerating corpuscles, of lymphoid and epitheloid type, while on the extreme outer boundary are the enlarged and spheroidal cells that approach very nearly in approach to the description given by Schneppel. C, C, C, are cross-sections of bronchioles, and D is an alveolus in the condition of catarrhal pneumonia.

In Figure 2, an example of human tubercle in the omentum, the miliary body (A), is seen in close connection with one of the fibrous trabecles, having possibly originated from a lymphatic or blood-vessel of the part. Curiously enough, at some distant points may be seen multi-nucleated corpuscles (B), as well as rounded lymph-corpuscles (E) and the proliferating endothelial elements (C) of the connective tissues. Now all of these elements are found in ordinary inflammatory deposits, so that, as already intimated, the whole process is suggestive of inflammation, and that it really is associated with an inflammation may be seen by inspection of the air-vesicles in Figure 3, where, as already said, the histological characters are those of catarrhal pneumonia.

In the so-called laryngeal phthisis we have, according to my investigations, less pronounced forms of tuberculosis, though the miliary bodies are also found, but it is not improbable that in some such organs there may be diffused inflammations, tending, it is true, to caseous change, which exhibit modifications of the typical miliary tubercle. And now we come to the hereditary question.

No one can doubt, notwithstanding all the discussions on the infective quality of the disease, that tuberculosis is hereditary, for this fact has been abundantly proved by statistics. How then can the contagionists explain a fact apparently so at variance with their theory? In the following way: Rindfleisch says that the virus requires for its soil a diathesis, which he calls the scrofulous. Koch also admits that the soil must be suitable, or, which is the same thing, that there must be a predisposing condition, though, singularly enough, he tells us that he can invariably inoculate dogs with tubercle, and yet dogs have no tendency to the disease.

The disease is thus admitted by the most ardent of contagionists to be connected primarily with a vicious constitution, which only blooms into the full vigor of tubercular maturity when it has been attacked by the infecting agent.

[2] Ziegler: Lehrb. d. allg. u. spec. Path. Anat., i., p. 156 et seq.
[3] Koester, loc. cit.

There are then two factors: a predisposing condition and an infecting agent, and tuberculosis may be called, as Baumgarten claims, a *latent disease.*

Looking, therefore, at the origin of the disease from this standpoint, scientific treatment should be addressed, in the main, to the primary condition.

For is it supposable that in the event of the disease being conclusively shown to depend for its origin on a peculiar parasite, we can escape it successfully, or safely endure such treatment as will render it harmless?

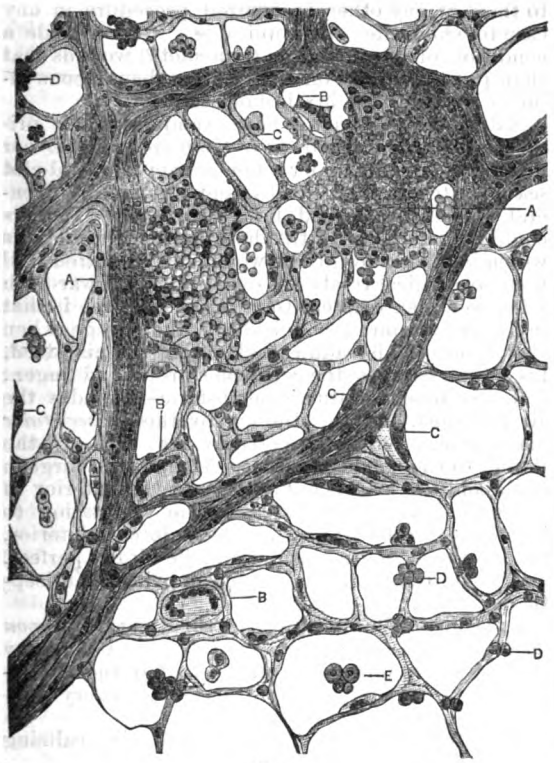

FIG. 4.

I now venture to propose the following conclusions, which I think may be fairly drawn from a study of this question:

1. Tuberculosis is a disease that deserves the name hereditary, for it attaches itself to certain families throughout many successive generations; and it is most apt to attack those members that are deficient in physical vigor, from whatever cause. Proper precautions often enable those that are thus liable to escape it or withstand it successfully.

2. The most distinguishing characteristic of tubercle is the occurrence, in the tissues, of minute, bright, glistening, translucent particles that have been called miliary tubercles, granula, granulations, etc.

3. They are the result of an inflammatory process, because they can be produced by the introduction of mechanical irritants into the system.

4. When these minute bodies coalesce to form larger bodies and undergo a change of color, they are known as crude or yellow tubercles.

5. Some of them contain the reticulated tissue that has been called adenoid, because it resembles the retiform tissue of lymphatic glands. As the miliary tubercle advances in age, one or more large multi-nuclear foci may be found, either at the centre or periphery of the nodule. Sometimes Schneppel's epithelioid corpuscles are found, sometimes lymphoid elements, and sometimes fibrous tissue, but no one of these tissue elements, which all belong to the connective-tissue series, is pathognomonic of tubercle.

6. The lungs and serous membranes are most frequently attacked, and it is here that the natural history of the tubercle is studied to the best advantage. In other regions of the body there may be modifications of the tubercle, so that its distinctive character is difficult to demonstrate.

7. In the gradual development of these bodies they undergo caseous change at the centre, which phenomenon is another marked feature of tubercle. Still, in some instances we have reason to suppose that the miliary tubercle may become organized, and thus a cure result.

8. Tubercles are rarely found without more or less contiguous inflammation that may be classed as a pneumonia or bronchitis. The latter is the *infiltrated tubercle* of Laennec, the *catarrhal pneumonia* of Niemeyer, or the *desquamative pneumonia* of Buhl. The pneumonia may, perhaps, be protective in some instances, serving to wall off a caseous process, thus preventing it from becoming disseminated, or it may eventually itself participate in the same process and lead the way to necrosis of the lung and the production of cavities.

9. Tubercles may be confined to a limited area and a single lobe of the lung, or a single lung, or they may be diffused pretty equally in different organs. Generalized, disseminated, or secondary tuberculosis is the most dangerous and malignant, and is probably due to transmission of the disease by the lymphatics or blood-vessels, usually the latter. In this secondary form the first manifestations are the gray granulations, as they are also in the primary form.

10. Tuberculosis is inoculable, producing its kind if it produces anything, but other substances will also, in a certain number of cases, produce the same apparent lesions; in fact, not only any organic substance that is capable of physical deterioration, but also a variety of non-organic substances.

11. There is some good evidence favoring the theory that consumption is contagious, *i.e.*, that it is capable of propagation by *cohabitation*, or, in other words, close association with persons that have the disease. The number of well-authenticated instances, in the human being, where the origin of the disease can be explained in this way, is sufficient to give considerable strength to the theory. The best evidence on this point is obtained from a study of phthisis in the domestic animals, especially in horned cattle.

12. And yet the morphological differences between their form of phthisis and those of the human being are such as to put us on our guard against forming hasty conclusions from a comparison between them.

13. Nor does it appear that we have good grounds for believing that the meat or milk of phthisical cattle, when taken as food, has ever produced a single instance of tuberculosis in the human being.

14. But we should, none the less, discountenance the sale of such meat or milk, since even if they are not infectious, they are deficient in proper nutritive elements, and for this reason alone should be debarred from sale.

15. And so in the case of bovine virus, though it does not appear that any person has been rendered tuberculous, yet no vaccine virus should be held to be suitable for vaccination purposes unless proper assurances have been given that the animals yielding the vaccine were in every respect free from tubercle, as determined by inspection after slaughtering.

16. Pulmonary tuberculosis and pulmonary phthisis are, in the majority of cases, interchangeable terms.

17. As a natural deduction from the above views attention should be directed chiefly, in prophylaxis and treatment, to the vicious constitution which is conceded to be an essential prerequisite of the disease, rather than to a contagion that at best plays only a comparatively infrequent and subordinate rôle.

PRIMARY ANTISEPTIC OCCLUSION IN MILITARY PRACTICE,

With Cases from the Big Dry Wash Fight, near Generals' Springs, Arizona, July 17, 1882.

By H. I. RAYMOND, A.M., M.D., U. S. A.,

late house surgeon to bellevue hospital.

A perusal of Karl Reyher's pamphlet on "Antiseptic Military Surgery," published among Volkmann's Klinischer Vorträge and giving the author's own experience in the "Battle of the Red Cross," convinces the reader: first, that the "antiseptic occlusive" method of treatment of injuries inflicted by the cylindro-conoidal bullet projected from a Springfield or other modern rifle or carbine is, when applicable, *the best treatment*, and, second, that this method by occlusion has a *very wide range of application*.

In this article Reyher sets forth the merits severally of (1) *non*-antiseptic occlusion or the healing of a wound, as, for example, under a blood-clot scab, without surgical interference; (2) primary antiseptic occlusion or the healing of a wound under an occlusive covering, as in the first instance, but with antiseptic precautions; (3) primary antiseptic drainage, or the thorough disinfection of a wound inflicted by contact with the surgeon's probe or finger, or air and dust particles or other foreign body, and the insertion of drainage-tubes to drain off the secretions of the wound before the setting in of the suppurative stage—indeed, intended to forestall suppurative action, to head off and prevent the setting in of inflammation, and to allow of reparative reaction and secretion; (4) primary resections and amputations; (5) intermediary drainage, resections, and amputations; (6) secondary methods of treatment (drainage, resection, and amputation), treatment established after suppurative action has set in.

All these methods, when properly employed, are conservative, although all are not antiseptic. The two adjective terms are not synonymous, since conservative surgery was practised long before antisepsis was known, but antiseptic treatment makes conservatism in surgery more widely applicable.

Karl Reyher's tables of statistics, collated from his own experience, are so overwhelmingly convincing and yet apparently so incredible, and withal an innovation in respect to his primary antiseptic occlusive method as applicable to so large a proportion of wounds inflicted by the cylindro-conoidal bullet, and the per cent. of mortality of primary antiseptic occlusion as compared with even primary antiseptic drainage so surprisingly small, that one may justly hold the theory in reservation until afforded an opportunity for a practical test of its claims in the treatment of wounds under his personal supervision.

This opportunity came to the writer when he was ordered to proceed at once to the scene of the recent engagement with hostile Indians near Generals' Springs, and take charge of those wounded in the fight with the White Mountain Apaches.

These cases, numbering seven (exclusive of slight wounds), together with two pistol-shot wounds of the knee-joint occurring in Bellevue Hospital during the writer's interneship, will serve in this paper to illustrate the primary antiseptic occlusive method and emphasize its claims and merits as paramount to those of any other recognized procedure in any case to which they are applicable. "To provide a condition of our operation (gun-shot?) wounds that shall put them fully on a par with subcutaneous injuries is plainly the ideal of our art."

Nature affords us the best examples of the primary occlusive method *without antiseptics*, as in her healing of wounds under a non-antiseptic blood-clot scab. After the Nez Perces campaign in 1877, General Howard remarked how surprisingly Indians could bear hardships; that he had often met Indians whom he had known to be wounded and gotten well without surgical treatment *again* upon the war-path a few weeks subsequent to injury. The fact is that in Indian warfare (on horseback) the savage, when shot, keeps in his saddle, and, riding on his steed, his wound escapes the surgeon's probe and finger; a clot of blood—Nature's hemostatic—excludes the air and dust, and the Indian, by this *lasser faire* management, virtually entrusts the care of the wound to the hands of nature. If, now, the surgeon could add thereto his antiseptics to the exterior of the wound without yielding to the temptation to insinuate a probe or pass his finger into its interior, the treatment of the case would be ideally perfect, and would illustrate an instance of primary antiseptic occlusion.

To secure the application of this treatment *upon the battle-field* to the majority of wounds before any meddlesome interference on the part of the attendant or surgeon should be the aim of every well-informed military surgeon.

That there is nothing impracticable in realizing this desideratum at or near the field or place of reception of shot wounds ought to be apparent, since all that is absolutely necessary are carbolic acid solution (the carbolic acid may be transported chemically pure), iodoform in crystalline form, pledgets of cotton-flannel, and roller bandages.

It is to be lamented that too often in civil life, with all its practicabilities, a shot wound adapted to treatment by primary antiseptic occlusion loses its golden opportunity by contamination from an ill-advised inspection, and must fall one notch below in the category and come under treatment by primary antiseptic drainage, which, though more desirable than intermediary or secondary methods, does not afford results comparable with those which may be obtained by primary antiseptic occlusion; by which is meant, treatment sans *probe, sound or finger,* sans *extraction of bullet,* sans *drainage,* sans *everything except disinfection of the exterior of the wound and occlusion of the same.* It is astonishing how widely applicable to the treatment of wounds inflicted by the cylindro-conoidal bullet of modern warfare is this primary antiseptic occlusive method, for the entrance of the missile is small, and since in war the aim is to wound and not to kill, this slot-like *entrée* would seem to accord with the humane principle; and, moreover, the projectil

in its transverse diameter is so small and its velocity so great that seldom are large shreds of clothing carried within, as was too often the case with the round bullet.

To illustrate how insignificant the entrance of a bullet often is, and how well adapted for primary occlusion such a wound is, being virtually from the moment of reception a subcutaneous injury, the lips of the wound being alone infected by contact with the external world, I might cite an instance which occurred in the hot month of August, 1870, while a scouting party were following an Indian trail in one of the Western territories. After a brief encounter had taken place and the medical attendant and hospital steward were caring for the wounded, they came upon a man lying in a moribund state.

At a glance no external sign of injury could be detected about his chest or abdomen, and the case was supposed to be one of sunstroke or apoplexy, when by close inspection a narrow button-hole slot, situated over the manubrium, came to notice. Here, then, was a wound which might have been dealt with as a *subcutaneous* lesion, with the single addition of antiseptic cleansing of its superficies. This principle of antiseptic occlusion is carried out by Prof. E. von Bergmann in his treatment of compound fracture of the penetrating variety, as cited by the *Quarterly Epitome* for December, 1881, to Braithwaite's Retrospect, as appearing in a paper translated in the *London Medical Record* from the *Wien. Med. Woch.*, No. 10, 1881. The *Quarterly Epitome* states that Prof. E. von Bergmann, in his treatment of penetrating fracture, deviates from the rules laid down by Volkmann for the management of open fractures in general. "By penetrating fracture is meant that form of fracture in which the skin is perforated at one small spot by the sharp extremity of bone." In dealing with such a case from the start, Dr. von Bergmann does not dilate the wound and endeavor to establish primary disinfection. He restricts his action to careful cleansing, by solution of carbolic acid, of the surface of *the injured limb*, and to washing out of the small wound. In case of compound fracture with large and gaping wound, this author follows Volkmann's practice of attempting primary disinfection. The latter case is comparable, of course, to large shell wounds, which demand primary antiseptic drainage, and do not permit of occlusion, or to a case complicated with primary hemorrhage in which the necessity exists to cut down upon the bleeding vessel and ligate, or in the event of clothing and other foreign material exclusive of the bullet being carried into the wound in such quantity as to necessitate its removal and a thorough primary disinfection of the entire wound.

On the other hand, Prof. von Bergmann's treatment of a compound penetrating fracture is identical in principle to the management of virtually a subcutaneous (penetrating) gun-shot injury, whether complicated or not with fracture of the bone, inasmuch as his object is to exclude all irritating and infecting entities by occluding the stoma of the wound. Now, in certain purse-like constricted wounds which are not uncommon from the cylindro-conoidal bullet projected from a Springfield rifle, this stoma becomes an outer vestibule and prevents the admission of infecting media into the sanctum within. Whether the bone be fractured or not, the lacerated veins and lymphatics stand ready to carry any obnoxious material into the circulation, and thus induce systemic infection, and it is obligatory upon the surgeon to prevent, by primary antiseptic occlusion, the possibility of infection in these flesh wounds, as it is plainly his duty in the probability of the same when the medulla of the bone is exposed.

Although of all methods of primary treatment of gun-shot injuries, including *non*-antiseptic occlusion as under a blood-clot scab, primary antiseptic occlusion, and primary antiseptic drainage, none will be found more widely applicable than the primary antiseptic occlusive method, yet, however, if a wound that is fresh be certainly infected by the entrance of dust particles or floating germs, or from any source whatsoever, the occlusive method is not applicable without harm, in that it would shut up foul secretions within. The entrance of air in such small quantity that it may be readily absorbed, or the presence of a small spiculum of bone as of a rib, or a small shred of flannel shirt or leather belt, does not, as a rule, preclude occlusion, for the former may be absorbed before putrifying, and the latter may become encapsulated like a retained bullet or may work its way out later when the dangers of suppuration and putrid infection are past.

These conditions of the entrance of air and the presence of particles of foreign substances are exemplified in two of the cases cited below and treated by the occlusive method. It becomes, therefore, in certain cases of doubtful infection, a nice question to discriminate whether the wound should be treated by occlusion or openly.

To excite a debate upon these vexed and mooted questions, Langenbeck, in the congress for surgery, proposed the following interrogatories: 1. "What cases of wounds should be treated under the scab (antiseptic)?" 2. "What under primary and secondary drainage?" 3. "What wounds are adapted to the open treatment?"

This paper has to do mainly with the first interrogatory.

So much, then, for the theory of occlusion with antiseptic precautions from the start; now as to its practical workings and results. The principles of primary antisepsis should be introduced upon the field of battle or place of reception of wound. Nos. I. and II. are cases of pistol-shot wounds of the knee-joint—one a girl and the other a boy of about the same age, twelve years, who were admitted into Ward —, Bellevue Hospital, in 1881, immediately upon receipt of injuries. The cartridge in the girl's case sank deep into the patella, from which it was immediately extracted by the surgeon, and a probe passed into its bed to determine whether or not the missile had opened the joint cavity. The wound was then occluded antiseptically, but not without being previously infected by contact with the foul air of a hospital ward and the surgeon's germ-carrying probe and finger. The further history of the case was the substitution of primary drainage for occlusion, the setting in of phlegmonous erysipelas, but finally recovery, with an anchylosed joint.

Heeding the lesson, the surgeon in the case of the boy, whose bullet grazed the lower edge of the patella on the inner side of the mesial line, applied, without preliminary manipulations, a primary antiseptic occlusive dressing, and caused the limb to be kept at rest. In six weeks the lad was about on his limbs, and the affected joint was restored without anchylosis. The temperature during the first ten days ranged at about 1° above the normal.

The surgeons, seeing the result of this primary antiseptic occlusive treatment, were divided in opinion. Some said the ball did not enter the joint

proper, but had lodged in the abundant loose cellular connective tissue below the patella.

These based their judgment upon the preconceived supposition that did the boy recover with full use of his limb, it would be evidence on its face that the injury was not *intra*-articular.

I am persuaded to the contrary since my perusal of Professor Karl Reyher's article, to which I had access through the choice library of Dr. Albert Adler, U. S. A., on the treatment of gun-shot injuries of the joints. In this article are cited five cases of shot injuries of the joints, with lodgment of the projectiles, all of which healed without anchylosis under a dry blood-scab, *i.e.*, by primary occlusion *not* antiseptic. Why, then, should we expect less from primary *antiseptic* occlusion?

In one of Reyher's tables, comprising 16 cases of knee-joint shot injuries, with lodgment of the projectile, treated from the start by *conservative* treatment, 4 of the 16 cases recovered and retained their movements, being treated *from the beginning* on *antiseptic principles*. In 8 of the 16 cases, on the first day after the injury there were no antiseptic precautions, but probing and digital examination and no drainage being the steps taken, and then the antiseptic treatment was applied. All 8 cases proved fatal. The remaining 4 cases received at no time antiseptic treatment, and were also fatal. Fresh from a perusal of Karl Reyher's pamphlet, and impressed with the lessons of his experience, the writer, being sent to the scene of hostilities to take charge of the wounded, determined, if no infection had been communicated to the wounds by probe or finger or other foreign body, to occlude the same antiseptically, and without extraction of the bullet unless, as in one case, it presented subcutaneous. On arrival at Generals' Springs I found the wounded under the charge of a surgeon who had immediately applied to all the wounds—for it was applicable to all without exception—a primary antiseptic occlusive dressing.

Although, as the sequel shows, the occlusive method in the case, complicated by pneumonic solidification and resolution, could not be strictly carried out on account of an abundant serous effusion within the chest, and, later, the discharge of some laudable pus, yet, however, no drainage-tubes were required, or the introduction of an instrument or injecting fluids within the external wound. Drainage was allowed to proceed through the wound and to seep through the loosely packed oakum or other porous antiseptic material placed as an "occlusive" covering over the wound.

The manner of the dressings applied to all these wounds on the battle-field was simple in the extreme, and it proved no less simple in execution than effective in beneficial results. It is sometimes as imperative to know what not to do as what to do. An error of commission is as gross as one of omission. In these dressings the wounds were not probed; their interiors were not disinfected, for the reason that they had not become infected; no drainage-tubes, capillary or larger, were inserted, and no bullets would have been searched for and extracted, if any had lodged, unless presenting immediately beneath the skin. The stomæ of the wounds and the superficies were given an antiseptic cleansing with a two and a half per cent. carbolic acid solution, and a pledget of cotton-flannel, smeared on its inner surface with iodoform salve, was applied to the mouths of the wounds and retained by adhesive straps and roller bandages. If antiseptic gauze and bandages had been at hand they might have been employed, the latter in lieu of the common bandage and the former as a moistened antiseptic layer immediately superimposed upon the pledget of cotton, or upon the wound itself if the crystalline iodoform had been previously dusted upon the part. In case of a wound of the chest followed by an abundant serous or sanguinolent effusion, as in one of the cases cited below, being complicated by an extensive pneumonia, the escape for this fluid through the stoma of the wound should not be obstructed by a pledget of lint or allowed to become clogged by the iodoform crystals being matted together into a pultaceous mass by the effusion. In case of such effusion the occlusive method should give way in part to the method by drainage, for the secretion, especially if it became thick and purulent, must be gotten rid of.

Reyher's tables Nos. X. and XIV. give to antiseptic occlusion a large majority of recoveries over antiseptic drainage, in proportion to the number of cases, both in shot injuries complicated by compound fracture and by opening of a joint cavity. Of 18 joint shot injuries treated by primary antiseptic occlusion, 1 died; of 9 treated by primary antiseptic drainage, 3 died; of 8 primary antiseptically handled compound fractures treated by occlusion, 1 died; of 14 by drainage, 3 died. All the cases of wounds (excepting abrasions), numbering seven, received at the Big Dry Wash fight, are presented below, and added thereto is one pistol-shot wound received at target practice two months later. The occlusive method was applicable to all. Of these eight wounds treated by antiseptic occlusion, not one proved mortal.

Case III.—Lieutenant ——, Third Cavalry, was wounded through the fleshy belly of the biceps while that muscle was in contraction; the left humerus suffered an oblique compound fracture at junction of middle with upper third. The bullet passed out of the arm, impinged upon and fractured the fourth rib a little anterior to mid-axillary line, and was reflected by this rib around and outside the chest wall to a point near the inferior angle of the scapula. At this point it became subcutaneous, and was extracted by Dr. Ewing through an incised wound which healed by first intention.

The wounds were dressed within twelve hours after reception by an antiseptic cleansing of their superficies and an occlusion of the entrance and exit by a square of sheet lint spread with iodoform ointment. A plaster-of-Paris splint for the fractured limb was applied from the wrist over the elbow, and upon the shoulder like a cap. A fenestrum exposed the seat of the wounds to view. This splint held the bones securely and in good position during transportation by a mule litter over ninety miles of rocky and hilly country. While en route from Generals' Springs to a post hospital the condition of the pulse, respiration, and temperature for the fourth, fifth, and sixth days after the fight was as follows:

July 21st.—8 A.M.: pulse, 172; respiration, 28; temperature, 99¾°. 2.30 P.M.: pulse, 72; respiration, 25; temperature, 99¾°. 11 P.M.: pulse, 72; respiration, 23; temperature, 100½°.

July 22d.—8 A.M.: pulse, 62; respiration, 28; temperature, 99¼°.

July 23d.—8 P.M.: pulse, 60; respiration, 20; temperature, 99°.

It is fair to state that the lieutenant's pulse is normally far below the average in the number of its beats, as ascertained previous to the fight.

The wounds were re-dressed about every forty-

eight hours for the first week, and at intervals of three or four days thereafter. The incised wound that had healed by first intention opened again to give exit to a fragment of a fractured rib, and then immediately united once more. The other wounds were filled by granulation tissue and closed before a month had passed by. Sufficient callus had, by this time, been thrown about the ends of the fractured humerus to insure a good union, *and the healing of this compound fracture seemed beset with no more dangers than those attending a fracture of the bone where the integument has remained intact.*

The only "constitutional treatment" that could be instituted for ten days subsequent to the fight was a soldier's ration, inasmuch as neither milk nor other suitable nourishment, nor ice, nor tincture of iron as an internal antiseptic and tonic, could be had for administration.

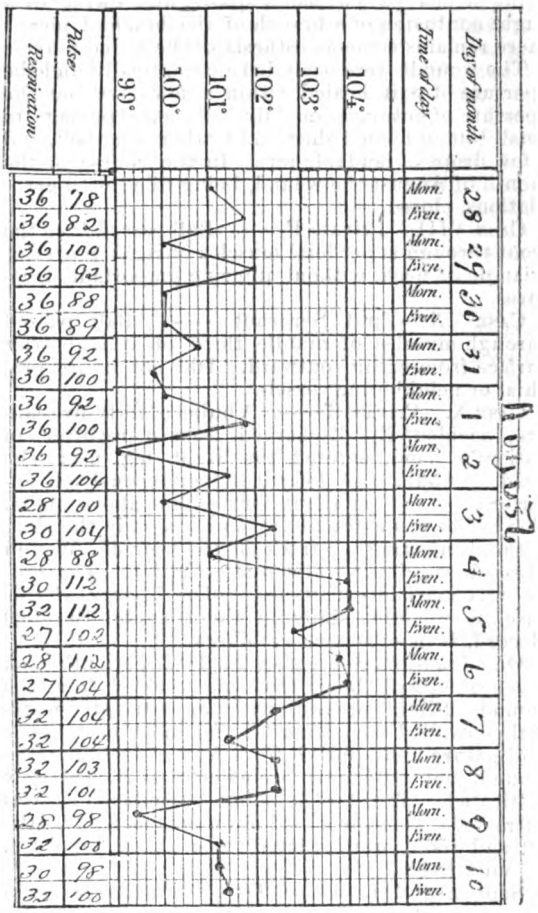
But as Mr. Lister, in *The Lancet*, November, 1881, intimates that if we can provide a condition that shall put our operation wounds (shot wounds) fully on a par with subcutaneous injuries, why should we feel any more concern for the constitutional condition of our patient who has a wound that can be antiseptically occluded than we do for a patient who has a simple dislocation or fracture?

The bullet extracted from Morgan's back was cylindro-conoidal and of forty-five calibre. The treatment in Morgan's case was typical of that instituted in the other seven cases.

Case IV.—Lieutenant C——, Sixth Cavalry. The ball struck near the external angular process of the frontal bone, immediately over the suture, uniting this process to the malar bone. The wound looked most like an abrasion, and gave no indication that the ball had entered and lodged in the orbit. An ophthalmoscopic examination by Assistant Surgeon J. V. Skinner, U. S. A., did not reveal the disc, and as by indirect examination by reflected light the anterior chamber appeared normal, the supposition was that the ball, by its concussion, had ruptured the choroidal vessels and caused a detachment of the retina with hemorrhage into the posterior chamber. The flesh wound, for the most part, healed by primary union under an antiseptic occlusive covering. The mischief done the eye by the bullet in its course was so serious that it was feared sympathetic ophthalmia would be set up, and therefore the lieutenant was advised to consult some eminent Eastern oculist. On consultation in New York it was deemed necessary to remove the eye, as sympathetic trouble threatened. On enucleation of the eyeball the bullet was found lodged in the orbit near the base of the frontal lobe of the brain. The query arises whether or not the damage to the eye was caused by the bullet in its course or by its lodgment and presence? Or, in other words, would probing for and removal of the bullet immediately upon receipt of the injury have prevented the inevitable loss of the eye or the setting up of sympathetic ophthalmia in the sound eye?

Was there any contra-indication, at the start, to the application of the primary antiseptic occlusion to this wound also? This case will at least serve to illustrate how slight may be the abrasion of the skin from a bullet, and hence how well adapted for occlusion such wounds are.

Case V.—Private M——. Ball entered right chest just below sixth rib, and escaped at lower border of tenth rib, at a point crossed by the mid-axillary line. The ball passed through the lung and pleural cavity, fracturing the tenth rib at exit. From moment of reception patient's breathing was oppressed, owing to aspiration of air through the wound at each inspiratory act. This aspiration continued until the wound was occluded and bandaged by the surgeon. No pneumonia followed. Both wounds closed within a fortnight (July 31st).



Case VI.—Private W——. Ball entered one-half inch to right of the eleventh dorsal spine, and escaped between sixth and seventh ribs, fracturing sixth rib. In five days the crepitant râle was heard, and a pneumonia was set up which involved successively the three lobes of the right lung, and after resolution had set in in the right lung the lower lobe of the left became involved in the pneumonic process. The heat of the atmosphere was oppressive, and the journey long and tedious. Stimulants were given freely as the heart began to fail, and the pulse and respiration went up respectively to 140 and 44. On the tenth day after the injury a serous effusion began to discharge itself from the pleural cavity by way of the aperture of exit of the bullet. This effusion amounted to an ounce or two a day, and emitted a sweet, healthful, non-putrefactive odor. On August 3d, corresponding with the rise of temperature on the chart, this liquid effusion became of a creamy consistence, and consequently did not drain away so readily. In the meantime the posterior opening or aperture of entrance had closed.

Two months after injury the post surgeon in charge of this case kindly communicated to me that the wound on anterior aspect of chest had not yet

closed, and that there was a slight discharge of healthy character.

Case VII.—Sergeant C——. Ball entered at a point along the posterior border of the sternocleidomastoid, on a perpendicular line dropped from mastoid process, and made an exit of one-fourth of an inch to the right of seventh cervical spine. Immediately on being struck patient had a spasm, and owing to a slight contusion of a branch of the brachial plexus there remains some anæsthesia of the radial nerve.

The wounds were occluded antiseptically and the aperture of exit healed within a few days, but the aperture of entrance, on July 29th, gave passage to small bits of flannel shirt and leather sling-belt, and a few drops of laudable pus. In the course of the month of August the wound, being filled with granulations, closed.

Case VIII.—Private F——. Ball passed from the front through superficial muscles of right posterior triangle of neck, without injuring important structures.

Case IX.—First Sergeant ——. Ball passed through muscles of middle third of arm, anterior surface from within outward. Did not injure brachial or neighboring vessels.

Case X.—Private T——. A bullet of forty-five calibre, accidentally discharged from a revolver in patient's hand, entered the right leg near the head of fibula, and lodged subcutaneously on anterior aspect of leg about four inches above ankle. The bullet was extracted by an incision in the skin, without infecting the track of the wound. Wound dressed by primary antiseptic occlusion. The bullet was markedly flattened. The history of this case, as recorded daily in the Hospital Surgical Record, is in substance as follows:

On admission, September 21, 1882, patient's sock was soaked with blood that had trickled from the wound. Slight pressure with an antiseptic material controlled the oozing for the most part, hence no ligature was applied from fear of infecting the wound, but antiseptic occlusion was immediately instituted. The bullet, being subcutaneous, was extracted. Tinct. iron and quinia respectively, gtts. xv. and grs. v., were ordered to be administered t. i. d., milk freely.

September 22d.—Pulse, 95; respiration, 20; temperature, 100°. The dressings being wet from oozing of blood, the wound was again dressed and bandaged as on the day previous. Assistant-Surgeon Skinner and Dr. Allen, U. S. A., were present. This was the *second and last dressing of the wound for ten days*, at the expiration of which time I unbandaged the limb in the presence of Dr. Allen, and found the track of the wound healed and closed, the incision made for the extraction of the bullet healed by first intention, and a superficial ulcer alone marking the entrance of the missile.

September 23d (third day).—Temperature, pulse, and respiration nearly normal. No indication for change of dressing. Nothing done.

September 24th to September 30th.—Nothing done.

October 1st.—Dressings removed; healing accomplished; the wound dressed and treated further as a small superficial ulceration.

Any military surgeon could treat at one time fifty cases, without fatigue, of shot wounds of such character as Case X., *i.e.*, to which the primary antiseptic occlusive method was applicable.

In a recent paper referring to shot injuries an eminent German surgeon observes: (1) That if suppuration be prevented, the worst kind of bullet wounds can be cured; (2) that the bullet inflicts its injury in its course, and that its presence is not, as a rule, the cause of suppuration, but the bullet usually becoming encapsulated, is innocuous; (3) that septic matter causing infection of the wound and leading to suppuration is generally introduced from without by probing and digital examination, or in the attempt to extract the bullet; (4) that the principle in the treatment of shot wounds "do not do any damage," and the observations of Reyher, Bergmann, and others upon this subject are sound doctrine; (5) that the laity should be taught how small is the damage done by the bullet itself in most cases, and how fearful and real is the danger of infection of the wound from extraneous causes.

Progress of Medical Science.

Transplantation of Muscle.—Dr. Helferich, of Munich, after the removal of a large fibro-sarcoma from the biceps muscle of a woman, aged thirty-six, refilled the gap left vacant with a freshly cut piece of muscle taken from a dog, fastening the same with six lower and thirty upper catgut ligatures. A cure followed the antiseptic treatment. The patient can now readily flex and extend the arm. An electrical examination instituted by Ziemssen did not show any abnormality, and it appears therefore that the transplanted muscle has retained its vital functions.—*Berliner Klinische Wochenschrift*, No. 26, 1882.

An Undescribed Disease of the Newly Born.—From the most prominent symptoms this disease has been described under the name of "Cyanosis febrilis enteritica perniciosa cum hæmoglobinuria." The disease makes its appearance on the first, second, or sometimes as late as the fourth day after birth. The following are the most prominent symptoms alluded to: Cyanosis, icterus; urine of a light color, or more or less of a dark-brown, which may contain hæmoglobin, normal bladder epithelium, large quantity of "granular casts," red blood corpuscles, micrococci, detritus, urate of ammonia, and a small quantity of albumen; subnormal temperature; frequent dark yellow alvine discharges; increase of the white blood-corpuscles, and the blood contains the remains of the broken-down red corpuscles and movable bodies. No increase or hardening of the connective tissue; liver a little enlarged, almost entire absence of "chest symptoms," convulsions, subsultus, nystagmus, convergent strabismus. Post-mortem examination revealed the following changes: Infarction of the papillæ of the kidney, dilatation of the stomach, ecchymoses in the intestines; enlargement of Peyers' and the mesenteric glands, hyperæmia and congestion of the mucous membrane of the larynx and bronchi; œdema of the brain, dilatation of the ventricles, congestion, with here and there effusion of blood. Of the etiology nothing is known.—*Obstetric Gazette*, August, 1882.

Mediastinal Sarcoma.—At a recent meeting of the Dublin Pathological Society, Dr. J. W. Moore presented a mediastinal sarcoma, obtained from the body of a female servant, aged fifty-five, who had died at the Meath Hospital soon after admission.

She had been complaining for the past four months of pains in her arms, chest, and limbs, which were getting worse every day. On inspection, the right side of the chest was almost motionless. The

percussion-note was exceedingly dull, and, on auscultation, one or two loud bubbling râles were the only evidence of respiratory movement. The left lung appeared to have taken on compensatory action, and was doing its work well. The right arm had become œdematous two or three days previously, and was cold, but had a distinct radial pulse. The lower extremities and the left arm were normal in size and warmth. The head was healthy, and her mental faculties were unimpaired. Her state did not seem urgent; but at ten o'clock at night a change for the worse set in, and she died at seven o'clock next morning.

At the autopsy, on cutting through the right costal cartilages, a new growth of a brownish yellow color, having the appearance of hyaline cartilage, was noticed between and around them, extending from the second rib to the level of the diaphragm. This mass was thicker below, where it formed an ill-defined tumor one inch in thickness. The new growth passed backward to the spine along the diaphragm, principally on the right side, which was thickened in consequence. Along the spine it extended upward to the third dorsal vertebra, and downward to the fourth lumbar. The tumor was intimately adherent to the spine. The right lung was completely collapsed and absolutely airless; it was covered by a greatly thickened pleura, in which there were adhesions of very old standing. The left lung was congested, and in a condition of collateral hyperæmia, and the pleura on that side was considerably thickened. The heart was apparently healthy. The thoracic aorta and the abdominal aorta were surrounded by the growth, in which they had formed a tunnel or canal. The upper part of the growth was close to the trachea, and it surrounded the innominate artery, although it did not seem to have occluded it. The lymphatic glands behind the liver were much enlarged. The liver itself presented appearances of perihepatitis of old standing, and the left lobe was considerably atrophied, and in a state of cirrhosis.—*Dublin Journal of Medical Science*, September, 1882.

Treatment of Chronic Cystitis by the Vesical Curette.—Dr. W. H. Mussey, of Cincinnati, has devised a curette for scraping the surface of the bladder, where such a manipulation appears to be indicated. The instrument consists of a solid steel sound (No. 20 American scale), with a very long curve, in contrast with the so-called "Van Buren curve," which is short and abrupt. After suitable dilatation of the urethra the surface of the bladder may be thoroughly scraped, and the scrapings removed. The organ is then subjected to careful irrigation by means of a large silver catheter.

In several cases of suspected stone, Dr. Mussey claims to have effected a rapid and complete cure by scraping out the bladder, followed by irrigation. As a wash for the bladder he uses an emulsion of gum benzoin, one ounce in one pint of water, which should be boiled for six hours, and filled to one pint. In some cases he finds it advantageous to add carbolic acid or boracic acid in varying proportions to this emulsion.—*Columbus Medical Journal*, September, 1882.

The Blood of Animals Living at High Altitudes.—The difficulty of respiration which affects animals, as well as man, suddenly removed from plain or champaign country to lofty mountain regions is well known, whilst after residence in such regions for some time the system seems to accommodate itself to the new conditions, and exercise can be undertaken and efforts made which at first were impossible. The recent observations of M. P. Bert afford to some extent an explanation of this, for he has shown that the blood of the natives of elevated regions, and the blood of animals acclimatized to such regions of low barometric pressure, are characterized by having an unusually great capacity of absorption for oxygen, much greater than the blood of animals living at the level of the sea, and this is due to the greater richness of their blood in hæmoglobin. They have, therefore, a greater area for the storage of oxygen, which may be drawn upon for the usual metabolic changes of the body, and for that extra call for oxygen which is involved in the performance of violent muscular efforts. To invalidate this conclusion it must be shown that animals inhabiting mountain ranges possess a smaller absolute quantity of blood, which has not been noticed by any observer.

Skin Eruptions in Locomotor Ataxia.—Charcot, Vulpian, and others have observed the presence of skin eruptions (papulæ, maculæ, etc.), in cases of sclerosis of the posterior columns. These eruptions have been found to be in intimate connection with the lancinating pains of tabes. J. Strauss ("Des ecchymoses tabétiques, à la suite des crises de douleurs fulgurantes)" *Arch. de Neurologie* has now noted ecchymoses in the skin appearing in tabes after the paroxysmal pains. These ecchymoses show themselves only after the attacks are over, and they resemble the spots which result when the skin is pinched severely. They have an irregular, round shape, and their size varies from that of a split pea to that of a silver half dollar. There are, usually, several (3–4) spots in one extremity. They are painless, and are observed only after a very severe attack of pain, and according to the nature of the latter the spots are one- or double-sided. The spots are mostly to be found above the seat of the pain, and differ from Charcot's skin eruptions by not following the course of the nerve. Exceptionally, they appear on the extremity which is not the seat of the pain. Strauss considers these spots as rather frequent in locomotor ataxia, and brings them in direct connection with the morbid alteration of the posterior columns of the spinal cord. He thinks that they are reflex phenomena (irritation of the vaso-dilators). This seems possible, if we remember the hemorrhages which have often been observed in cases of tabes after gastric and rectal crises (paroxysms of intense pains beginning either in the stomach or in the rectum).

Action of Quinia and Salicylic Acid on the Ear.—In order to ascertain whether the noises in the ear produced by salicylic acid and by quinine are due to a congestion of the labyrinth, Dr. Kirchner (London *Lancet*) has instituted some experiments in the pharmacological laboratory at Würzburg. The noise in the ears is sometimes accompanied by giddiness and deafness, which, usually ceasing when the medicine is discontinued, sometimes persists as a serious malady. Kirchner employed in his experiments rabbits, cats, dogs, and guinea-pigs. His conclusions are that both these agents cause hyperæmia of the tympanum, which may go on to hemorrhage, and that the whole of the labyrinth participates in the congestion. It may become so intense that, if it last long, it will cause, of necessity, an alteration in the nerve-filaments, and it may lead to exudation. This congestion be

regards as produced by a vaso-motor mechanism. In this conclusion, however, another series of observations made by Weber-Liel and Guder does not agree. They observed carefully the symptoms produced in certain healthy individuals by a moderate dose (fifteen grains) of quinine, and noted, during two hours and a half, a gradual fall in the temperature of the external auditory meatus, corresponding to the diminution in the general temperature of the body. No hyperæmia could be detected in the meatus, the membrana tympani, or the handle of the malleus, either during this period or later. On the contrary, in five cases a slight hyperæmia which existed previously was found to disappear. The subjective noises in the ear come on at the end of an hour or an hour and a half, and continue for ten or twelve hours, while the deafness comes on one or two hours later than the tinnitus, and is greatest at the time that the general temperature of the body is lowest. Similar experiments were made with salicylic acid. Four or five grammes of salicylic acid caused a diminution in the temperature of the external auditory meatus, which falls in the course of two or three hours to 95°. No indication of congestion could be discovered, and, as in the case of quinine, previous hyperæmia became lessened. Noises in the ear came on later, and lasted longer than in the case of quinine. The deafness is very marked, and continued in some instances for several days, and in some cases in which there existed previous ear disease, the loss of hearing was more prolonged, enduring in one case for nine months. In more than half the cases giddiness came on a little after the subjective symptoms. Comparing the effects of salicylic acid and quinine, it appears that the former causes less depression of temperature and a more prolonged diminution in hearing. It is difficult, therefore, to ascribe the aural effects either to congestion or to anæmia, and if these observations are reliable, it would seem to be due to a primary nervous influence.

Curable Ascites of Alcoholists.—Ascites occurring among alcoholists is generally regarded as the result of hepatic cirrhosis, and hence incurable. In two patients, Dr. Bouveret (*Lyon Médicale*) has noticed a perfecty curable ascites. The first case was a man aged forty-five, who was a clear case of alcoholism. Following certain intestinal and gastric disorders a marked ascites made its appearance, to which relief could only be given by tapping. The patient fully recovered after nine months of treatment. Bouveret brings this case and a second similar case which he reports into relation with the ascites which Murchison has reported as accompanying hepatic congestion and Semmold has found to exist in certain cases of interstitial hepatitis, and finally with the ascites found in chronic peritonitis by Leudet and Lancereux. Differential diagnosis is impossible and only the progress of the affection can throw light on the nature of the ascites.

Myositis of the Floor of the Mouth Simulating Malignant Disease.—A previously healthy man, twenty-six years of age, complained for a few days of difficulty of deglutition, with a burning pain in the anterior portion of the tongue. Three weeks later a swelling appeared under the chin, the tongue seemed to be increased in size, speech was indistinct, and eating of solid food caused pain. When admitted to hospital, five weeks later, the tumor extended from the symphysis to the hyoid bone, was hard, elastic, and painful on firm pressure. On each side of the swelling was an enlarged lymphatic gland. The rapid growth of the tumor, together with the enlarged lymphatics, pointed to cancer of the sublingual gland, but at the operation it was found to be a diffuse infiltration of the lingual and mylo-hyoid muscles. The mass was entirely removed. Upon examination, it presented the characters of a chronic interstitial myositis, and in no part could any sarcomatous or cancerous structure be discovered. Upon the mucous membrane of the floor of the mouth was seen a small but deep ulcer, extending down to the indurated tissues. This was, perhaps, the cause of the myositis.—O. Kappeler, in the *Deutsche Zeitschrift für Chirurgie*, vol. xvi., 1882.

The Presence of Sugar in Dropsical Fluids.—Rosenbach found the existence of sugar in dropsical effusions, in the proportion of $\frac{1}{16}$ to $\frac{1}{4}$ per cent., to be almost constant. The fluid was generally taken from œdematous subcutaneous connective tissue, though sugar was also found in ascitic and pleuritic effusions, and, in one case, in congenital hydrocephalus of an eight months' child. In nearly every case the urine was carefully tested for sugar, with negative results.—*Breslauer Aertzliche Zeitschrift*, No. V., 1882.

Periodical Vomiting.—Leyden reports in the *Zeitschrift für clinische Medicin*, vol. iv., 1882, a number of cases of periodical vomiting. Sometimes these occur in connection with various affections of the spinal cord, notably tabes dorsalis, and are then known as gastric crises. Other cases of periodical vomiting occur, not dependent upon spinal cord lesions, yet often accompanied by marked nervous symptoms. These sometimes come on without apparent cause, sometimes they follow a slight indigestion, a cold, or some mental disturbance. The attacks last from a few hours to several days, and are marked by an irregular periodicity. The commencement is usually sudden. Extreme nausea and vomiting set in, together with severe pain in the epigastrium, and a number of other symptoms resembling migraine. The stomach is intolerant of all ingesta, or at most, will retain a little ice, champagne, or tea. After the cessation of the vomiting the patient feels well and enjoys a good appetite and normal digestion. Accompanying the attacks is observed a retraction of the abdomen, with obstinate constipation, which does not yield to purgatives or enemata. The urine is scanty and high-colored, and may be suppressed. The pulse is frequent, without fever. In addition to the pain in the epigastrium, there are often tearing pains in the extremities. The attacks should be treated with ice and morphine. To prevent recurrence, change of air and diversion of the mind are of most avail.

Acute Miliary Carcinoma.—Drs. Raymond and Brodeur (*Archives Générales de Médicine*, August, 1882) report a case of primary acute miliary carcinoma affecting the thoracic and abdominal serous membranes. The patient, a man seventy-six years of age, previously of excellent health, had noticed a gradual loss of appetite for four or five months, with increasing dyspeptic symptoms and progressive emaciation. Upon palpation of the abdomen, a peculiar sensation was imparted to the hands, as if a bladder filled with gelatinous material were squeezed. In the epigastrium and iliac fossæ could be felt little nodosities of the size of a pea or haricot. There was no ascites present, and though the percussion-note was a little dull, it did not vary

with the position of the patient. The abdomen was sound and but slightly sensitive, though a little pain was complained of on pressure in the epigastric region. Examination of the chest revealed nothing abnormal. The urine contained neither sugar nor albumen. The patient died six weeks after coming under observation. At the autopsy the entire peritoneum was seen to be thickly studded with smooth, reddish colored nodosities from the size of a hemp-seed to that of an almond. The peritoneum was injected, especially around the bases of the little tumors, but there were no adhesions in any part. The same conditions were noted on the pulmonary surfaces of the pleuræ and on the visceral surface of the pericardium. Some nodules were even found in the endocardium covering the tricuspid valve. These tumors were composed of a delicate, almost fibrillated stroma, enclosing a great number of variously shaped cells with large nuclei. In some places these cells were arranged in rows, as is ordinarily observed in cancer developing from mucous surfaces. Nothing of note was discovered in any of the abdominal or thoracic viscera. The brain and spinal cord with their membranes were normal. From a study of this case and of others reported by various observers, the authors derive the following conclusions: The disease is one of advanced life, and is not hereditary. The symptoms are those of indigestion, the mild nature of which, however, together with the absence of pain, exclude the idea of cancer of the stomach. A valuable sign is the sensation imparted to the hands as of a bladder filled with gelatine. Miliary carcinoma of the serous membranes is not secondary to cancer of any of the viscera. The prognosis is fatal, the disease progressing rapidly and always terminating in death.

Hydatid Cyst of the Heart.—Dr. Arnold reports the case of a young man, twenty-one years of age, who had been subject to fainting spells—heart's action energetic, but the pulsations regular and normal—cyanotic condition of skin, without true respiratory embarrassment, general and confluent urticaria, manifest tendency to algidity. The autopsy discovered three hydatid cysts at the apex of the left lung; in the pulmonary artery numerous free hydatids of all sizes, still more hydatids in the right ventricle. In the right auricle a cystic tumor, semi-collapsed, with an enlarged slit-like opening toward the tricuspid orifice, and filled with hydatids; the liver and spleen contained no cysts.—*Canadian Journal of Medical Science*, October, 1882.

Tumors of the Fourth Ventricle.—According to Drs. Spillman and Schmidt, tumors of the fourth ventricle may be divided into two classes: those arising in the parts around the ventricle, and those springing from the ependyma and choroid plexus. The tumors arising from the choroid plexus are usually of epithelial structure, sometimes very vascular, at others without a trace of vessels. Those which take their origin from the ependyma are formed at the expense of the connective tissue, and may be either soft sarcomata, gliomata, or fibromata. Occasionally we find cysticerci and tumors of syphilitic or tubercular origin. The varying symptoms of this condition depend upon the direction of growth of the tumor, with consequent pressure upon various parts. In some cases there is a remarkable tolerance of the new growth, so that almost no symptoms are produced. In other cases the presence of the tumor is manifested by a single symptom, as diabetes. The most frequent symptom is cephalalgia, seldom localized, often intense, and occasionally presenting regular intermissions. Tactile sensibility is usually normal, though in a small number of cases incomplete hemianæsthesia has been observed. Motor disturbances are very common. Sometimes there is a general paresis of all the muscles, at other times more or less complete hemiplegia. An ataxic gait, increased or not by closing the eyes, has been occasionally observed. Choreic movements may occur. In one-half of the recorded cases there were disturbances of the intellectual faculties, loss of memory, apathy, slow response to questions, or even delirium. Epileptiform convulsions sometimes occur. Vomiting is a very frequent symptom. Sudden death was noted in over one-half of the cases. The diagnosis is usually difficult, the only symptom directly referable to a lesion of the fourth ventricle being diabetes. This condition is often absent, and even when present is not sufficient, taken by itself, to render a diagnosis certain.—*Arch. Gén. de Médicine*, August, 1882.

Delivery with Membranes Unruptured.—Dr. Van Peyma relates this case with somewhat unusual features. He was called to attend Mrs. B—— in fourth labor; previous parturitions normal. On arriving at the house and making an examination, he discovered protruding from the vulva a smooth amniotic sac containing the fœtus. Upon applying slight traction by means of a towel wrapped around the mass, it was easily removed. The uterus immediately contracted firmly, and so continued. Upon examination of the sac and contents, it was found to be the entire unruptured amniotic sac, containing the dead fœtus, as well as placenta, etc. The contents were easily recognized on account of the transparency of the membranes. The mother's last menstruation occurred more than six months previous, and the fœtus had the appearance of having passed that age.—*Buffalo Medical Journal*, August, 1882.

Eye Diseases in General Diagnosis.—It cannot be denied that ophthalmology is one of the most advanced of all the branches of medical science; and considering the intimate relation of all parts of that wonderful structure of the human system, we would naturally expect to find that a knowledge of eye diseases would be of material assistance in enabling the general practitioner to arrive at a correct diagnosis of disease processes in localities far remote from the organ of vision. In fact we find it so. Therefore the paper by Dr. Wm. C. Ayers, in the *American Journal of the Medical Sciences* for October, in which he calls attention to some of the salient points in which eye-symptoms can aid in general diagnosis and prognosis, is particularly valuable.

He divides his paper into two parts: 1, internal eye diseases, or those detected with the ophthalmoscope, and, 2, the relation of external eye disease to the general system, or where the diagnosis can be made without instruments. Under the first heading he refers to diagnostic points gained by the use of the ophthalmoscope in meningitis, alcohol and tobacco poisoning, leucocythæmia, and Bright's disease, while under the second he shows how examination of the eyes can assist in the localization of tumors, clots, etc. The practical nature of the paper commends it to the perusal of the general practitioner.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 28, 1882.

POST-GRADUATE STUDIES.

THE interest which is taken in post-graduate instruction is quite manifest by the number of letters of inquiry we are receiving in regard to the details of proposed plans of carrying out the idea.

The practitioner who has a limited amount of time and money at his disposal is anxious to learn in what manner he can turn both to the best account. There seems to be but one voice as to what should be done to make the course successful. Clinical instruction is insisted upon as the prime necessity, while the hope is expressed by the would-be patrons that didactic lectures will seldom, if ever, be delivered. The latter method of instruction is thought to be well enough in its place, but not adapted to the real requirements of the physician who wishes to study the diagnosis and treatment of disease by direct and practical methods. In all this the general practitioner takes the proper ground, and, as far as we can learn, the different post-graduate schools are in accord with him in their endeavors in that direction. In all these courses the aim appears to be to make clinical instruction the pivot of success. Each school has a dispensary attached to it which furnishes the material for illustrating practical points in diagnosis and treatment of the commoner as well as rarer diseases. In order to utilize such material to the best advantage a large corps of teachers seems to be necessary, thus making possible the systematic division of the students into small classes and giving each one the opportunity of studying the disease in the actual presence of the patient. This plan is certainly an admirable one, and must commend itself to every one interested in the better education of medical men. We make these statements in the way of a general answer to the letters of inquiry which are now being sent to us and to which we have already referred.

We have always maintained that there was but one way of making clinical instruction a success. Not in sitting in a large amphitheatre listening to a clinical lecture and looking at the patient through an opera-glass, but by actual personal contact with that patient with a competent demonstrator at hand. Hence it is that clinical instruction, as ordinarily carried on in our medical colleges, amounts to little or nothing; and hence it has been said with truth, at least concerning schools in a neighboring city, that it is possible for a student to graduate in medicine without having had the opportunity of clinically studying a single case. The college professors, no doubt, do their best to give such opportunities to every student, but with the large classes in attendance, and the impossibility of crowding into a session more than a given number of clinical lectures, the demonstrations must necessarily be made in rather a wholesale manner. Then, again, only a certain class of patients are available in an ordinary college clinic. Such cases, for instance, as can come or can be conveniently brought to the amphitheatre. We mention these facts not so much for the purpose of complaining against a system which is seemingly the best that can be adopted in our medical schools as for the opportunity of saying that the post-graduate schools to be successful in their particular line must make a new and radical departure in this very matter of clinical teaching. From present indications there is good reason for believing that this will be done, or at least a good commencement will be made in the direction indicated.

It is a matter for congratulation that this is so, and that a desirable impetus will thus be given to clinical teaching in this city, not only in the post-graduate schools, but in all our large hospitals and dispensaries, so freely opened to the profession. The facilities for this kind of work on the part of our hospital physicians and surgeons are immense. They have at their disposal an amount of material which far exceeds that in any other city in this country, and there is every reason to believe that they will be stimulated to do their utmost to make the best use of their opportunities in systematizing clinical instruction in New York. To such an end it might be well for the different hospitals to set apart regular days for operation, and the different post-graduate schools to so arrange their demonstrations as to afford their patrons opportunities for still wider fields of clinical experience. There need be no conflict of interests in so doing, as the hospitals are open to all practitioners who care to follow the attending physician or surgeon through the wards, or to witness any of the operations performed by the latter.

If post-graduate instruction, as thus auspiciously commenced by the different post-graduate schools, proves to be successful in New York, the utility of actual bedside instruction will be a demonstrated

fact, and this city, with its well-equipped hospitals and dispensaries, will be in a position to make available, in a more direct and systematic way than it has ever heretofore done, its vast clinical resources. The medical colleges themselves will not care to be left behind, and clinical study will become a still more recognized feature of the regular medical course.

IN RE POULTICE.

The editor of *The Practitioner*, Dr. Brunton, has been directing attention to the subject of poultices, and, in a recent issue of his journal, describes how to make them. He offers apologies, which we hereby second, for calling the attention of a learned profession to a subject confessedly old and apparently trivial. The poultice is indeed a venerable appliance; it is coeval with man's pains and is doubtless but briefly antedated by Creation's morn. Some philosophers have even contended that the universe itself was once but a warm and mushy mass in whose homogeneous pultaceousness was contained the promise and potency of the evolved poultice soon to be described. Thus, according to these authorities, the primeval Cosmos now finds its most suggestive homology in the warmth and simplicity of the subject in hand.

However, this may be, it is certain that the poultice is a very useful thing, and it is no doubt true that many persons make poultices wrongly, and thus convert what might be made an angel of Joy into a demon of Woe.

There are cases where the poultice is needed for surgical, and other cases where it is needed for medical purposes. Often on this account some difference in its manufacture is required. In surgical cases, it is desirable to have the warmth and moisture directly upon the surface. It is the English custom, therefore, says Dr. Brunton, to make the poultice with crushed linseed or with linseed meal and oil, spread upon tow and applied to the skin without anything intervening. Such a method, though useful for wounds, ulcers, and abscesses, is not the best form of application in cases of inflammation of viscera or where spasm is present without inflammation. In these cases it is better to apply the poultice in such a way that it will be very hot and yet will not scald the skin. Dr. Brunton's method is to have made a flannel bag, a convenient size being twelve inches by eight. This is closed on three edges, the fourth having a flap. Four tapes are attached to the corners. Besides this, a strip of flannel is prepared, long enough to be wrapped once or twice around the bag. The bag and flannel, and a bowl, are then to be thoroughly heated. The poultice is made of crushed linseed and should be of rather thin consistency. It is poured into the bag, the flap turned down and fastened and the warmed flannel roller wrapped about the whole. In this way a poultice may be applied boiling hot to the skin. The heat may be retained better by applying over the whole a layer of cotton wool, or oiled silk.

The difference between a poultice made in the ordinary way and in the manner just described is often, says Dr. Brunton, very striking, especially in cases where there is spasm. Persons suffering from intense abdominal pain have been at once relieved by this form of poultice after a succession of the ordinary poultices has been used in vain.

Dr. Brunton's essay upon the poultice illustrates a fact which should be made more prominent in our therapeutics. We need to know better how to use the measures already at our command; while the experimenting with and search for new remedies should be made a more secondary matter.

THE PROGRESS IN MEDICAL EDUCATION.

The Report of the Commissioner of Education for the year 1880, just issued, contains a considerable amount of statistical information regarding medical schools.

The schools for medicine, dentistry, and pharmacy in 1880 numbered 120, against 63 in 1870. Of these there were 72 regular medical colleges, besides 6 eclectic and 12 homœopathic institutions. In the regular medical schools were 1,131 instructors and 9,876 pupils, of whom 2,673 graduated in 1880. The number of pupils and graduates from the irregular schools was: in the eclectic, 188, homœopathic, 380.

As eclecticism and homœopathy are so often associated in the popular mind with growth and progress, it is interesting to see whether such advance is really being made. We give, therefore, a comparative table for the years 1878 and 1880.

	Number.	Instructors.	Students.	Graduates.
Regular Medical Schools, 1878.	68	915	8,279	2,506
" " " 1880.	72	1,131	9,876	2,673
Eclectic Schools, 1878	6	51	448	211
" " 1880	6	65	833	188
Homœopathic Schools, 1878...	11	158	1,215	363
" " 1880...	12	188	1,220	380

From this it will be seen that homœopathic schools have increased by one, but that in students and graduates they show hardly any advance.

The eclectic schools have not increased in number, and have diminished in graduates. The number of pupils is reported to be larger, however.

It will be noticed that while medical students increased in number from 8,279 in 1878 to 9,876 in 1880, the increase in graduates is proportionately much less. We may perhaps interpret this as meaning that the requirements are more rigid than formerly.

The remarks of the Commissioner of Education upon the subject of medical education express nothing new. He finds that many medical colleges are somewhat more careful in their instruction and exacting in their requirements than they were ten years ago. He notes, also, as one of the most hopeful signs, that the profession has been roused to self-activity in the matter. On the whole, some progress, he thinks, is being made in medical education.

THE PHENOMENA OF HYPNOTISM EXPLAINED.

A WRITER in the *Philadelphia Times* takes some credit for placing before English readers a full and satisfactory explanation of the hitherto very puzzling phenomena of hypnotism. This condition, we are told, has now nothing supernatural or unexplained about it, the only uncertain thing being, perhaps, the exact anatomical condition of the nerve-centres.

The hypnotic state, as now elucidated, consists simply "in an increased neuro-muscular excitability of the cerebro-spinal axis."

The writer alluded to (Dr. Engel) bases this view upon the experiments and observations of Charcot and of Tamburini and Seppelli. The studies of these gentlemen were made upon hysterical persons, a fact which does not seem to have been borne in mind by their American interpreter. They announced that in the hypnotic state there are three different conditions: the lethargic, the cataleptic, and the somnambulic. Each is characterized especially by a peculiar change in the muscular *tonus* or neuro-muscular excitability. In the lethargic condition there is a peculiar sensitiveness of the neuro-muscular mechanism characterized by contraction of muscles on simple mechanical irritation. In the cataleptic state there is a slight general increase in the muscular tonus, causing plastic flexibility of the extremities. Finally, the somnambulic state is characterized by general rigidity of all the muscles.

The observers quoted describe and catalogue a list of agents or irritants which directly or secondarily produce these various interesting and highly scientific conditions. Certain vascular and respiratory changes peculiar to them are also noted.

The observations which our writer finds so rich in pathological significance were, no doubt, carefully made, and may apply to the hypnotic conditions produced in a certain class of hysterics existing chiefly upon the continent. That they furnish any explanation of the general phenomena of hypnotism will at once be doubted by persons at all familiar with the subject—as our writer plainly is not. The lethargic condition, into which the American hypnotic goes, is not, as a rule, characterized by any neuro-muscular hyperexcitability, such as has been described by Charcot. The phenomena that may be evoked in him are the result of suggestion or expectancy, not of irritants in the sense used, and these phenomena occur quite as often in the psychic or sensory as in the motor sphere. There is a suspension of ordinary consciousness with certain of the inhibitory and volitional powers connected therewith. There is, doubtless, an increased excitability of lower centres and mechanisms, including, doubtless, at times the neuro-muscular. But all this has been known and stated long ago. Our American elucidator of trance phenomena will learn a great deal more about his subject by studying home authors than by translating the provincial productions of Italy.

PLUMBERS AND ZYMOTIC DISEASES.

THE excellent and suggestive article on plumbers and their relations to zymotic diseases, by Dr. F. A. Burrall, has naturally commanded considerable attention. It is a matter of surprise, if not of mortification, concerning the theories regarding the propagation of sewer diseases that the plumbers above all others should escape the sickness and death which befal ordinary mortals. There are many physicians and householders who, for reasons not necessary to mention here, would be glad to know that the case was otherwise. It is quite possible that in the majority of cases in which sewer-gas is supposed to escape, and in which a plumber's services are called for and rendered, that the diagnosis is a mistaken one, although the plumber who was the first to scientifically introduce sewer-gas into our houses should know most about it. Certain it is, that such sewer-gas as they ordinarily find, they are proof against. Occasionally the plumber tells the truth, and conscientiously makes a correct diagnosis, but he is pretty certain to sicken and die as the result. At least, such, we believe, is the experience of physicians who are lucky enough to treat these cases. Unfortunately, however, for the sake of the sewer-gas theory at least, the mortality among plumbers is smaller than it should be. Their supposed immunity from disease may, in a measure, be explained by well-known influences of the mind over the body. The inevitable association of sewer-gas with a long and well-itemized bill naturally results in a state of mental exaltation, which has a tendency to ward off disease. The fouler the smell the broader the smile and the larger the bill, while conversely, it is proved that the really sick man is the one who has had the work done. There are doubtless other reasons than those referred to, or than those ingeniously and thoughtfully suggested by Dr. Burrall, which may account for the supposed immunity. But Dr. Ridlon attempts to upset all our theories by significantly asking what special influences of good or evil protect the plumber when he innocently sleeps.

THE RECENT FLOODS in New Jersey have been followed by a large amount of malarial disease.

Reviews and Notices of Books.

STUDIES IN PATHOLOGICAL ANATOMY. By FRANCIS DELAFIELD, M.D., Adjunct Professor of Pathology and Practice of Medicine in the College of Physicians and Surgeons; Visiting Physician and Pathologist of the Roosevelt Hospital; Visiting Physician and Curator of Bellevue Hospital. Royal 8vo, pp. 126. New York: W. Wood & Co.

PROFESSOR DELAFIELD'S "Studies in Pathological Anatomy," to which we have referred so frequently on the appearance of the different parts, have thus far been collected in a single magnificent volume, royal octavo size, and superbly illustrated with ninety-three full- and double-page plates. The author's object has been to describe and figure the minute lesions of disease from the material which has fallen under his own observation. In this respect the book has a peculiar value, in representing individual work in a wide and carefully cultivated field. The results of these labors are presented for what they are worth as demonstrated facts, nothing more and nothing less. As very modestly stated by our author, his plan of study simply involved the following of nature wherever she might lead. Consequently, in viewing the admirable presentation of microscopical appearances, we are privileged to sit, as it were, beside the master and almost view the specimens with his eye. And here let us say that probably in no similar work ever before published is there collected so many beautiful and valuable representations of pathological lesions than in the one before us. The processes by which these admirable results are obtained are as follows: Autographic, photolithographs from original drawings, heliotypes from original drawings, wood engravings of original drawings on the block, etchings on copper, lithographs from original drawings on the stone, artotypes of original drawings, photographs of specimens. The fidelity of these illustrations is beyond praise, while their execution in the different methods alluded to make them specimens of high art. The subjects specially treated of in the first volume are phthisis, peritonitis, pleurisy, pneumonia, empyema, hydrothorax, bronchitis, tuberculosis. The pathology of each one of these diseases is tersely and comprehensively described in connection with the plates, thus giving the reader the advantages of clinical as well as pathological study of the different lesions.

We cannot congratulate the author too warmly on the results of his labors thus far, nor can we recommend the work too strongly to the progressive student and the advanced pathologist. The volume is elegantly printed, tastefully bound, and aside from its other merits is a triumph of typographical art.

PROSPECTIVE CHOLERA.—The following theory is disturbing the minds of some of our lay contemporaries. It is that the great outbreaks of cholera in Europe and this country have occurred at intervals of sixteen or seventeen years: as in 1817, 1833, 1850, and 1866. Between these great attacks of the epidemic there were minor returns of it, occurring at intervals of six years after the more fatal visitations, namely, in 1837 and 1854. According to this view, a most destructive prevalence of this pestilence is due in England and the States in 1882–83.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 19, 1882.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

DR. T. E. SATTERTHWAITE, read a paper (see page 477) on

THE ORIGIN AND NATURAL HISTORY OF TUBERCULOSIS.

The discussion was opened by DR. FRANCIS DELAFIELD, who said that his own interest in tuberculosis had been principally with regard to its morphology; to the actual lesions found in the bodies of those who die of pulmonary phthisis in any form. The following were some of the conclusions he had reached from such study. It had seemed to him that there was a definite anatomical product which could be conveniently called tubercle tissue; a tissue composed of basement substance and cells, which, while it has nothing different in its essentials from other inflammatory products of connective tissue, can usually be recognized by its general character. But such tubercle tissue was not by any means identical with miliary tubercle. The term miliary tubercle simply expressed the gross appearance of certain little nodules which were found under certain circumstances, some of which were composed of tubercle tissue, and others were not. The terms miliary tubercle and tubercle tissue, therefore, might mean two different things. More than that, such tubercle tissue could be found, not merely arranged so as to form miliary tubercle, but so as to form diffuse infiltration. A somewhat coarse, but not altogether inapt, comparison existed in the condition in which pus was found; sometimes in the form of abscesses, sometimes as a diffused infiltration. So in this instance, he believed that inflammatory products might be so arranged as to form either miliary tubercle or diffuse infiltration. The study of tubercle was always complicated by the fact that tubercle tissue, if it was granted that there was such a thing, was scarcely ever produced by itself; it was almost always present in combination with ordinary inflammatory products, either acute or chronic, or both, and they were mingled in a great variety of ways. The simplest combination was found in acute tuberculosis, where the complicating products were the result of acute inflammation; that is, were serum, fibrin, pus, and new connective tissue cells, which were distinguished from tubercle tissue proper with comparative ease. When, however, investigations were extended to chronic forms of pulmonary phthisis, complicated by the products of chronic inflammation, the morbid anatomy became exceedingly difficult.

There were a few chronic forms of phthisis which were simpler than others; one form especially which might be called chronic miliary tuberculosis, in which there was simply the production of tubercle tissue in the form of miliary tubercles, with a certain amount of interstitial pneumonia and a slight amount of intra-alveolar pneumonia, but both the interstitial and the alveolar pneumonia were present in such moderate amount as to leave the tubercular lesion perfectly distinct. But in the majority of cases of chronic phthisis this did not hold true, and the tubercle tissue was complicated

by ordinary inflammation involving the cavities and walls of air-vesicles, the walls of blood-vessels, the bronchi, and the pleura; all the component parts of the lung becoming the seat of inflammation and yielding complicating products. In that manner lesions of very great complexity were produced, and yet, as he believed, in all of this class of cases, the tubercular element took a real share. So far as he knew, pulmonary phthisis never occurred *in adults* without the production of tubercle-tissue. Here he made one exception, namely, pure interstitial pneumonia, which, up to a certain degree, gave the history of phthisis, but in its entire development differed completely from ordinary phthisis. These cases of pure interstitial pneumonia were rare in New York; they were more frequent in some other localities, but they were to be excluded from the consideration of phthisis proper. Ordinary chronic pulmonary phthisis occurring in *adults* was, so far as he knew, always accompanied by the production of tubercle tissue, and more than this the quantity of tubercle tissue was such as to give one the idea that it was really the essential part of the process; that although the complicating inflammatory products were present the tubercular product occupied a greater space and was more apparent; that if the tubercle tissue had not been developed there would not have been the complicating inflammatory products; that the two conditions were associated with each other, but that the essence of the process was the tubercular part.

Dr. A. Jacobi believed that Koch's theory concerning tuberculosis was far from being proved. It was only another parasitic theory such as had been presented a number of times.

With regard to the question, Are tuberculosis and phthisis identical? he was inclined to the opinion that they were two distinct diseases. This much was certain, namely, there were many cases of tuberculosis without phthisis, and also many cases of phthisis without tuberculosis. That view, however, did not include that they could not be found together, nor did it include that tuberculosis could not become phthisis, nor that phthisis could not subsequently become or produce tuberculosis. This view afforded the only way in which he could explain a large number of clinical facts.

Concerning the parasitic theory, he had about the same objection to it as Dr. Satterthwaite had already made, and it was that it did not explain what a large number of observers held to be an essential, namely, that a diathesis was always necessary to the development of tuberculosis or phthisis. By some this family predisposition was called scrofula, meaning thereby, a condition of the individual in which cells have a particular disposition to proliferate copiously and undergo degeneration rapidly. If this diathesis is essential to the development of tuberculosis or phthisis, the old question whether so-called scrofula and tuberculosis or phthisis were not essentially one and the same process, was not at all settled.

It appeared to him that there were other important questions with reference to the subject, as it was well known there were quite a number of cases of phthisis occurring in persons belonging to families in which there was no such diathesis. In a certain number of these cases there were congenital reasons; as for instance, the children in whom the sterno-vertebral diameter was too short, were almost predestined to suffer from phthisis in later life, and only *one* individual suffered in a family where there was neither tuberculosis nor phthisis. In such cases the lungs were not allowed to expand to their normal capacity, and, although it was not an absolute necessity, phthisis frequently followed.

Again, there might have been no phthisis in a family for generations, but there had been syphilis or rachitis. A baby born under such circumstances was very liable to have a number of glandular swellings, first the bronchial glands and then the tracheal glands on both sides. In some cases these glands attained an immense size without being noticed at all, but in consequence of such enlargement there was always irritation of the mucous membrane of the bronchi with which they were intimately connected. These babies, without having pneumonia, began in early life to have a chronic cough, which got well one day and returned the next, occasionally developed broncho-pneumonia, and they suffered during the first years of their lives from bronchial catarrh, and were very apt to become phthisical from no other cause except the existence of a large number of bronchial and tracheal glands affected primarily. The lungs became affected in the same manner as did the intestines when irritated by enlarged mesenteric glands that give rise to slight or serious intestinal catarrh. When these glands underwent caseous degeneration, when they suppurated, phthisis was a very frequent consequence. In a healthy baby, catarrh of the ear, sometimes chronic nasal catarrh, might be accompanied by enlargement of lymphatic glands and when these suppurated, phthisis finally resulted in a number of cases. So also measles and whooping-cough were frequently accompanied by broncho-pneumonia, and tuberculosis or phthisis, or both, made their appearance. There were then, quite a number of cases of tuberculosis or phthisis which depended upon causes such as he had mentioned, and it would take much more evidence than he had yet seen, to convince him that the *bacillus* must be in every case the cause of the phthisis. There was a local irritation somewhere which was the cause of such processes as give rise to local disease of the lungs.

This view he regarded as one that had an important bearing upon the treatment of tuberculosis or phthisis. It was true that in some cases a vicious constitution must be attended to, but in a large number of cases, preventive treatment was entirely local. Broncho-pneumonia must not be regarded as a simple disease, for it might kill the child after six months, or a year, or five years, and it must be carefully and persistently treated. The safest way was to prevent its occurrence, and that could be done by attending to the condition of the neighboring lymphatic glands; perhaps preventing the development of abscesses about the neck by attending to an eczema of the head, and so on. He went still further; he was not one of those who believed that because morbilli and whooping-cough were self-limited diseases they could be left to themselves. So long as they were allowed to run their full course there was opportunity for broncho-pneumonia to develop. These diseases, therefore, should be cut short if possible; for, by so doing, the dangers attending the development of pulmonary complications were diminished, and the chances of prolonging life were advanced. If we could do no better we should mitigate the symptoms.

Again, it was a peculiar fact that tuberculosis and phthisis were seen especially at certain periods in life—tuberculosis mostly in early infancy, phthisis

with or without tuberculosis in later life. He believed the observations of Benecke were important in this respect. That investigator had studied the size of blood-vessels, and had laid stress upon the fact that in the infant the pulmonary artery was very much larger than the aorta, not only at its beginning but farther on. After a time this relation between the two vessels changes, but a number of years elapse before the two arteries become equal in size. Further, he also refers to the fact that, relatively speaking, the right heart is more powerful than the left at that early age. These two facts together might explain why the lungs of babies were so much more succulent, so much more given to œdema and to the development of catarrhal inflammatory processes than the lungs of adults. These facts, Dr. Jacobi thought, were worthy of consideration, particularly with the other fact that miliary tubercle was mainly found in young children. He thought that these facts required as much study as did the bacillus question, and believed that investigations in this direction would be productive of equally as good results. He did not wish to say that it would not be a great blessing to have a bacillus for every disease, for then pathology would be very simple indeed.

Dr. W. H. Welch thought that Dr. Satterthwaite's paper showed not only the prevailing views concerning the pathology of phthisis, but, at the same time showed that recent investigations tended to establish the fact that pulmonary phthisis is essentially tuberculosis. The doctrine advanced by Niemeyer that tubercles played a comparatively unimportant rôle in phthisis, that catarrhal pneumonia underwent a caseous degeneration and so produced phthisis, had been essentially changed, and at present received but little support from histological and pathological investigations. It was interesting to note that both histological and etiological investigations, conducted independently of each other, had led to the same conclusion, namely, that pulmonary phthisis was essentially tubercular in character. He was fully in accord with the views expressed by Dr. Delafield concerning the morphological changes found in the disease, and that miliary tubercle remained for us the most important anatomical criterion of the tubercular affections; but, as Dr. Delafield had shown, this miliary tubercle presents a great diversity of structure in different organs, and even in one and the same organ. It sufficed to state that histologists met with no little embarrassment when they undertook to give an histological criterion of tubercle, and its gross appearance remained for us the essential criterion. The diffuse changes which occurred in phthisis, and which we had been led to believe were tuberculous in character as much as the miliary tubercle itself, was an advance that had been made in histological observations within the last few years, particularly by the French school. What was familiarly known as caseous pneumonia, or scrofulous pneumonia, etc., had been determined to be the special result of the tubercular process, and that it presented histological structures which allied it with miliary tubercle he thought had been established. He also corroborated the statement made by Dr. Delafield that the complexity of the subject was due to the complex anatomical structure of the lung, all parts of which were usually involved in pulmonary phthisis, but at the same time there was underlying it all a tuberculous impression. It would lead too far to attempt to give in detail all the grounds upon which this opinion was based, namely, that the diffuse changes were to be regarded equally tuberculous as the nodular.

The infectious or specific nature of pulmonary phthisis had been determined by experiments concerning its inoculability and by the discovery of the bacillus. He thought the inoculability of the disease had been established. The uniformity with which tubercular eruption appears after inoculation with specific tubercular material, he thought, could not fail to convince us of the inoculability of the disease. The discrepant results which had been obtained in many cases could be explained partly on the ground of untrustworthy experimenters and partly on the ground of improper material used and improper precautions exercised.

With reference to the bacillus of tuberculosis, his observations had been eminently satisfactory. They had been largely confined to the examination of the sputum of consumptive patients, and he had been surprised at the uniformity with which the bacillus appeared. It had been demonstrable with special ease in the sputum, but so far as his observations extended it could be obtained also in the lung-tissue with absolute uniformity.

Dr. Jacobi had called attention to certain clinical facts which seemed to militate against the acceptance of the infectious theory of phthisis, but they had not seemed to him to be of sufficient weight to justify us in discarding the exact experiments and observations of Koch and other observers. The great stumbling-block seemed to be the question of heredity, but it seemed to Dr. Welch that there was one fact which had not been sufficiently impressed, and it was that the *disease* known as tuberculosis was not inherited, but it was simply a lack of resistance to the special poison of the disease which was inherited. The majority of persons possessed a certain degree of immunity against tubercles, but there were others who acquired a lack of toleration, and in such cases as Dr. Jacobi had mentioned, namely, those in which there was a short sterno-vertebral diameter of the chest, phthisis developed because the lungs were not capable of resisting the poison to which they were exposed. There were analogous difficulties with reference to other diseases, as, for example, typhus fever, to which some persons seemed to have complete immunity while others contracted the disease upon the slightest exposure. He thought, therefore, that the mere fact of immunity against the disease did not seem to be sufficient argument to justify us in discarding the more exact observations made by pathologists and histologists.

The multiple forms of phthisis had also been regarded as a serious argument against tuberculosis and phthisis being identical. But it must be remembered that a regular succession of events was frequently absent in other affections, as for example in syphilis, and the same thing had also been seen in experiments concerning inoculability. The experiments with reference to the inoculability of phthisis had shown that there was a great variety of conditions developed, varying sometimes according to the animal used, sometimes according to the amount of material used, and again according to the manner in which it was injected, etc. He believed, therefore, as Dr. Satterthwaite had concluded, that we were justified in assuming that phthisis was essentially pulmonary tuberculosis; that the diffused processes as well as the miliary nodule were essentially the same.

With reference to the inoculability of phthisis he thought the discovery made by Koch was of the

utmost importance, and that the results had not been overthrown by clinical facts, and that clinical facts could not in any degree overmatch the exactness of pathological and histological studies.

Dr. Satterthwaite, in closing the discussion, remarked that it was a matter of surprise to him that there was such uniformity of opinion upon the subject of tuberculosis. Five or six years ago nearly all held different opinions from those already enunciated, and believed that miliary tubercle was a separate and distinct disease from caseous pneumonia, or the catarrhal phthisis of Niemeyer. But, as Dr. Welch had observed, the results of clinical study and histological work had been such as to unite in declaring that the diseases heretofore known as phthisis and tuberculosis were one and the same. One important point developed was that it seemed to be the unanimous opinion of those gentlemen who might be classed as having taken the histological side of the question that tubercle is an inflammatory product. With reference to the question whether phthisis is always tuberculosis he thought that possibly he should not take quite so strong ground as had been taken by Dr. Welch; he did not feel quite sure that phthisis was always tubercular. He then referred to a form of pneumonia which he had not had an opportunity to study, but which occurs in the colored race, and which goes on to caseous change without being associated with tubercle. Although he had not had the opportunity to study such cases, he had been told by competent observers that this form of pneumonia existed in the colored race, and that it was especially liable to be followed by phthisis. The reason why it had been held that tuberculosis and phthisis were the same was that the results had been obtained from post-mortem examinations. They were not found in every instance, but in the majority of cases they were present when they were looked for. Niemeyer had put us all astray by making certain statements which were not true, and claiming that tubercle was always preceded by caseous pneumonia or by some deposit of caseous matter in the body. These two points were incorrect, because miliary tuberculosis was found without pneumonia, and in other cases the most careful search for caseous deposits at some other part of the body did not reveal a single one. It was an absolute fact that such cases were found, perhaps not very frequent, but sufficient in number to prove that Niemeyer's position was incorrect.

With reference to scrofula and tubercle, it was interesting to notice that with the advancements which had been made in the study of tubercle corresponding advancements had also been made in the study of scrofula. In other words, what we used to call scrofulous disease of the glands was now classed under the head of tuberculous changes. He thought it was not improbable that we should class those sluggish forms of disease in which lymphatic glands became enlarged, bones became involved, and also inflammations of mucous membranes and skin manifested themselves as belonging to certain forms of tubercle. Doubtless whooping-cough and measles developed conditions which invited tuberculosis or phthisis, and he thought that they must be placed as forerunners of phthisis, both in cases in which there was an hereditary tendency and an acquired disposition to pulmonary disease.

With reference to heredity, statistics from hospitals for consumptives had shown that sixty per cent. of cases of phthisis could be referred to hereditary predisposition. In a less number of cases the disease had been traced to an acquired predisposition. He thought that the direct influence of contagion must be slight in comparison with hereditary taint. That an hereditary taint was necessary had been assumed by Koch, who said that a predisposition to phthisis must exist, else the parasite does not take root. With reference to contagion it was quite probable that there was a certain degree of danger as it seemed to have occurred in about thirty-two per cent. of the cases. It was well to know this, for those who argued in favor of contagion also argued that the disease was preventable by certain measures, as for example, isolation of the patient and disinfection of the sputa, so that after all the question of contagion was quite subordinate.

SECTION IN PRACTICE.

Stated Meeting, October 17, 1882.

Andrew H. Smith, M.D., in the Chair.

ORTHOPÆDIC NEUROSES.

Dr. V. P. Gibney reported cases to which he gave the above name. They were special in character, and characterized mainly by marked deformity. For example, the lower extremities of one patient were folded and fixed in the position assumed by a tailor when seated upon his bench, and had been supposed to be the result of spinal caries. Spinal irritation was the term by which they were more commonly known, and in all the cases relief, prompt and apparently permanent, followed the use of counter-irritants and poultices.

Dr. Janeway referred to cases which might have some bearing upon certain obscure cases in which contractures and paralysis of the extremities were developed. One patient whom he saw was suffering from well-marked symptoms of cerebro-spinal meningitis. Close inquiry elicited the fact that the boy had received a kick upon the sacrum some time previously, and that his legs had been stiff preceding the development of diffused meningitis. As a cause for the peripheral trouble, it was expected that some lesions low down would be found, and at the autopsy a lesion was revealed that had attacked primarily the contents of the sacral canal. Had he not known of the injury, probably that part of the body would not have been examined, nor would the changes in the muscles have been especially noticed, but the case doubtless would have been regarded as one of ordinary cerebro-spinal meningitis limited to the base of the brain and upper part of the spinal cord.

In addition to the perimeningitis in the sacral region there was a spot of carious bone corresponding to the place where the boy was kicked. Besides, the perimeningitis had produced pus outside of the dura mater in the course of the nerves given off in that region. This case illustrated the fact that sometimes, as the result of injury, inflammatory disturbances were developed around the nerves, and so might explain certain obscure phenomena the cause of which could not be reached in the milder cases where recovery took place.

Dr. L. Weber said that he had seen many cases of simulated hip-joint disease, similar in character to those reported by Dr. Gibney, and in all recovery had taken place in a comparatively short time. He thought the term "orthopædic neuroses" was not quite satisfactory, because it would probably lead to the inference that the writer referred to disturbances following the use of orthopædic apparatus.

He thought the terms "nervous coxalgia" and "spinal irritation" were generally understood and perhaps might as well be retained.

Dr. Gibney was not strenuous with reference to retaining the term, and accepted the suggestion that it might, perhaps, lead to confusion.

Dr. E. C. Seguin then read a paper on

MYELITIS FOLLOWING INTOXICATION BY PARIS GREEN (ARSENICAL PARALYSIS).

In none of the books on nervous diseases had he found reference to paralysis following acute intoxication with arsenic. Turning to other departments, however, he had found that arsenical paralysis was noticed as early as the thirteenth century, and that from time to time attention had been directed to it by different writers, but most extensively by Leroy d'Etiolle, of France.

A brief outline of several cases was given, together with the detailed clinical history of those cases that had come under his own observation. He believed that they were reflex in character, and that the myelitis was due to inflammatory action upon the nerves of viscera.

Dr. Janeway had seen three cases, two in which there was paraplegia following the ingestion of Paris green for suicidal purposes, and one in which there was paralysis of the arms as well as of the legs. In the last case he reached the conclusion that the patient had polio-myelitis until he learned that he had taken Fowler's solution for chorea, and at one time swallowed a drachm. In that case there was atrophy and descending degeneration. He was of the opinion that arsenic given in excessive doses in the treatment of chorea had produced, in some cases, anterior spinal paralysis with a certain amount of sensory trouble. He thought any one who had read of the spinal symptoms reported in some of the fatal cases of chorea, could hardly fail to be impressed with the similarity which they bore to the effects produced by drugs, and he had no doubt that death, in some of these instances, had been due to toxic influences rather than to the disease itself.

Dr. L. Weber directed attention to cases of chronic arsenical poisoning which he saw at a manufactory in Germany, between 1856 and 1860. The prominent features in the clinical histories were, after working there two, three, or four years, general malnutrition, gastric symptoms not very well marked; some died paraplegic, and dropsy in a large number in the later stages. Some of the workmen had phthisis, whether due to the effect of arsenic or not, he was unable to say. Dr. Weber suggested that the myelitis described by Dr. Seguin was of vaso-motor origin rather than reflex or sympathetic, the primary step being deprivation of the nervous centre of blood-supply, and second an inflammatory process produced in a manner not unlike that which follows obstruction of blood-vessels from embolism.

Dr. Putzel said that two years ago he published a case of subacute myelitis due to arsenical poisoning. Within two weeks after the poisonous quantity of arsenic had been taken well-marked symptoms of myelitis developed. The patient made a complete recovery within a few months. He had also met with a case of general paralysis, in which the patient was a worker in the dye-works for artificial flowers.

With regard to the theory advanced by Dr. Seguin that the myelitis was due to reflex influences, Dr. Putzel thought that the absence of gastric symptoms in the chronic cases seemed to indicate that it was not due to reflex action.

Dr. J. C. Peters said that some twenty years ago he was concerned in the publication of a book on materia medica, in which were collected cases of poisoning and cases of cure by the use of a single remedy. In the article on arsenic there were fifteen or twenty cases of arsenical paralysis, and of those there were several in which the paralysis was produced by arsenic administered in medicinal doses.

Dr. Birdsall raised the question whether the paralysis in Dr. Putzel's case might not be due to lead instead of arsenic.

Dr. Janeway said he had had occasion to investigate the subject of coloring substances used for such purposes, and found that arsenic was not used; that the green colors commonly ascribed to arsenic were produced in other ways.

Dr. Putzel said that his belief was based upon the statement made by the patient, who told him that arsenic was used, and also that it was not an uncommon occurrence for the workers to get paralyzed. Besides, in his case there was no evidence of lead-poisoning.

Dr. Seguin said that he did not wish to speak dogmatically with regard to the manner in which the myelitis was produced. It had seemed to him that the theory he had given was a rational one, and yet it might be that in the vaso-motor doctrine mentioned by Dr. Weber could be found the more probable explanation.

The point against the reflex origin, raised by Dr. Putzel, was a valuable one in the study of chronic cases, but the paper was on acute arsenical poisoning.

With regard to the possible injury that might be done by the administration of large doses of Fowler's solution in cases of chorea, he had not seen, strictly speaking, nervous symptoms developed by the drug under those circumstances. As to cases of death occurring from acute chorea, so far as his recollection went, he had not known of any in which the patients had been treated with arsenic. Such cases were usually treated with remedies which act promptly, such as chloral, conium, etc. He had not seen a fatal case of chorea in which death could have been attributed to arsenic, and still felt that he should not hesitate to continue to employ the drug in such doses as were at present in common use.

Dr. Janeway thought that the inflammatory process could be explained readily in accordance with Cohnheim's views, namely, that the arsenic acted upon definite vessel tracts, setting up such changes in the wall of the vessel as allowed diapedesis to occur throughout the area over which the injured vessel presided.

Forcing a Recognition of Homœopathy.—The *U. S. Medical Investigator* proposes, as the only way to settle the status of the homœopaths among the regular physicians, that one of their number bring suit against Dr. N. S. Davis, as chairman of the judiciary council of the American Medical Association, for slandering the homœopaths as dogmatists. The suit could be carried, it thinks, to the Supreme Court of the United States and decided. Thus, it thinks, homœopathy would compel its recognition in both ethics and science. It is ready to contribute $5 or $10 toward the expense.

Correspondence.

SPONGE-GRAFTING—A SUCCESSFUL CASE.

To the Editor of The Medical Record.

Sir: Dr. J. D. Hamilton, of Edinburgh, published in *The Edinburgh Medical Journal* for November, 1881, a series of cases in which he had grafted sponge into indolent ulcers and healed them—the sponge becoming organized in the tissues. Dr. Hamilton's method of preparing sponge for grafting is the following: A piece of surgeon's sponge is soaked in dilute nitro-hydrochloric acid, to dissolve all the saliceous and calcareous salts, washed in liquor potassæ until all the acid is removed or neutralized, afterward washed in distilled water, pressed dry, and soaked in a one to twenty solution of carbolic acid and water. When sponge so prepared is thoroughly carbolized it is ready for use. I will not review Dr. Hamilton's cases nor refer to the interesting microscopic studies which he made during the organization of his sponge grafts, but will refer my readers to the original article in *The Edinburgh Medical Journal* of November, 1881.

At the time I read Dr. Hamilton's paper—December, 1881—I had charge of a case of which the following is the history: Mr. M——, of Scranton, twenty-three years of age, consulted me in March, 1881, on account of a swelling on the left side at the junction of the tenth, eleventh, and twelfth ribs and their cartilages. He had severe pleuro-pneumonia in the spring of 1876, from which he did not recover for one year. Since then has been moderately healthy, although he looks white, anæmic. I saw him again in April, and diagnosed abscess, which diagnosis was confirmed by Drs. W. T. Bull and the late Samuel Whitall of New York, whom he consulted about May 1, 1881. On May 11th, fluctuation being distinct, I opened the abscess freely and evacuated about two ounces of thin pus, washed out the cavity, and put in a drainage-tube. The abscess did not heal, and my friend, Dr. P. M. Burke—who kindly took charge of the case for me—made a counter-opening and passed a drainage-tube through. On July 23d we discovered a sinus leading downward and backward from the abscess cavity. The abscess and sinus were then laid open and the bottom packed with oakum and balsam of Peru. Dr. Burke saw the case daily and watched it closely, and I saw it twice a week. About August 10th a point where the pus had begun to burrow was discovered and treated with nitrate of silver and iodoform, but the burrow extended deeper, and was laid open, August 24th, by Dr. Burke. Caustics were of no use in arresting the morbid process, and after this the sinuses were laid open as soon as discovered and filled with oakum and balsam of Peru. During all this time the wounds were kept clean by using a one to twenty solution of carbolic acid. The patient was kept on cod-liver oil, quinine, and iron—iodine was not borne—but grew so weak that it seemed nothing could restore him. He sweated profusely, and for three weeks his temperature varied from 97.5° F. to 106° F. This was in December, 1881. He was now too weak for a cutting operation, although six sinuses existed, and after reading Dr. Hamilton's paper on sponge-grafting, I hastened to give it a trial, for all other measures had failed. I prepared a piece of sponge according to Dr. Hamilton's method, using carbolized oil where he used carbolized water. There were six sinuses, varying in depth from three-fourths of an inch to two and one-half inches, and in breadth from one-twelfth inch to one-half inch.

Two of the shallowest were tried first, the prepared sponge being nicely fitted into the cavities, and a compress of carbolized cotton wool placed over the openings, and secured with a bandage drawn tight enough to exert moderate pressure. One graft had become adherent on the fourth day and the other on the fifth; a slight discharge of pus occurred and was washed away with carbolic acid and water. On the sixth day the grafts bled when pricked, and in three weeks from the introduction of the sponges, the two sinuses were healed firmly, the sponge being organized in the tissues. The other openings were filled with sponge, but in three of the four failure occurred at first trial, owing to the difficulty of fitting the sponge accurately to such long and narrow cavities. The longest sinus two and one-half inches in depth, was grafted three times before union took place. The failures were owing to the irregularity of the cavity, and the difficulty of carrying the sponge to the bottom. In this sinus the cartilage of the eleventh rib was denuded, and the sponge would not adhere to it—this was irritated and healed by granulation when the patient's strength improved. One shallow ulcer, half an inch in diameter, and one-eighth inch in depth, was also grafted with sponge. Here the sponge did not unite nor become organized, but it stimulated the ulcer to healthy action and healed it.

One case is not sufficient from which to draw positive conclusions as to the manner in which sponge-grafts heal wounds or ulcers. Pressure has long been recognized as an important factor in the healing of indolent ulcers, and my observations in the foregoing case lead me to conclude that pressure—moderate elastic pressure with a pure animal porous substance is the first essential in healing an indolent ulcer. Pressure with the sponge in the long narrow sinuses of my patient had the same effect upon the walls of the cavities that Mr. Callender's hyperdistention of abscess has—both stimulate healthy granulation, the difference being that in the latter case a liquid is used which distends temporarily, and is then removed; in the former a semi-solid substance is allowed to remain and exert moderate, equable pressure, and finally to become a part of the tissue. Sponge, from its porosity, is one of the best agents to thoroughly drain wounds, and prevent septic absorption. This action of sponge was noticed more than a century ago by Mr. Charles White of Manchester, in a paper entitled: "An Account of the Successful use of Sponge in the Stoppage of Hemorrhage occasioned by Amputation below the Knee, and the Remarkable Effects of that Application in Preventing the Absorption of Matter." Mr. White concludes his paper with these words: "The sponge keeps down fleshy granulations, partly by a removal of that matter in which they would be soaked, and partly by a compression, the most easy and equal that can possibly be imagined from the natural elasticity of the sponge." (See S. Gamgee, London *Lancet*, February, 1882.) In my case the sponge never became foul or broken down when it was fitted closely and carried to the bottom of the sinus. I learned that the outside or surface of the sponge unites with the tissues better and sooner than the cut surface. Mr. M—— is now

as well as he was before the abscess formed, and is performing the duties of a hotel clerk.

I feel confident that sponge prepared as above described will be a valuable agent in healing indolent ulcers. It combines stimulation, pressure, and drainage better than any other substance with which we are acquainted, and these are the essentials in the treatment of indolent ulcers. A case reported by Dr. Norman Porritt, in the *Edinburgh Medical Journal*, May, 1882, shows how useful sponge-grafts are in wounds of the face with considerable loss of tissue. Dr. Porritt grafted sponge into a wound of the face caused by coming in contact with a rapidly revolving wheel which made a wound that could not be covered by the integuments. The sponge united with the tissues leaving a cicatrix *without depression*.

J. BURNETT, M.D.

CARBONDALE, PA.

PLUMBERS AND ZYMOTIC DISEASES.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: I cannot be content to let Dr. Burrall's article on "The Exemption of Plumbers from Zymotic Disease" go before the unsuspecting public without questioning the correctness of his conclusions. They are as follows: "Therefore I would explain the plumber's exemption from zymotic disease while others of the community suffer from it, by the proposition that others are *in a continued exposure during a condition of diminished physical resistance*, while the exposure of the plumber is intermittent and during wakefulness," which being interpreted means that plumbers do not sleep in rooms permeated with sewer-gas, like the rest of us.

Every one recognizes the fact that tailors' children go ragged, and shoemakers' children out at the toes, and many say that ministers' sons and deacons' daughters are no better than the rest of the community.

We all, I think, will acknowledge that our children become ill quite as often and remain ill quite as long as the children of our patients; and those of us who have had it in our way to visit professionally the homes of plumbers, can testify that they are no better plumbed and no better ventilated than the dwellings of their customers; and that their children, though sleeping in the same room with their parents, suffer from zymotic diseases quite as often as other children.

It seems to me that the plumber does not escape zymotic disease by being in league with Satan, as some believe, nor by a wisdom so great that he can free his three rooms from sewer-gas, while the rest of the tenement reeks with poison as others seem to think, but that, if he really does escape, it is by some law of nature as yet not fully known to us.

Yours,

JOHN F. RIDLON, M.D.

102 WEST FIFTY-FOURTH STREET.

DIAGNOSIS OF UTERINE DISEASE BY THE LARYNGOSCOPE.—Dr. Seiler was consulted by a young girl with general relaxation of the mucous membrane of the throat, which he concluded to be due to uterine disease, for which he advised her to put herself under the treatment of her family physician, as local treatment of the throat would be of no use to her. Her reply was, "Doctor, if I had known that you could see all the way down I would not have come to you."—*Maryland Medical Journal.*

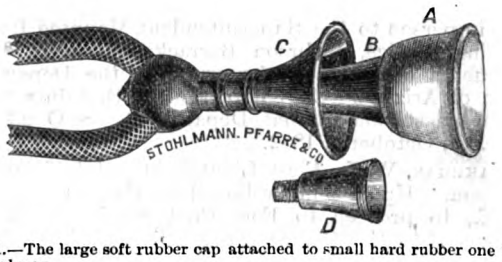
New Instruments.

IMPROVED CAMMANN'S STETHOSCOPE.

BY CHARLES WARE,

NEW YORK.

WILL you allow me, through your paper, to suggest an improvement in Cammann's stethoscope, whereby the large and small cup-shaped pieces are attached together to the rest of the instrument? The small cup only is removed whenever it is desired to use the larger one.



A.—The large soft rubber cap attached to small hard rubber one in usual way.

B.—The small cup is attached to the stethoscope by screwing into the large cup and not by removing the larger one. The calibre of opening is not diminished and is continuous with that of the body of the instrument.

C.—The large cup remains permanently on the instrument.

D.—The small cup, showing the mode of attachment.

The benefit to be gained by this little device is that the *two* cups (large and small) can be conveniently carried with the instrument; one of them is not detached, to be left at home or lost. The advantage of having both cups with the instrument will be apparent to those who have occasion to use it frequently.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from October 7, 1882, to October 21, 1882.

BARNETT, RICHARD, Captain and Assistant Surgeon. Relieved from duty in Department of the Platte and to report in person to Commanding General Department of the East for assignment. S. O. 237, A. G. O., October 11, 1882.

BIRMINGHAM, H. P., Assistant Surgeon. To proceed to Fort Bayard, New Mexico, when relieved at Fort Elliott, Texas, and report to the Commanding Officer for duty. S. O. 198, Department of the Missouri, October 3, 1882.

BRECHEMIN, LOUIS, Assistant Surgeon. Relieved from duty in Department of Dakota and to report in person to Commanding General Department of the East for assignment. S. O. 237, A. G. O., October 11, 1882.

CRAMPTON, LOUIS W., Captain and Assistant Surgeon. To be relieved from duty in Department of Dakota and to report in person to Commanding General Department of the East for assignment. S. O. 237, A. G. O., October 11, 1882.

EWEN, CLARENCE, Assistant Surgeon. Relieved from duty at Fort Elliott, Texas, to proceed to Fort Gibson, I. T., and report to the Commanding Officer at that post for duty. S. O. 198, Department of the Missouri, October 3, 1882.

CALDWELL, D. G., Captain and Assistant Surgeon. Granted leave of absence for one month, with permission to apply for an extension of three months. S. O. 105, Department of the Platte, October 3, 1882.

GRAY, W. W., First Lieutenant and Assistant Surgeon. To be relieved from duty in the Department of the Columbia and to report in person to Commanding General Department of the South for assignment. S. O. 237, A. G. O., October 11, 1882.

KANE, JOHN J., Assistant Surgeon. Granted leave of absence for one month, with permission to apply for extension of three months. S. O. 202, Department of Missouri, October 9, 1882.

MCCREERY, GEORGE, Assistant Surgeon. To report in person to the Superintendent Mounted Recruiting Service, Jefferson Barracks, Missouri, to conduct a detachment of recruits to the Department of Arizona. On completion of that duty to rejoin his station in that Department. S. O. 233, A. G. O., October 6, 1882.

WAKEMAN, W. J., First Lieutenant and Assistant Surgeon. Upon being relieved at Fort Douglas, U. T., to proceed to Fort Fred Steele, W. T., and report to the Commanding Officer at that post for duty in the absence of Assistant Surgeon D. G. Caldwell, on leave of absence. S. O. 106, Department of the Platte, October 6, 1882.

WATERS, W. E., Surgeon. Ordered to Madison Barracks, New York, for duty as Post Surgeon. S. O. 178, Department of the East, October 5, 1882.

WOODWARD, J. J., Major and Surgeon. Leave of absence extended four months on account of sickness. S. O. 233, A. G. O., October 6, 1882.

MOORE, JOHN, Major and Surgeon, Medical Director, Headquarters Department of the Columbia. Granted leave of absence for one month, with permission to apply to Headquarters Military Division of the Pacific for extension of one month. S. O. 145, Department of the Columbia, October 3, 1882.

LORING, LEONARD Y., Captain and Assistant Surgeon. Granted leave of absence for four months. S. O. 243, A. G. O., October 18, 1882.

EVERTS, EDWARD, Assistant Surgeon. Assigned to duty at Fort Cœur d'Alene, I. T. S. O. 145, Department of the Columbia, October 3, 1882.

CARTER, EDWARD C., Assistant Surgeon, now at Camp Price, to proceed to Fort Thomas and report to the Commanding Officer of that post for duty. S. O. 159, Department of Arizona, October 11, 1882.

TAYLOR, A. W., Assistant Surgeon. Relieved from duty at Fort Supply, I. T., and assigned to duty at Fort Cummings, N. M. S. O. 208, Department of the Missouri, October 16, 1882.

BYRNE, CHARLES B., Captain and Assistant Surgeon. Leave of absence extended ten days. S. O. 243, A. G. O., October 18, 1882.

APPEL, A. H., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month. S. O. 168, Department of Dakota, October 14, 1882.

BUSHNELL, GEORGE E., First Lieutenant and Assistant Surgeon. Leave of absence extended one month. S. O. 244, A. G. O., October 19, 1882.

WILLIAMS, JOHN W., Surgeon. To proceed to Vancouver Barracks, W. T., and report upon arrival to the Commanding General, Department of the Columbia, for assignment to duty in that department. S. O. 168, Military Division of the Pacific, October 13, 1882.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK. — At the Annual Meeting held October 23, 1882, the following were elected officers for the ensuing year. *For President*, David Webster; *For Vice-President*, Andrew H. Smith; *For Secretary*, Wesley M. Carpenter; *For Assistant Secretary*, Charles H. Avery; *For Treasurer*, Orlando B. Douglas; *For Censors*, F. R. Sturgis, Daniel Lewis, W. R. Gillette, J. D. Bryant, H. B. Conrad. *For Delegates to the Medical Society of the State of New York*, J. W. Howe, F. P. Foster, E. Gruening, D. Lewis, A. Gerster, R. M. Fuller, J. S. Warren, A. V. B. Lockrow, W. F. Mittendorf, D. Webster, C. L. Dana, A. H. Smith, J. H. Ripley, S. Sexton, P. F. Mundé, C. S. Bull, E. L. Partridge, W. M. Carpenter, L. Johnson, V. P. Gibney, O. D. Pomeroy, A. Hadden, W. T. Alexander, G. B. Fowler.

THE MARINE HOSPITAL SERVICE.—The annual report of Surgeon-General Hamilton has just been made. From it we learn that 36,184 patients were treated during the year 1881-2, an increase of 3,571 over the previous year. Of these, 13,048 were treated in hospitals. Dr. Hamilton urges the necessity of new hospitals at Savannah and Norfolk, also of a home for decrepit seamen.

During the past year the operations of the service have been extended to a number of new ports. There were 2,090 pilots and 273 seamen examined for color-blindness. Sixty-three of the former (about three per cent.) and four of the latter were found color-blind.

The following are the recent changes in the service: Surgeon Hatton has been ordered to Louisville, Ky., to relieve Surgeon W. H. Long, who is transferred to Detroit, Mich. Dr. L. Gibson of Arkansas has been appointed an Acting Assistant Surgeon at Little Rock, Ark.

CONCERNING THE CHECKING OF PULMONARY HEMORRHAGE.—Dr. A. C. Post writes: "In a recent number of THE RECORD is an article entitled 'A Simple Means of Checking Pulmonary Hemorrhage with Shawl-straps.' For more than thirty years I have been in the habit of arresting internal hemorrhages by bandaging the arms and thighs so as to shut off from the general circulation a very considerable portion of blood in the veins of the extremities. From the time of my connection with the Medical Department of the University of the City of New York I have strongly recommended the practice in my lectures. The practice did not originate with myself, but I cannot refer to the source from which I ob-

tained it. The use of shawl-straps to compress the veins, as advocated by Dr. Curtis in the article referred to, is a convenient mode of accomplishing the object.

"P. S.—On page 418, near middle of second column, occurs the expression 'nearly two drachms (75 centigrammes).' I suppose that the writer meant to say 750 centigrammes."

THE LATE DR. J. W. S. CLEMENTS.—At a meeting of the Board of Surgeons of the Police Department of the City of New York it was resolved that a suitable minute be prepared on the death of Dr. J. W. S. Clements. The following was unanimously adopted:

Resolved, That his long connection with the medical profession of New York, his extensive and varied experience as a practitioner, his indomitable perseverance in the discharge of duty even when suffering from the effects of disease and the infirmities of advancing years, and his excellent private character commend him as a man worthy of our kindly regard.

It is therefore directed that this minute be placed on record and published in THE MEDICAL RECORD, and a copy transmitted to his family, with the assurance that his colleagues in the Board of Surgeons extend to them their sincere sympathy, and unite with them in their sorrow and regret.

THE AMERICAN ACADEMY OF MEDICINE held its seventh annual meeting in Philadelphia, on the 26th instant.

ENLARGEMENT OF ST. VINCENT'S HOSPITAL.—A very successful fair was held under the auspices of the Sisters of Charity during the past week, for the benefit of St. Vincent's Hospital. The money obtained is to be used for enlarging the building. The addition is to have fifty feet frontage, with two wings eighty-two and a half feet in length. It will have accommodations for eighty beds, in three stories of wards.

RESIGNATION OF DR. HOLMES.—It is reported that Dr. O. W. Holmes, Professor of Anatomy in the Harvard Medical School, has resigned.

THE NEXT INTERNATIONAL CONGRESS OF HYGIENE will meet at Haag, in January, 1884.

DAMAGES FOR INJURIES brought about by drinking impure water have been obtained by a lawyer in England, from the town in which he resided. The sum awarded him was $10,000. Such cases furnish a practical stimulus to sanitary science.

DIPHTHERIA IS A DISEASE OF THE LIVER, according to Dr. Reiter (Squibb's *Ephemeris*). The liver does not destroy fibrin as it normally should. Dr. R. cures all cases by giving calomel in a scruple dose, followed by ten-grain doses every hour.

THE MUCH TALKED OF ARTIFICIAL QUININE made by M. Maumene has been tested by M. Combe for the Paris Academy of Medicine. He finds that the substance made according to M. Maumene's directions is not quinine at all.

THE ANNUAL MEETING OF THE SOCIETY OF GERMAN PSYCHIATRISTS was held at Eisenach September 15th and 16th.

THE GARLICKY ODOR IN THE BREATH PRODUCED BY BISMUTH is not due, says Squibb, to either arsenic or tellurium, and its cause is as yet unknown.

THE PATHOLOGICAL SOCIETY of Philadelphia has offered a prize of fifty dollars for the best original paper, based upon pathological investigation, read during the winter by a member who is a hospital resident.

FREQUENCY OF GONORRHŒA.—A correspondent of *The Lancet* finds, by reference to notes and inquiries among other medical men, that seventy five per cent. of adult males have had gonorrhœa once; forty per cent. twice; fifteen per cent. three or more times; yet no two medical men treat the disease in the same way.

DR. HOLMES ON PHYSICAL DIAGNOSIS AND SPECIALISM.—I have often felt, when seeing hospital patients worried by hammering and long listening to their breathing, in order that the physician might map out nicely the diseased territory, the boundaries of which he could not alter, as if it was too much like the indulgence of an idle and worse than idle curiosity. A confessor may ask too many questions; it may be feared that he has sometimes suggested to innocent young creatures what they would never have thought of otherwise. I even doubt whether it is always worth while to auscult and percuss a suspected patient. Nature is not unkind in concealing the fact of organic disease for a certain time. What is the great secret of the success of every form of quackery? *Hope kept alive.* What is the too fatal gift of science? *A prognosis of despair.* "Do not probe the wound too curiously," says Samuel Sharp, the famous surgeon of the last century. I believe a wise man sometimes carefully worries out the precise organic condition of a patient's chest when a *very* wise man would let it alone and treat the constitutional symptoms. The well-being of a patient may be endangered by the pedantic fooleries of a specialist.—*Boston Medical and Surgical Journal.*

A POISON FOR THE BACILLI OF TUBERCLE.—A paper has been recently communicated by M. de Korab to the Paris Academie des Sciences on the action of a substance called *helenine* upon the bacilli of tubercle. He cultivated the *bacilli* according to Koch's method, in bovine serum, which was daily heated for a week, in order to sterilize it. Tubercles from a guinea-pig were then introduced into ten tubes, to three of which the helenine was added. All were kept at a temperature of 37° C. for a week. It was then found that the tubes having no helenine caused tuberculosis when inoculated. Those containing the helenine were innocuous. Some glowing inferences are drawn by M. de Korab from his experiments.

THE FIFTY-FIFTH ANNUAL MEETING OF GERMAN NATURALISTS AND MEDICAL MEN was held at Eisenach during the week ending September 24th.

Of the general addresses, the most notable was that by Professor Ernest Haeckel on Darwin, Goethe, and Lamarck.

There were several medical sections, but the papers read were not very numerous.

The Association will meet next year at Fribourg.

JOURNAL OF CUTANEOUS AND VENEREAL DISEASES.—We have received the first number of this journal. It is edited by Drs. H. G. Piffard and P. A. Morrow, and is published monthly. It contains an excellent colored lithograph of a case of trichophytosis cruris, several original articles, reviews, selections, and items. Altogether the *Journal* is excellent, and shows judicious editorship.

BRAIN WEIGHT AND BRAIN POWER.—Surgeon-Major J. P. H. Boileau reports in *The Lancet* a case of a man of very active and vigorous intellect who died at Metley recently. The brain weighed 59.72 ounces. This exceeds others usually quoted, except Cuvier's (64½ ounces) and Abercrombie's (63 ounces). The specific gravity was also very high, 1.049, the specific gravity of the average brain being 1.036.

"THE PHYSICIAN HIMSELF"—D. W. Cathell, M.D., of Baltimore, Md.—has advanced to the second edition, which is enlarged, rearranged, and divided into chapters. We reiterate our good opinion of the work. It is published by Cushings & Bailey, Baltimore, Md.

THE YELLOW FEVER EPIDEMIC.—The daily number of new cases at Pensacola, Fla., has decreased, being at date of writing from 30 to 40. On October 22d, there were 37 new cases reported, and 1 death. This makes a total of 2,007 cases, and 163 deaths.

The fever has nearly disappeared from Texas.

THE CARTWRIGHT LECTURES.—Dr. W. T. Belfield, Lecturer on Physiology in Rush Medical College, will deliver the Cartwright course of lectures in New York the coming winter. He will probably choose for his subject the recent investigations in disease-germs.

PROFESSOR PAUL VOGT succeeds the late Professor Hueter as Professor of Surgery at Greifswald.

DR. SONNENBURG has been appointed Bergmann's successor at Würzberg, Bergmann having taken Langenbeck's chair at Berlin.

THE DEATH OF MR. J. T. CLOVER, F.R.C.S., is announced. His name is connected with improvement in the mode of administering anæsthetics and with a special inhaler devised by himself.

THE PROVINCIAL BOARD OF HEALTH OF ONTARIO has sent us a specimen of its weekly bulletins. This is accompanied with a colored chart and various diagrams which show at a glance the meteorological and health conditions of the province. The bulletin is quite superior to the average of this form of literature.

THE USE OF THE CONDOM IN GONORRHŒA is recommended by Dr. C. H. Chalkley (*Southern Clinic*), instead of the ordinary bandage. He covers the glans with a thin layer of disinfectant cotton and then draws the condom over it.

A CASE OF TYPHOID FEVER AT SEVENTY-TWO YEARS OF AGE is reported by Dr. Charles H. Miller in the *Southern Clinic*. Dr. Miller states that no other case in a person so old has before been reported. The maximum generally given is fifty to fifty-five years. The details of the case, however, are not given with sufficient care to prove that it is the disease claimed. The patient recovered.

THE MAJORITY OF THE CHEAP CIGARETTES contain more nicotine in proportion to the tobacco in them than does an ordinary cigar; one reason for this being that many of them are made from cigar-stumps, which are carefully collected for this purpose, and these cigar-stumps are saturated with nicotine distilled into them by the slow combustion of the cigar.

ASSOCIATION JOURNALS.—Dr. J. Milner Fothergill writes a long letter to the *Medical Times*, giving an account of the *British Medical Journal* and of the dissatisfaction at its management. The writer volunteers much advice to our American Medical Association. His chief complaint against the organ of the British Association seems to be that its editor has advocated the compulsory notification of infectious diseases. He does not make out a very strong case, though he writes a long letter. Dr. Fothergill will have to beware, or he will be accused of having become intoxicated with the exuberance of his own picturesque rhetoric.

THE TROUBLES IN LUNATIC ASYLUM MANAGEMENT.—Much scandal has been aroused over the management of the Central Lunatic Asylum at Anchorage, Ky. It was charged that a system of "ducking" has been used, with fatal results in some cases. A judicial investigation has resulted in bringing indictments against several employees. It was shown that obsolete methods of treatment were employed.

THE LATE DR. J. FOSTER JENKINS, OF YONKERS, N. Y.—The following resolutions were passed by the Yonkers Medical Association, N. Y.: *Whereas*, It has pleased Almighty God in his mysterious providence to remove from our midst, by death, our much esteemed and beloved member, Dr. J. Foster Jenkins; and, *Whereas*, We, the members of the Yonkers Medical Association, have by his removal lost a faithful and regular attendant upon our meetings; one who was always ready to do his part, contributing largely to the scientific interest, and by his eminent ability and peculiar qualifications as a physician and man he gave to the meetings a superior tone and dignity; *Resolved*, That we shall ever remember him as one whose upright character, pure example, and blameless life is worthy of our highest admiration and profound respect. *Resolved*, That we tender to the family and friends of our departed brother our heartfelt sympathy in the dark hour of their affliction. *Resolved*, That we attend in a body the funeral of Dr. Jenkins from his late residence. *Resolved*, That a copy of these resolutions be sent to the family of deceased, and also published in THE MEDICAL RECORD and local papers.

DR. VALENTINE BROWNE, *President.*
N. A. WARREN, M.D., *Secretary.*

DR. CARL KROG.—At a late meeting of the Medico-Chirurgical Society of German Physicians the following preamble and resolution were adopted:

Whereas, After a long and painful illness death has ended the sufferings of our beloved president, Dr. Carl Krog; and *Whereas*, During his long period of membership he manifested a deep interest in our society, and latterly as its president left nothing undone that could promote its welfare; and *Whereas*, His qualities both as man and colleague called forth our admiration, as did his patience in long suffering command the sympathy of all who knew him; therefore be it

Resolved, That the members of the Medico-Chirurgical Society of German Physicians transmit to the bereaved family the expression of their deep grief at the loss of their old friend and the assurance that the society, for whose growth and development he did so much, will ever treasure his memory in honor and esteem.

A POSITIVE HOMŒOPATH.—Dr. Samuel A. Jones, a very pronounced homœopath, writes to the *New York Medical Times* concerning the recent doubts expressed as to the value of high dilutions. He adds with much calmness that "all hell plus a great gross of Milwaukee tests" can never knock out of him a somewhat learned from a certain experience.

Original Communications.

ON THE USE OF THE OIL OF WINTERGREEN AS AN EFFICIENT SALICYLATE IN ACUTE RHEUMATISM.

By FRANCIS P. KINNICUTT, M.D.,

PHYSICIAN TO ST. LUKE'S HOSPITAL, TO THE OUT-PATIENT DEPARTMENT OF THE NEW YORK HOSPITAL, ETC.

In a paragraph of a few lines in the January number (1882) of the *Ephemeris of Materia Medica, Pharmacy and Therapeutics*, reference is made to the use of the oil of wintergreen, as an efficient salicylate in acute rheumatism. Mr. P. Cassamajor, a well-known chemist of Brooklyn, it is stated, arguing from a purely chemical position, was led to expect better results from the use of this oil (which is mainly a methyl salicylate), in rheumatic affections, than from other salicylates of a more fixed character. Carrying out his ideas, he treated himself and several friends suffering from acute rheumatism with ten-drop doses of the oil, frequently repeated. The results were very satisfactory. The method seemed to me worthy of an extended and careful trial. I therefore directed that all cases of acute rheumatism received in my wards at St. Luke's Hospital, during the months of May, June, and July of the present year, should be placed upon this treatment.

Before stating the results obtained, it will be useful to briefly consider the properties of this essential oil. The oil of gaultheria, or wintergreen, contains 90 per cent. of the methyl ether of salicylic acid, and 10 per cent. of a terebene, separable by fractional distillation. It mixes in all proportions with alcohol and ether, and is slightly soluble in water. When taken internally, it is speedily absorbed into the blood, and is excreted *mainly* by the kidneys, imparting to the urine its characteristic odor.[2]

Its elimination is very rapid; the presence of a salicyl compound has been readily detected by me, by the ferric chloride test, in the urine passed one hour after the administration of twenty drops of the oil. Its antiseptic properties are very marked. One part of the oil to two hundred of urine preserves the latter for eighteen days. "Urine voided one hour after taking twenty drops of the oil remained perfectly free from decomposition for twelve days, while urine passed immediately before its administration became putrid and ammoniacal in the usual time."[3]

The cases, the details of which I shall present to you, were very carefully observed by me from the time of their reception into the wards. They were all well-marked cases of acute rheumatism, several of them of a severe type. The method adopted in the earlier cases was to administer the oil in ten-minim doses every two hours, daily, until eight doses had been taken. Its use being unattended with any gastric disturbance or toxic effects, the daily amount was gradually increased, until in the later cases fifteen-minim doses were given every two hours, except during sleep, and in severe cases during the twenty-four hours. The mode of administration varied according to the individual taste of the patient, and consisted in floating the oil on water (a wine-glass or more), on milk, saturating lumps of sugar with it, and finally in giving the oil in capsules incorporated with a little carbonate of magnesia.[1]

It was found that the patients took the drug very willingly, many expressing a decided liking for it. In none of the cases were the occasional toxic effects (viz., disturbed or perverted vision, delirium, etc.), of the acid observed; ringing in the ears, the symptom of the full physiological effect of other salicyl compounds, was of infrequent occurrence. In only one case was the slightest gastric disturbance excited, and in this instance consisted in a single rejection of the medicine.

Cases of *acute* rheumatism are alone included in the following table. The oil of wintergreen was, however, employed in my wards during the same period in a number of cases of a sub-acute character, also in a single mixed case of gout and rheumatism (with marked benefit), and in other affections in which the salicyl compounds have been employed with more or less benefit, with results corresponding in all respects with those obtained from the latter.

TOTAL NUMBER OF CASES TREATED WITH OIL OF WINTERGREEN, 12.[2]

Number of case.	Maximum temperature, first day.	Temperature normal.	Complete freedom from pain.	Pericarditis, endocardial murmurs.	Relapses.	Stay in hospital.
1	103⅜° F.	4th day.	4th day.	Fourth day, faint systolic apex bruit.	0	23 days.
2	99⅘ "	1st "	5th "	0	0	19 "
3	100⅖ "	4th "	6th "	0	0	16 "
4	101⅖ "	2d "	5th "	0	Pyrexia and joint pains, 15th day.	29 "
5	100 "	4th "	6th "	Faint systolic apex bruit on admission.	0	18 "
6	100⅘ "	4th "	6th "	0	Pleuritis and phlebitis, 11th day.	50 "
7	100 "	4th "	4th "	0	0	27 "
8	103⅕ "	3d "	3d "	Distinct systolic apex bruit on admission.	0	20 "
9	102⅕ "	4th "	4th "	0	0	15 "
10	99 "	1st "	4th "	0	0	18 "
11	102 "	3d "	4th "	Ninth day, systolic apex bruit.	0	22 "
12	103 "	3d "	3d "	30th day, systolic apex bruit.	Pyrexia and joint pains, 14th and 29th day.	35 "

Average duration of pyrexia, 8-12/12 days.
Average duration of joint pains, 4¼ days.
Average duration of stay in hospital, 24¼ days.

The mistake of reducing the daily amount of the medicine at too early a date and in not confining the patient in bed for a sufficient period, accident-

[1] Read before the Practitioner's Society of New York, October, 1882.

[2] A portion of the methyl salicylate is certainly eliminated by the kidneys unchanged; I have been unable to assure myself that it is *wholly* so eliminated.

[3] Glasgow Medical Journal, July, 1882, p. 66.

[1] Fifteen or twenty drops of the oil in two ounces of water, the mixture being thoroughly shaken before use, constitutes a simple and very agreeable mode of administration.

[2] The total number treated was really seventeen. The results in the remaining five cases correspond very closely with those given in the table; they are not included, from the fact that the temperature-charts were very carelessly lost in the transference of the patients to another ward, during temporary repairs to the hospital.

ally was made in one or two instances.[1] This error, I believe to be a very common one and encouraged by the very rapid subsidence of the pyrexia and arthritic pains under full doses of any of the salicyl compounds. I would add a word in regard to the advantage to be derived, in my estimation, from the method of giving the salicylates in *frequently repeated* doses. As a rule, salicyl compounds are rapidly eliminated and the effects of comparatively temporary duration.[2] The maximum benefit to be obtained from them in acute rheumatism will therefore be found, I believe, in conforming the dosage to the rate of elimination of the drug, in so far as is possible.

Although my intention has been simply to compare the efficiency of the methyl salicylate with other salicyl compounds, in the treatment of acute rheumatism, a careful study of the cases recorded is not devoid of interest.

Duration of Pyrexia.—The efficiency of the methyl salicylate in controlling the pyrexia would seem to be slightly more marked than in ameliorating the joint pains, judged by the duration of each of these symptoms; a result which corresponds with Dr. Sydney Coupland's observations in regard to other salicyl compounds.[3]

Pericarditis, endocardial murmurs.—Pericarditis was developed in none of the cases. In Case 1 the systolic apex bruit was very faint, heard only over the mitral area, and disappeared during convalescence. In Case 5 the bruit was also faint and not transmitted. In Case 8 a distinct systolic apex murmur, transmitted, was present on admission. In Case 11 there was a roughening of the first sound over the aorta and pulmonary areas on admission, and on the ninth day a faint systolic apex bruit, heard only over the mitral area, was detected. In Case 12 a systolic apex bruit, not transmitted, was developed only on the thirtieth day. The pathology of many systolic apex murmurs in rheumatism is at least a debatable question. In the cases recorded, with the exception of No. 8, I was disposed to believe that they were due to the anæmia associated with the disease, possibly in Cases 11 and 12 to the conjectural anæmia produced by the salicyl compounds.

Relapses.—In the three cases in which relapses occurred, pyrexia and joint-pains were both present, an association which is by no means constant in relapses of the disease.

In Case 4 the patient by mistake was permitted to be out of bed at an earlier date than was intended, and on the sixth day the daily amount of oil was diminished to one drachm. During a violent northeast storm, on the fifteenth day, a relapse occurred. The duration of the pyrexia of the relapse was three days; of the joint-pains six days.

Case 6, although classed among the relapses in the table, is more properly illustrative, I believe, of the efficiency of the salicyl compounds in controlling the pyrexia and arthritic pains of acute rheumatism without necessarily destroying the rheumatic virus.

With the daily administration of two drachms of the oil, the pyrexia and joint-pains disappeared on the fourth and sixth days respectively. Although the drug was given continuously in similar doses, a pleuritis and femoral phlebitis were developed on the eleventh day, but without further arthritic symptoms. In Case 12 a relapse occurred on the fourteenth day, the dosage having been gradually diminished from the ninth day. The duration of the pyrexia was three days, of the joint-pains seven days. A second relapse, lasting only twenty-four hours, occurred on the twenty-ninth day, the medicine having been discontinued on the twenty-seventh day, and salicin in gr. xv. t.i.d. substituted, partially for its tonic effect. The occasional inefficiency of the methyl salicylate, *given in full doses, and where all other precautions are carefully observed*, in preventing the occurrence of relapses, corresponds with the experience of other observers and with my own in the use of other salicyl compounds.

Duration of stay in hospital.—The rule adopted in my service is to discharge convalescents from acute rheumatism only after a period of a full week or ten days of their being about the wards and on full diet. In Dr. Francis Warner's[1] analysis of 352 cases of rheumatism treated by salicyl compounds in the London hospitals, the average time in hospital was 34.9 days. In Dr. Sidney Coupland's[2] statistics of 317 cases similarly treated, the average time in hospital was 31.4 days. The average duration of stay in hospital in the 12 cases treated with the methyl salicylate was 24½ days.

CONCLUSIONS.

First.—That in the oil of wintergreen we possess a most efficient salicylate in the treatment of acute rheumatism.

Second.—That in its efficiency in controlling the pyrexia, the joint-pains, and the disease it *at least* ranks with any of the salicyl compounds.

Third.—That the best method of its administration is in frequently repeated doses, continued in diminished doses throughout convalescence.

Fourth.—That its use possesses the advantages of being unattended with the occasional toxic effects, the frequent gastric disturbance produced by the acid or its sodium salt, even when prepared from the oil of wintergreen; that its agreeable taste and finally its comparative cheapness are further recommendations in favor of its employment.

I cannot conclude without expressing my obligations to the members of the resident staff, Drs. Campbell, Moffat, Remsen, and Devlin, for their valuable assistance in the above observations.

[1] The rule adopted in my wards in the treatment of acute rheumatism with the salicyl compounds has been to continue them in diminished doses throughout convalescence.

[2] The continued presence of a salicylic compound in the urine after the discontinuance of the drug, as observed in a case reported by Dr. Habershon, and in several of Dr. Coupland's, should be regarded, I believe, as instances of an individual and exceptional retarded elimination.

ELECTRO-CAUTERY IN EYE DISEASES.—Electro-cautery is being used extensively in Paris in various affections of the eye, I might almost say promiscuously. It is used in entropion, extropion, pannus, leucoma, ulcers of cornea, scleritis, anterior staphyloma, conical cornea, and detachment of the retina. It is exceedingly difficult, as every one knows, to ascertain the relative value to be attached to these operations in cases thus seen. The one advantage in many cases seems to be that it takes only a very little time to complete the operation, an advantage not always on the side of the patient.

In detachment of the retina M. De Wecker is using electro-cautery two rows of points in the lower cul-de-sac—so, : : : : : : : .—*Cor. Chicago Medical Journal and Examiner.*

OBSCURE CASES OF INEBRIETY.

By T. D. CROTHERS, M.D.,
HARTFORD, CONN.]

In all etiological studies of inebriety, there are certain cases whose physiological history is involved in mystery. The first use of spirits was obscure, and grew so gradually that it escaped all notice. Such cases have drank spirits for a long time, without any intelligent comprehension of the reasons or nature of the act. When in the later stages attention is called to them, the theory of vice and sin is urged vehemently, on the supposition that any other view would take away personal responsibility and personal effort to recover. The delusion of strength to stop at will, so common in all of these cases, is stimulated by this theory, and the method of prayer and pledge is readily adopted. Henceforth they are alternately buoyed up on this delusion of self-control and help from the pledge and prayer, or depressed with the utter hopelessness of all means. Any vague impression which they may have of a physical causation has no support from others, hence all physical inquiry is ignored. The old divine, Thomas Aquinus, in the twelfth century describes the sin of inebriety as follows: "The whole life of a drunkard is a battle-ground in which the flesh and the spirit are contending for the mastery. Sometimes the drunkard is on the side of the flesh, then he joins the spirit, and the conflict goes on, either embracing the devil or casting him off. But the devil triumphs at last in most cases." This is the theory, slightly varied, urged to-day in explanation of many cases whose origin is not clear. In all ages of the world, the mysterious and that which could not be explained has been attributed to a spiritual origin. Hence inebriety has been referred to a low moral nature, and to vice and sin. When from a better knowledge this theory was untenable, a compromise was made, and now it is urged that a stage of vice and sin is followed by disease. Or in other words, the inebriate is always vicious and sinful at first, and the result of gratifying this low moral nature is disease. This pernicious doctrine has put back the scientific study of inebriety for half a century. It is the obscure border-land cases whose mystery has attracted clergymen and reformers that have furnished support for these false theories. The presumption of the advocates of this doctrine, who insist on the vice origin of all cases, whose chain of causes are not clear, is misleading and unnatural. If in ten cases of a similar disease the physical origin can be traced in five, it is most reasonable to suppose that a similar physical causation exists in the others, although not clearly traceable. Can any one doubt the physical origin of typhoid fever, insanity, or any other disease long known, simply because the causation in some cases is obscure? Inebriety is a more complex disease than insanity, and has never been studied thoroughly, but the natural history of some cases, starting from a well defined physical standpoint, passing over a regular course which can be traced from stage to stage, furnishes the best of evidence of physical causation and physical law, which a wider knowledge will make clear.

The following case is one in which the causation was clear and traceable: A——, a strong, vigorous merchant, aged thirty, with no heredity and temperate, suffered from a partial sunstroke. He remained greatly debilitated for two months in bed, then began to use spirits to excess, and was a continuous inebriate up to death, four years later. He made great exertions to recover by the pledge and prayer, but failed and died of dementia. The drink craving was clearly traced to the brain injury from sunstroke. No possible causation of vice could be traced to the first use of spirits, and the progress of the case was regular in spite of all means to check it.

The next case is a border-land one, full of mystery, but when carefully studied has clear outlines of an unmistakable physical causation. B——, was born of healthy parents and grew up a vigorous man, temperate and correct in all his habits. He was a prosperous mill owner and attentive to business. At thirty-one years of age he married, and his wife was killed on the wedding tour in an accident. His grief was very profound; for two months he was unable to do any business except to walk to the mill a few moments every day and direct some little matters. He took tonics under the direction of a physician, and complained generally of sleeplessness and poor appetite. A year after he began to frequent low places and use spirits over the bar and associate with bad company. Later he was intoxicated in public. Then he neglected his business, bought fast horses, and became dishonest, doing many things that were foreign to his previous character. Gradually he sank from bad to worse, and finally was sent to State prison for forgery. His property was gone and he became a gambler and inebriate of a low type.

In this case the most prominent symptoms were low, vicious propensities seeking an outlet in bad society and drink. When the history was studied it was clear that the shock of the sudden death of his wife produced a psychical traumatism; some change in the normal functional action of the nerve-centres, which became the starting-point of a general moral and physical degeneration; some loss of nerve-force, manifest clearly in departures from health and changes of thought and action. The sudden shock of grief produced permanent alterations of character. His disposition changed; all his previous motives and ambitions in life vanished. He left the church and began to lead a most irregular life, giving no reason except that he was discouraged. At times he seemed to manifest grief at his conduct and make an effort to recover, but soon relapsed. His brain retained, during the sober moments, an appearance of health in thought and action. He talked and reasoned clearly, and made efforts to recover; signed the pledge; asked the prayers of the church; then, in the moment of greatest promise of success, fell precipitately into the lowest company and state of drinking. There was no reasoning or calculation in this; the mind seemed at a certain point to be incapable of forming any views of the subject, and to act under a diseased impulse that was beyond control. The radical change of character and of motive, beginning at a certain point, leading rapidly to ruin, pointed to a physical cause uninfluenced by any moral state previous to this time.

In the following case a similar obscure history was found from a closer study to spring from the same cause. He was a wealthy merchant who had by long industry amassed a fortune. He was temperate in all things, a man of much character and deliberation, a church member with a family, and very exemplary in conduct and honorable in business. No history of heredity in the family, and no spirits were ever used, partly from principle and an

inherent dislike to their taste and smell. A financial storm made him suddenly poor; his wife died and his family scattered, all in a few months. His hair turned gray and the shock of grief for a long time left strong marks of physical suffering. He resumed business again but frequented low saloons and drank to intoxication. He was forty-eight years old at this time, and seemed to have the same intellectual force, only more quiet and reserved in his manners. He succeeded, but was noted for dishonesty and prevarication. Seemed to take pleasure in overreaching and deceiving others. He drank to excess every night, and was low in his tastes, company, and associates. Great efforts were made to reform him by his church friends. He seemed pleased with these efforts, and was rational in aiding them, promising with great earnestness to do all that was required, but in secret drinking and living as before, all efforts to conceal this becoming more and more imperfect. He gradually became worse, and was sent to Blackwell's Island for drunkenness and fraud several times in the next five years. He is now, ten years from the time of failure in business, a hostler in a small hotel, drinking regularly, and a wreck in body and mind. This was clearly psychical traumatism, beginning at the time of his financial ruin, and marked by the changes of character, disposition, and conduct. His mind to the general observer gave no hint of such change. He reasoned with others clearly about himself, but was unable to carry out any plan when left alone. Two distinct beings seemed to exist, one that would live a natural healthy, pure life as before, the other that sought relief from alcohol and the lowest impulses of nature. As the latter grew he could give no reason for this course, except that he could not help it. He gradually failed, the mind becoming feeble with the body, and the one dominant impulse for alcohol seemed to supersede everything. A diseased condition of the brain centres was present. There was failure of co-ordination, or acting upon the impressions received or sent out from the central ganglion.

Psychical injury from varied causes are traceable in these obscure cases of inebriety, as in the following very common instances: A man with a neurotic inheritance receives a blow on his head and soon after becomes an inebriate. He is confident that this concussion has broken up his health, although he may not trace inebriety to it. It may be in another case a sunstroke, followed by months and years of nerve debility; then inebriety comes on. Some latent inherited nerve-defect may spring into activity from the shock of grief, or sudden powerful depressing emotions. A man fixes all his hopes and ambitions on some special object in life, and suffers from sudden disappointment, the sweeping away of every expectation, followed by intense grief and sorrow, then inebriety. It is these psychical storms which not only break up the normal molecular action of the brain, but prepare the soil for inebriety in the future.

There is another form of traumatism, which is undoubtedly a cause of inebriety, that has never been noticed. It may be termed physical, because it springs from disease and injury that is always apparent. A man has some injury or severe illness from which he recovers, but is never the same after. He is conscious that he has lost some element of force and vigor, and this event has been the switch or the point of departure from the main line of health. In many nameless ways this fact is apparent. Sometimes changes in disposition and character are apparent to his friends, in others want of physical strength and endurance are the prominent signs. Whether he is aware of it or not, changes both psychological and pathological may be traced from such events that merge into insanity, inebriety, or other disorders. A man previously modest and retiring, after an attack of typhoid fever, becomes boastful and assuming, and exhibits decided changes of character. Later he is an inebriate or insane, or has some form of paralysis. Although the direct chain of causation may not be clear back to the typhoid fever, yet there can be no doubt that this was the starting-point.

A patient now under treatment, with a history of ten years' drinking in fast society and bad surroundings, was found to have a period anterior to this as follows: Six years before he began to use alcohol his leg was broken in a railroad accident. An artery was wounded and severe hemorrhage followed, which threatened to be fatal. Convalescence was slow and it was nearly a year before he could resume his business as bookkeeper. From this time his habits became more and more irregular, especially in eating and sleeping, also in work. He was depressed and complained of neuralgia, and could not concentrate his mind on his work. Would take the correspondence home, and after a sleep in the night or early in the morning complete it. Was morbid in his credulity of patent medicines and efforts to find something that would bring relief. His mind seemed the same in his business, and his social relations were unchanged, and yet he was a nervous invalid or neurasthenic, suffering from some alterations of nerve-structure and function. The inebriety really began in this period in the favoring conditions and increasing degenerations, which at last developed into the drink craving. All superstitious notions of vice in the origin of this case disappeared when the history was understood, and a general outline chain of causes were traceable from the time of this injury.

Both of these forms of traumatism have been noticed as causes in inebriety by both English and German authors, but no study has been made of such cases, owing to the impression that they were rare, and always associated with insanity. A wider study will dispel this error. The evidence will appear, from a study of many of these obscure cases, fully sustaining this view of remote injuries to the brain and nerve centres, resulting later in inebriety. No matter how changeable and obscure the progress of the case may be, there will always be a certain regular progression or march, from some point or event of life on to the full development. These physical and psychical storms either alone or together, leave traces and marks that are seen all along the future. The normal vigor and integrity of organism is disturbed or broken, the great outer circle of health is left behind, and life goes on over the border of the shadowy inner circle where health and disease blend and contend.

John B. Gough, in his biography, mentions a severe injury received in childhood, followed by delirium, which, in his opinion, has influenced his entire life physically. This testimony, unconsciously given, of both a pathological and psychological state, is of great significance. The great practical facts which may be demonstrated in the study of every physician, are that all these obscure cases of inebriety are suffering from disease, which is more or less curable if recognized and properly treated—

an affection that cannot be reached by moral means or by appeals to pride or religious emotions, but only from the exact application of physical means suited to the wants of each case. This may be secured in most cases, but only from an absolute quarantine of the patient from every exciting cause. All the surroundings and conditions of life must be under the care of a physician, and every means known to science applied to build up and restore the last energies.

The following conclusions will help to further studies in this field, and may be said to outline some leading facts from which the laws of this disease may be deduced:

First.—All cases of inebriety should be studied carefully to ascertain not only the heredity, but the possible history of traumatism, either psychical or physical. As in epilepsy scars on the scalp may often furnish clear indications of the chain of causes. Fevers, and any disease or events which have profoundly influenced the organism and nervous system are always prominent factors in the history.

Second.—Inebriety is a central disease of the nervous ganglia, which may either follow a regular line of march down to chronicity or death, or be attended with uncertain halts, long pauses, or rapid progress, from some unknown causes; but, whatever its course may be, always following a certain order and regularity, in the stages of degeneration, that is seen and may in many be predicted.

Third.—From a knowledge of the cases the varied means of treatment can be applied which will be most effectual in restoration. If the case is chronic and incurable such a study will point out the best means to limit and control its progress in the least harmful channels.

Fourth.—Inebriety and its problems must be studied by medical men above the superstitious theories of reformers and clergymen, before we shall have any positive facts upon which to base accurate methods of treatment and cure.

ADDITIONAL REMARKS ON

AMPUTATION OF THE REDUNDANT SCROTUM FOR THE CURE OF VARICOCELE.

BASED ON ADDITIONAL CLINICAL OBSERVATIONS AND SUCCESSES.

BY M. H. HENRY, M.A., M.D.,

LATE SURGEON-IN-CHIEF OF THE STATE EMIGRANT HOSPITALS OF NEW YORK, FELLOW OF THE NEW YORK ACADEMY OF MEDICINE, ETC.

THE interest that has been developed and manifested in the treatment of varicocele by excision of the redundant scrotum by the method and with the instruments to which I first called attention eleven years ago, and more recently by the publication of a little work exclusively devoted to this subject, as well as the indorsement and reference of cases from many distinguished friends, tempts me to add further testimony in support of the value of the operation and improvements in the method of operating, based on additional clinical observations and experiences.

The pathological and clinical features of the disease and the theory and *modus operandi* of the operation I perform were so fully explained and so widely circulated in my former contributions that I shall now confine my remarks to some points of practice and further clinical observations, to which my attention has been directed by my own experiences and the inquiries of friends interested in the subject.

The fear of hemorrhage excited in the minds of a few timid and inexperienced persons, through the loose and unfounded remarks of a surgeon of some notoriety, is now entirely set aside by the successes which invariably follow the operation, and by the "perfect facility, precision, and efficiency of the procedure."[1] The theory of the operation is to avoid interference and division of any of the important vessels. With ordinary care there need be no hemorrhage beyond the loss necessarily following the division of the tissues. The spermatic veins and the enlarged veins of the scrotum proper can be avoided in the incisions by attention to the rule, and to which I called attention—to hold the parts that are to be removed in front of the light, and be careful that no vessels are included in the integuments beyond the flat-convex surface of the clamp and the line of division. In the ordinary daylight essential to the performance of any surgical operation, the redundant scrotum will be found perfectly transparent. The division of any vessels beyond the small and superficial scrotal vessels must be the result of carelessnes or want of appreciation of the essential details of the operation.

Regarding the amount of scrotum to be removed, I can only say that I take away all not absolutely necessary to form a covering to hold and retain the testicles in a normal and comfortable position. There is no danger whatever of removing too much in this operation if the clamp is skilfully applied—without skill there is more probability of a second operation being called for to remove more tissue. To one who has had no experience in the operation, it at first seems as if too much were removed, but there is invariably more or less tendency to relaxation of the scrotum. With the recovery and renewed resiliency of the spermatic veins—by shortening of their axes and less dependent condition—there is less strain, and with this lessened strain and increased tonicity of the scrotal integument there is less probability of much further relaxation of the scrotum, at least, not more than can be tolerated with perfect comfort. Skill and experience can only be acquired in the performance of operations—it will enable the operator to decide with the nicest precision the amount of tissue to be removed.

The clamp should not be applied until all the other arrangements for the operation are perfected and the patient placed under the full influence of the anæsthetic. This is to avoid compression of the parts longer than is absolutely necessary. The pressure and constriction of the parts when embraced within the blades of the clamp is great, and it is of decided advantage to remove the instrument as soon as convenient, thus enabling the parts to recover from the pressure more quickly and increasing the chances of an early union. In spite of the distress and frequently intense pain endured by persons suffering from varicocele, many authors still advise the temporary expedient of suspensory bandages or soft metal rings—bent to suit the wearer—a continuance of which may afford a partial relief from very severe pains, but does not in the least retard the progress of the disease. Many surgeons still ligate the veins and assume risks to life or risks of the loss of the function of the testicles quite beyond any corresponding advantage which this operation can afford. Among the persons upon whom I

[1] Remarks by Dr. R. J. Levis, before the Philadelphia County Medical Society (Medical Times).

have operated this year, one was especially interesting as a typical case, embracing all the worst features of the physical disease associated with intense mental suffering. He is forty years of age, of a nervous temperament, very tall and slender, and, if I may use the expression, of a neuralgic diathesis. He describes his case and the result of the operation so well in a letter to me, three weeks after the operation was performed, that I know my readers will not object to my putting it in evidence, omitting only references to my manner of operating.

"NEW YORK, April 8, 1882.

"*My Dear Doctor*—It is three weeks to-day since you performed on me the operation of removing redundant scrotum, an operation so earnestly advised by you to relieve me of the painful consequences of the excessive enlargement of the veins along the spermatic cord of the left testicle, which for twenty years had assumed proportions as large as a small apple, distending the scrotum to five or six inches in length, causing unceasing pain and unspeakable annoyance, the constant use of a suspensory bandage, and, besides, a supreme disgust at such a malformation. and dejection of spirits at the thought that I should be doomed to endure this horrid malady for the remainder of my years.

"I cannot command words adequate to express the gratitude I feel toward you for recommending so earnestly the operation. . . . . The wound has entirely healed, showing hardly a sign of any disturbance at all, while I have been confined to my room less than a week, attending to my daily avocations the balance of the time.

"As to the advisability of the operation, there would seem to be no room to question it. Three weeks ago I was a hopeless, helpless invalid. To-day I am well—my symptoms or sensations being normal, that is, delightful. The comfort it has already afforded me can therefore be comprehended by nobody except him who has endured as I have the torments of this fearful malady. The local trouble is effectually cured, and unless I mistake other evidences, I am certainly improving in general health, for I had been dragged down and greatly enfeebled by this serious affliction. I wish I could proclaim to every like sufferer my speedy deliverance and commend to him the means by which it has been secured. Thanking you again and again for the boon you have brought me, believe me gratefully yours."

This is not an isolated case, it is one of many, or of a class to which my attention is now frequently called. I may state here that at the time of writing this article (October 20th) this gentleman is perfectly well, and has had no return of any of the painful symptoms so graphically described in his letter.

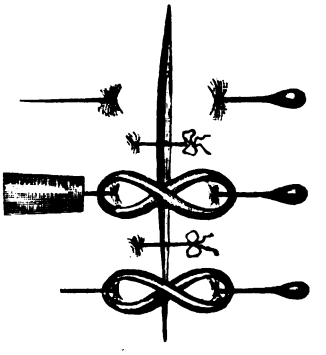
In my early operations I relied mainly on the ordinary interrupted suture. I now use only the silver pins one-half inch apart and a simple stitch to retain the skin-tissue edges in immediate contiguity in the intervening spaces. Success in the so-called after-treatment depends on the manner and care of the wound after the operation. This must always be dependent on the operation itself and the course pursued in the dressing and plan of subsequent treatment.

In the use of the ordinary interrupted suture there is some danger of the ligature ulcerating through the parts, and in case of much swelling it is sometimes tedious, difficult, and painful to remove the stitches. If there is much œdema the dragging sensation in the wound is a source of no small annoyance to the patient, and the suture excites a constant sensation resembling the cut of a knife. By the use of the pins the parts are more firmly secured, the edges are in more perfect apposition, there is no dragging of the edges of the wound, there is less danger of any ulceration of the edges, there is a better chance of union by first intention, a greater feeling of security against any opening or disturbance of the wound in the absence of the surgeon, and less danger of any superficial hemorrhage from the cut surfaces.

The pins are inserted through the divided tissues, so that the edges are maintained perfectly in apposition. In the intervening spaces a fine silk suture is used, only through the skin, for the purpose of preventing the edges from rolling outward. This obviates the necessity of a large number of pins. As an additional safeguard in preventing the edges from rolling outward, great care should be exercised against pressing and tying the edges too closely; *gentle* apposition, not *forcible* apposition, is the only way to secure the quickest and best union. I dwell on this point, because I have, on a number of occasions, been asked how to avoid this condition.

The pins are all inserted through the tissues directly under or close behind the concave surface of the blades of the clamp before the scrotum is removed. In this operation the anterior or convex side of the clamp is the guide for the incision. The detachable guide is not used when the operation is done in this way. Here let me remind my readers that Messrs. Tiemann & Co. and their agents are the only makers who have fully followed my instructions in the manufacture of the clamp. Many clumsy instruments by other makers are unwarrantably sold as mine.

I prefer stout silver pins, one inch and a half long. To facilitate the insertion of the pins and to prevent the small heads from burying in the flesh if swollen, I cover the heads with a little sealing wax; this also aids in retaining the ligature on the



one side of the wound. When the pins have all been inserted, I then fix a small cork in the pointed end of each pin, half the length of the cork, the exact size of which is seen in the accompanying illustration. This serves the double purpose of preventing the edges and wound from spreading wide apart when the clamp is removed, and affords ease in placing the ligatures on this side of the pins. As soon as this is accomplished the redundant scrotum is cut off and the clamp removed.

The next step is the application of the figure-of-

eight silken threads around each pin in the manner used in cases of hare-lip. The intermediate edges are then stitched with fine silk to prevent bulging, as already described. The corks are then removed, the pointed ends of the pins cut off and a strip of thick adhesive plaster placed parallel with the line of wound under the sharp edges of the pins to prevent them from irritating the skin. A simple dressing of cold water with a few grains of carbolic acid to the ounce is the only application necessary.

The pins are usually removed on the third day, and here I desire to call special attention to the manner of their removal. With a little skill they can be withdrawn without causing the patient any pain. Disregard of these details will induce intense suffering. The pins should be carefully selected—silver, or thoroughly plated. Many of the pins sold are of base metal and oxidize in the wound to such an extent that their removal causes great pain. Before the pin is removed the wound should be thoroughly cleansed and the ligatures softened and cut away. The pin should be very gently rotated before removed. The rotation, if gently done, breaks the little attachments formed by incrustation with the tissues and prevents dragging and tearing of the freshly united parts. These details may seem trifles. They are not; they prevent suffering to the patient, they assist in sustaining the integrity of the wound, and lessen the period of detention and confinement of the patient.

The swelling or œdema which follows the operation invariably subsides in a few days. The treatment following the removal of the pins consists mainly in keeping the wound perfectly clean. The little points that have not united by first intention, may—if thought necessary—be gently stimulated to advance the healing process. With my own increased experience, assisted greatly by cases furnished and observations afforded by my professional friends, I am thoroughly impressed with the advantages of this operation.

Among the surgeons who have adopted my method of treating varicocele none have been more eloquent in their praise of its merits than my friend Dr. R. J. Levis, of Philadelphia. Under my own title he recently contributed a short article to the *Medical Times*, and indorsed all that I have claimed of its superiority over other forms of surgical treatment. After enumerating the objectionable features of ligation of the veins—the danger to life—want of confidence in its permanent benefits, and the liability to loss of the function of the testicle on the side operated upon—a full account of which will be found in my work[1], and formulated in my conclusions on pages 23 and 24—he says: "It is now with much satisfaction that I adopt by preference a method of operating which seems to be entirely efficient, and which appears to be free from all the risks and other objections referred to." In alluding to the operation in a recent letter—September 29, 1882—he says: "I have operated very many times, and the operation grows in favor in my estimation. The results are excellent, and always satisfactory to the patients."

My attention was recently called to a case, operated on by a friend, in which there was bulging of one testicle in front of the other after the operation. This would not have occurred if the blades of the clamp had been placed parallel with the line of the raphé, and the major portion of the redundant scrotum removed from the anterior surface. This accident, or rather condition, was due to the removal of too much tissue from the lower and posterior surface of the scrotum, thus forcing the lower testicle upward and forward. It affords an additional reason for care and nicety in the adjustment of the instrument.

I am averse, on general principles, to enter into any discussion with reviewers of my works on the merits of any of my contributions. I cannot, however, forego the temptation to remind the distinguished reviewer of the *Lancet*[1] that his objections to the operation which I advocate were all disposed of in my work[2] by testimony that is beyond cavil or dispute—the testimony of time and the evidence of men whose intelligence and judgment no one can gainsay.

I am well aware "that laxity of scrotum is certainly not the cause of varicocele, but when present, is generally its effect, and it is unscientific and bad surgery to confuse cause and effect, and treat the latter for the former; and, after all, the operation does no more than can be effected by a good suspender."

These statements are so fully answered in my work that I mention them now only to fix the attention of my readers to the fact that such objections have been fully accounted for and refuted. I have in this communication furnished additional testimony to show that "a good suspender" *does not* afford the relief desired by sufferers from varicocele.

If any of my readers desire further evidence in support of the claims I have made of the value and advantages of this operation, I beg—aside from the testimony of the patients—to call their further attention to the testimony of my distinguished *confrères*—Gross, Van Buren, Ashhurst, Otis, Barton, J. C. Hutchinson, Bumstead and Taylor, Hammond, Clymer, D. H. Agnew, Little, and others. I mention these names because they have so kindly referred to my contributions in their published works, and by correspondence and reference of cases.

There is a pleasure in the practice of surgery, aside from the satisfaction and ability to relieve suffering and cure disease—it is the opportunity to advance and add to our resources improvements and additional means of cure the full benefits of which can only flow from the co-operation of a large number of toilers in the same field and with the same purposes in view.

Another Substitute for Cod-Liver Oil.—Among the numerous substitutes for cod-liver oil which have from time to time been brought before the notice of the profession, dugong oil, which is an extract obtained from the dugong, an herbivorous cetacean inhabiting the warm seas of the coasts of Australia and the Eastern Archipelago, has met with a most favorable reception. Dugong oil is free from the unpleasant odor and taste which characterize cod-liver oil, and is much less liable to change in keeping. At ordinary temperatures it is opaque, from the separation of its more crystalline constituents, but becomes clear and almost colorless when slightly warmed. The dose is the same as cod-liver oil.

SUCCESSFUL TRACHEOTOMY FOR DIPHTHERITIC CROUP, IN A CHILD ELEVEN MONTHS OLD.[1]

By GEORGE F. SHRADY, A.M., M.D.,

SURGEON TO THE PRESBYTERIAN AND ST. FRANCIS' HOSPITALS, NEW YORK, CONSULTING SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED, NEW YORK.

But a very small number of successful cases of tracheotomy in children under one year of age have thus far been recorded. Indeed, so fatal is the operation in subjects under two years of age that most of the authorities object to its performance during that early period of life. The reasons for the decision are founded upon extensive statistics furnished by the most experienced operators. Jacobi gives the rate of mortality from tracheotomy during the first year of life as high as 93.3. Cohen makes the general statement, based upon most exhaustive study of the subject,[2] that very few children under two years are saved by tracheotomy, even when the latter is performed under what might be considered advantageous circumstances. He quotes Isambert as saying that during a service of two years in the Hôpital des Enfants Malades, under Guersant and Blache, it was almost a rule that no case under two years of age, or at least under twenty months, should be operated upon, because of the non-success which attended them. Bourdillat gives three recoveries in one hundred tracheotomies upon children under two years of age. Wilms reports no success within that age.

Associated with the tender age of such patients are conditions which deserve to be considered as militating against the success in the operation. These are, in the main, the narrowness of the trachea, the shortness of the neck, the deficiency of vital power, the intensity of the traumatic fever, and the subsequent difficulty of nourishing the patient. It will be seen, then, that the following case of successful tracheotomy, on a child but *eleven months old*, for diphtheritic croup, is worthy of record.

I was called, January 29, 1882, to see Edward K——, aged ten and a half months, who was suffering from symptoms of advanced diphtheria. The tonsils and naso-pharynx were covered with the characteristic membranous deposit; the temperature was 104° F.; and the patient was in a feeble condition. The usual local treatment of the disease was followed, together with the internal administration of carbolic acid (syr. iod. phenique, Déclat), and the case progressed favorably until February 10th, when hoarseness and other symptoms of commencing laryngeal obstruction first showed themselves.

The following day, February 11th, the patient having lost much ground and the stenosis increasing, I availed myself of the counsel of Dr. J. H. Ripley, who kindly saw the case with me. Although every symptom pointed toward the probability of ultimate laryngeal obstruction, we agreed that the time for tracheotomy had not yet arrived.

On the 12th the symptoms progressed, but were still not considered sufficiently grave to demand the operation.

On the night of the 12th the child had a severe attack of suffocation, but the parents not having brought themselves to consent to tracheotomy did not summon me. Early the following morning, when I visited the patient, I deemed any further delay unwarrantable. An invitation was sent accordingly to Dr. Ripley, who was present at the operation and who rendered me valuable assistance. The parents were informed that the case was a desperate one, that in all probability the child would die of suffocation in a very short time and that tracheotomy might ward off only for a time the death struggle. In fact, the operation offered the last and only chance for saving the child. The responsibility of deciding was then left with the parents. This they bravely assumed in their dire extremity, and the child was delivered to me in the gasping throes of rapidly approaching suffocation. Chloroform was administered, on account of the struggles of the patient. The incision was made in the usual manner, the trachea readily exposed, being hardly larger than an ordinary goose-quill, and the opening made immediately below the cricoid cartilage, through two of the upper tracheal rings. The hemorrhage was slight. Immediately after the insertion of the tube there was a considerable discharge through it of bloody mucus. All the urgent symptoms of difficult breathing then subsided. The wound was closed by sutures above and below the tube, and a moist sponge secured over the latter. The child was then given to the parents, who had never expected to see it again alive.

Contrary to expectation, the surgical fever was not high, the temperature not ranging within the first forty-eight hours beyond 102½° F. There was no difficulty in swallowing after the operation. During the four days following there was a profuse discharge of ropy mucus and shreddy membrane through the canula, necessitating the changing and cleansing of the inner tube four or five times daily during that period. The lower portion of the wound became much swollen and inflamed on the second day, when the sutures were removed, and when a diphtheritic coating was noticed over its surface. Hardly daring to believe that a child so young could, under such circumstances, survive, it was, however, determined, by unremitting personal attention to the details of after-treatment, to secure, if possible, the desired result. Dr. Ripley, being also much interested in the case, saw it with me at different stages of its progress, and aided me by many suggestions based on his own extensive experience in the surgical treatment of croup. The outer tube was not changed until the fourth day, when a washer of soft lint, lubricated with carbolized vaseline, was applied, thus protecting the underlying granulations.

On the fifth day a considerable quantity of broken down diphtheritic membrane was ejected from the fauces during an act of vomiting, and later, on the same day, the child nearly suffocated during the escape of a similar material through the canula. On the evening of the seventh day the lower end of the canula became suddenly blocked, and except for the prompt action of the watchful mother, who removed both tubes, the child would have suffocated. Subsequently both tubes were changed every other day, until the thirteenth day after the operation, when they were removed permanently. The wound then rapidly healed by granulation, and finally closed entirely by March 1, 1882, by which time the child was cured. He still remains in perfect health.

It is quite evident to me that the success in this case was mainly due to the great care in keeping up the strength of the patient by stimulants and in

[1] Read at a meeting of the Practitioners' Society of New York, September, 1882.

[2] Croup in its Relations to Tracheotomy. J. Solis Cohen, M.D., Philadelphia, 1874.

guarding against plugging of the tube by frequent removal and cleansing of the latter. The mother, who nursed the child herself, was instructed to be in readiness for any emergency of impending suffocation. Aside from this, the case being in my immediate neighborhood, I was enabled to keep constant watch of it, making several visits daily during the first week after the operation. Considering the good effects claimed for the breathing of warm moist air after tracheotomy, this case was an exceptional one. The moist sponge could not be kept in position at the mouth of the tube even for short periods without occasioning distress to the child. He appeared to get along well enough without the vapor, and was consequently let alone. At no period in the after-treatment did any difficulty arise which might have been prevented or relieved by the use of moist air.

The point of greatest interest in this case is the result of tracheotomy for diphtheritic croup in a child so young. As far as I have been able to learn, this is the first case of its kind of recovery under one year of age that has been reported in this country. In fact, it forms one of a very few similar results recorded by European surgeons. With the assistance of Dr. W. D. Dietz, I have made an extensive search of the literature of the subject, and have been able to collect but seven of such cases. All of these were obtained either from Cohen's work on tracheotomy, or, since its publication, from him personally. For convenience, they are arranged, along with the case herein reported, in the following form, indicating the age of patient when the operation was performed, the name of the operator, time of permanent removal of tube, when stated, and the original reference.

There have also been reported a few other instances of recovery in very young infants after tracheotomy, but in none of them is it stated that the operation was for diphtheritic croup. It may be proper, however, to mention these in this connection for the purpose of including all the cases found of recovery under one year after tracheotomy, for whatever reason performed. Scontetten's case ("Soc. Méd. des Hôp. de Paris," 1867), in his own child, six weeks old, was evidently one of spasmodic croup, in the radical treatment of which the father's fears overbalanced his judgment. Annandale (*Edin. Med. Jour.*, 1862, p. 112) reports a case in a child three months old. Impending suffocation appears to have been due to a retro-pharyngeal abscess. The child lived but seven weeks, and was wearing the tube at the time of death. Evidently for the same disease Steinmeyer (*Berlin klin. Woch.*, 1880, No. 40, p. 572) performed the operation successfully on a child aged nine weeks. Mr. Croft had a similar result on a child aged six months (*Lancet*, 1880, p. 849) who was suffering from symptoms of œdema of the glottis, associated with an erysipelatous inflammation and œdema of the entire cervical region. No false membrane was found; neither did croupous cough exist. Mr. Lawson Tait, of Birmingham, mentions (*Brit. Med. Jour.*, April 15, 1871) a successful case at seven months, but no other particulars are given. The same is the case with another, aged nine months, in which he believes that the child was destroyed by its mother, who deliberately obstructed the tube, three weeks after the operation.

247 LEXINGTON AVENUE, NEW YORK.

[1] Sanné (Traité de la Diphthérie, Paris, 1877) gives ten months as the age of Dujardin's patient, as does also Cohen, but Dujardin, in his own report (Union Medicale, 1872, p. 46) states that the child was one year old.

Progress of Medical Science.

EUCALYPTUS GLOBULUS IN GYNECOLOGICAL PRACTICE.—This drug is destined to play an important part in gynecological therapeutics. It is only since 1865 that its therapeutic action has been tested, and, with the cloud of new remedies constantly before the attention of the profession, it has not received the full trial which it is sure to get eventually.

Dr. Andrew F. Currier reports in the *American Journal of the Medical Sciences* for October, 1882, five different cases of various natures in which the local application of this drug on vaginal tampons proved of the greatest anæsthetic value. Besides its anæsthetic effects, it is, as we know, antiseptic and antiperiodic, and hence it will be of use in that large class of cases where foul-smelling discharges exist, and also as an adjuvant in the treatment of malaria. The absorptive function of the vaginal mucous membrane has been comparatively little employed in constitutional treatment, and this is a field which yet remains to be worked up. A daily application of this substance must have more than a local influence. It will usually be difficult to give treatment so frequently, excepting in hospital practice. Much better results would follow could a continuous effect of this, as well as of some other means of treatment, be obtained, but the expense and the annoyance, and in many cases the dread of pain prevent. The very fair degree of success obtained in treating the cases described in this paper leads him to believe that in less severe cases we can feel almost positive that we can give great relief; indeed, his experience in private practice confirms that belief. In a quite different class of cases eucalyptus will also be serviceable. He refers to wounds of the breast after the removal of tumors. With the increasing favor of the open method of treating such wounds, especially when the growth removed has been of a cancerous nature, its stimulant and antiseptic properties will prove very acceptable.

THE DIGESTIVE POWER OF COMMERCIAL PEPSIN.—Dr. C. L. Dana reports, in the October number of the *American Journal of the Medical Sciences*, a num-

ber of careful experiments as to the digestive value of various forms of commercial pepsin, both in the stomach and in artificial digestion.

His experiments show, (1) that different brands have different strength; (2) that the same brand may vary in strength at different times; and (3) that there are a number of details connected with the process of artificial digestion by which the power of the pepsin can be greatly modified.

They further show that ten grains of ordinary commercial pepsin will generally digest ten or twelve times its own weight of coagulated egg-albumen, finely minced, in four to six hours. It has, however, very little effect upon lumps of albumen or upon boluses of lean or cooked meat.

This is the case outside the stomach. If it does no better when given medicinally, or even if it does considerably better, its power as a remedy must be very slight.

In conclusion, he holds that a physician in giving a dose of *good* pepsin may believe that it will have a value two or three times greater than that exhibited under ordinary artificial conditions, *i.e.*, it will digest twenty or thirty times its own weight. This conclusion is in harmony with much clinical experience, that *good* pepsin has a *real* though not a *great* medicinal value.

Points of practical importance are, that large doses should be given, even of so-called pure pepsins. The physician should always know how much pure pepsin there is in the saccharated preparations. Acid should generally be given immediately before, and the pepsin after meals.

EYE DISEASES DEPENDENT UPON SUPPRESSION OF MENSES.—In the *American Journal of the Medical Sciences* for October, 1882, Dr. R. J. McKay reports twelve cases in which suppression of the menses was accompanied by disturbance of vision. Cases of this kind demand prompt recognition as to their etiology (before vision is too much impaired by the internal eye disease) in order that they may be successfully treated and relieved. Partial loss of vision, and inability to use the eyes in young healthy looking females, without external eye disease, always suggest to his mind the probabilities of menstrual disturbance, and he makes it a rule to at once inquire about the matter.

Young school-girls often manifest asthenopia (weak and painful sight) about the time their menses are being established, and especially if their menses become irregular from any cause, which may produce partial or complete suppression for an indefinite time. Sometimes they manifest decided congestion of optic papillæ and retinæ, and others no internal eye lesion, with exception of strain of their accommodation. This is common to all such cases, for they have some refractive deformity of their eyes. The latter sooner or later causes their muscles of accommodation to rebel from their overtaxing and too continuous work.

THE TREATMENT OF EMPYEMA.—In an elaborate article on this subject in the *American Journal of the Medical Sciences* for October, 1882. Dr. William C. Dabney draws the following conclusions:

First.—"Medicinal" treatment, as it has been called, namely, treatment without operation, occasionally gives favorable results, but is not advisable, inasmuch as cases so treated are liable to terminate in one or other of the following ways: *a*, Sudden death; *b*, exhaustion; *c*, suffocation; *d*, phthisis; *e*, septicæmia; *f*, calcareous degeneration of the pus; *g*, secondary pneumonia and gangrene of the lung; *h*, peritonitis from the bursting of the empyema into the peritoneal cavity; *i*, amyloid degeneration of the liver, kidneys, etc.

Second.—Aspiration has given good results in the case of children, and should be tried in them before the radical operation is resorted to.

Aspiration and immediate washing out of the pleural cavity through the aspirator (Kashimura's treatment) has not been used sufficiently often for any conclusion as to its efficacy to be reached.

Third.—Free incision into the pleural cavity is usually necessary, and the best point for such an incision when only one is made is at the lowest point of the purulent collection, and directly below the angle of the scapula. Costal resection is to be avoided if possible, especially in children.

Fourth.—Continuous is preferable to intermittent drainage, because, *a*, the danger of absorption is thereby lessened; *b*, there is usually less danger of irritative fever; *c*, the empyemic cavity is placed in a better position for healing. Continuous drainage is best effected by a drainage-tube.

Fifth.—Through drainage is only advisable in cases where the discharge is very fetid, and where a single opening has proved insufficient.

Sixth.—The thoracic opening should not be allowed to close if more than two drachms of pus are discharged daily.

Seventh.—The danger of sudden death during thoracentesis or injection of the pleural cavity, when proper care is used, is so slight that it may practically be disregarded; but when injections are used, especial care should be taken to see that they have a free outflow.

Eighth.—Simple injections of pure water are often sufficient, but compound tincture of iodine, one part to four of water, is devoid of danger, and hastens recovery. This will usually check fetor also; but if it does not, salicylic acid or permanganate of potash in one-half or one per cent. solutions, may be employed. Carbolic acid is dangerous, as is boracic acid also.

Ninth.—Listerism would probably be advisable in city or hospital practice, but is of doubtful efficacy in the country, and under no circumstances should it be allowed to interfere with thorough drainage.

ECHINOCOCCUS DISEASE IN AMERICA.—In the *American Journal of the Medical Sciences* for October, 1882, Dr. William Osler, of Montreal, publishes sixty cases which he has collected from the museums, journals, transactions, and from private sources. In the inspection of over eight hundred bodies, only three cases were met with.

The accidental ingestion of the eggs of the tiny *Tænia echinococcus* of the dog produces the most serious and fatal parasitic disease of man. The affection prevails extensively in certain countries, as Iceland and Australia, where the habits of the people or the relations of the canine host to man insure easy means of communication. In Europe the disease is not uncommon, and at any one of the larger clinics several examples are sure to occur during the session. So far as we know, the facts of its occurrence in America have not been investigated and the object of this paper is to give an account of an inquiry into its prevalence.

THE CONTAGION OF LEPROSY.—In the *American Journal of the Medical Sciences* for October, 1882, Prof. James C. White contributes a valuable paper

in which he traces the origin of leprosy in the Hawaiian Islands, New Brunswick, Cape Breton, and the United States. In the study of the disease observed in these various localities, he finds evidence that it is communicable from man to man by direct transference, or facts which can be interpreted in no other reasonable way, and this conclusion he accepts as supported by the general history of the affection in past times as related by medical chroniclers. He accordingly feels justified in forming the following conclusions: Leprosy has spread under recent observation, when introduced into a previously unaffected stock, in so rapid and general a way as to prove that it may diffuse itself universally through a nation independently of the action of hereditary tendencies. There is no evidence to support the assumption that this wide and quick extension of the disease has been caused or aided by any peculiarities of soil, climate, diet, or other telluric agency in Hawaii. The history of the affection, on the other hand, leads to the strongest conviction (scientific proof is well-nigh out of the question) that it is communicated directly from person to person, while the peculiar customs offer a satisfactory explanation of its unparalleled spread. The history of the little centre of disease in Louisiana, watched, fortunately, from its very beginning, leads to the same conclusion, that it affects persons not under any law of heredity, but through the intimacy of personal relationship, the customs and morals determining largely the rapidity and universality of its spread.

As regards the bacilli of leprosy, Dr. White believes that there is nothing in the history or pathology of leprosy incompatible with the theory of its parasitic nature. Should a bacterium be constantly found in the disease, the leprous tissue itself, most pronounced in that in process of development, presenting the same characteristic features in cases occurring in all parts of the world, and not found in human tissues in connection with other diseases or in their healthy condition, it would constitute strong presumptive evidence that this parasite was the specific cause of leprosy. The proof would be positive if its inoculation were found to reproduce the disease. As yet, however, proof of this character has been merely negative. He is a strong advocate of the isolation of lepers.

Feeding with Dried Blood.—M. Regnard (*Le Progrès Médicale*, No. 23, 1882), suggests the employment of dried blood as food. In the case of six orphan lambs, three were fed on the ordinary vegetable food, and three on the same plus a certain quantity of cooked and dried blood. The first three died, while the others developed splendidly. He remarked that if these results are confirmed, these economical results will be considerable, as it will permit the utilization of the hundreds of thousands of pounds of blood wasted in the slaughter-houses of Paris alone. He quoted a case of rickets in a child in which this food had given excellent results.

A New Method of Reduction in Dislocations of the Humerus.—In the September number of the *Dublin Journal of Medical Science*, Dr. J. E. Kelley describes a rather novel method of reducing luxations of the humerus. He states that he accidentally hit upon this method in a case in which he had exhausted every means of reduction without effect. He has since then successfully employed it in over twenty cases. The selection of a couch or bed is of importance for his operation.

It should be firmly fixed and hard, and when a choice is practicable, he prefers it, for the subglenoid dislocation, to be about three inches lower than the great trochanter of the operator, whilst one lower still by a few inches, for the anterior dislocations, and a little higher for the posterior, allows the force to be applied advantageously in the direction of the glenoid cavity. The patient should be placed as close as possible to the edge of the couch, on his back, with his head low. In order to make the description of the procedure intelligible he divides the operation into two stages: The first, or preparatory stage in which the surgeon takes the most favorable position for the reduction, is assumed by placing the injured arm at right angles to the body, and standing against it with the side to the patient and the hip pressed firmly, but not roughly into the axilla. The operator folds the arm and hand of the patient closely round his pelvis, and fixes the hand firmly by pressing it against the crest of his ilium. The second stage, during which the reduction is effected, is very simple, consisting merely of a rotation or version of the surgeon's body, until his back faces the side of the patient, with a force and rapidity which necessarily varies with the peculiarity of the dislocation—some yielding most readily to a sudden and powerful effort, and others to gentle and gradually increasing traction.

For any additional "manipulation," the surgeon has the hand next the patient's axilla disengaged for such manœuvres as lifting the head of the humerus into its cavity, making traction upon it forward or pressure backward, according to the nature of the dislocation. The fixation of the scapula, a point of considerable importance, is secured by its position between the couch and the body of the patient, while its inferior angle is supported by the gluteal region of the operator.

One of the great advantages of this operation is the ease with which the surgeon can reduce almost any dislocation without assistance or the appearance of violent exertion. But should a case of peculiar difficulty present itself, additional extension may be applied by one or more assistants making mediate or immediate traction on the patient's arm; and the counter extension is as readily increased by pressure on his uninjured shoulder or his pelvis.

The importance of being able to dispense with anæsthesia in such operations is indisputable, especially when the surgeon is summoned to perform them suddenly and without assistance, as so frequently occurs in dislocations. Dr. Kelley claims this advantage to a very great extent for his method, as in only one case in his experience has he had to resort to that or any other auxiliary.

The Ether Spray an Immediate Cure for Neuralgia.—Dr. McColganan extols the value of the ether or rhigolene spray for the instantaneous relief principally of facial neuralgia. He first had occasion to observe its good effects upon his own person, he having suffered greatly from facial neuralgia. Since curing himself, he has had occasion to test its efficacy in about twenty cases. The result was invariably a most gratifying success. In many instances a permanent cure was established. He attempts to explain its action by supposing a complete change to take place in the nutrition of the affected nerve in consequence of the intense cold acting as a revulsive.—*Southern Practitioner.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, November 4, 1882.

THE ANNUAL REPORT OF THE SURGEON-GENERAL.

"THE Annual Report of the Surgeon-General of the Army," just received, gives a very satisfactory exhibit of the work done in his department during the fiscal year ending June 30, 1882. The statistics, which bear the evidence of much care and thoroughness in their collection, present many points of interest to such as are given to the study of military hygiene in its relations to the effective utility of standing armies. The data upon which this portion of the report rests cover many conditions of climate, situation, race and environment, giving the summarized results a proportionate value.

With an average mean strength of 20,778 white, 2,265 colored troops, and 245 Indian scouts, the total number of cases (white) of all kinds taken on the sick list was 34,880, being at the rate of 1,679 per thousand of mean strength. Of this number 4,527, or 218 per thousand of strength, were for wounds, accidents and injuries of all kinds. The average number constantly on sick-report during the year was 942, or 45 per thousand of mean strength. The total number of deaths among the white troops was 216, or 10 per thousand of mean strength. Of these, 141, or 7 per thousand of strength, died of disease, and 75, or 3 per thousand of strength, of wounds, accidents, and injuries. The proportion of deaths from all causes to cases treated was 1 to 161.

The number of white soldiers discharged the service on "Surgeon's Certificate of Disability" was 848, or 41 per thousand of mean strength.

The total number of cases of all kinds among the *colored troops* reported was 4,099, or 1,810 per thousand of mean strength. Of these, 618, or 273 per thousand of strength, were due to wounds, accidents, and injuries. The average number constantly on sick report was 100, or 44 per thousand of strength. The total number of deaths of colored soldiers reported from all causes was 25, or 11 per thousand of mean strength. Of these, 16, or 7 per thousand of strength, died of disease, and 9, or 4 per thousand of strength, of wounds, accidents, and injuries.

The proportion of deaths from all causes to cases treated was 1 to 164.

The total number of colored soldiers discharged on "Surgeon's Certificate of Disability" was 98, or 43 per thousand of mean strength.

The total number of cases reported among the Indian scouts was 56; being at the rate of 229 per thousand of mean strength. Of these, 43 were cases of disease, and 13 of wounds, accidents, and injuries. The total number of deaths was 9; 4 from disease and 5 from wounds.

To such as care to analyze these exhaustive statistics it must be apparent that the usual relations of sickness to the other accidents of military life reach the ordinary average maintained by standing armies, and all other things being equal the mean working strength of our soldiers is at a high standard.

But what must interest the medical profession more particularly is the manner in which the Surgeon-General and his efficient assistants are endeavoring to utilize the immense amount of scientific material at the disposal of the department. The work in these directions has been immense, owing to the perfect system with which it is carried on. And too much praise cannot be bestowed upon the steady and untiring efforts, not only in the preparation of the forthcoming volumes of the "Medical and Surgical History of the War of the Rebellion," but in the more permanent preservation and more ready utilization of reports of sick and wounded constantly received from the various military posts.

It is gratifying to learn that the manuscript of the third surgical volume of the "Medical and Surgical History of the War" is now sufficiently advanced to allow the volume to be completed and laid before Congress during the coming session. The profession of the county will anxiously await its speedy publication. There can hardly be a doubt that Congress will grant the necessary appropriation to such an end.

The Army Medical Museum has been considerably enriched by the addition of specimens, while the library is constantly crowding its shelves with the choicest medical literature of this and other countries. At present, as a library, it is without a rival, numbering fully fifty-seven thousand volumes, and over sixty-three thousand pamphlets. Over three thousand volumes have been added during the past year.

In view of the value of the specimens in the museum, and of the volumes in the library, another timely recommendation is made by the Surgeon-General for a suitable fire-proof building to guard against accidents. There can be but one view of

the absolute necessity of such a measure, as we have often said before.

Notwithstanding that the number of vacancies reported last year have been filled by new appointments, there are, in consequence of retirements and promotions during that period, a vacancy in the office of Assistant Surgeon-General, and six vacancies in the grade of assistant-surgeon.

Although we have given a somewhat lengthened review of the report, we can scarcely do it the justice it deserves for the presentation of thorough systematic and valuable work done in the department during the past year. The profession have just reasons for being proud of the achievements of the Army Medical Staff, for not only has it proved itself equal to the emergencies of war, but is capable of improving to the uttermost the opportunities of peace. In no other similar corps the world over is better and more thorough scientific work done. The indisputable facts upon which this statement rests are, the Army Medical Museum, the National Medical Library, and the History of the War of the Rebellion.

THE SALICYLATES AND BLISTERS IN ACUTE RHEUMATISM.

The discussion upon the value of the salicylates in acute rheumatism, which took place before the London Clinical Society last winter, awakened a widespread interest which has not yet ceased. The general tenor of the debate, as we recall it, went to show that the salicylates were not specifics in inflammatory rheumatism, that they did not lessen cardiac complications, that subsequent joint affections were quite as common, and that the patients' stay in hospital was nearly as long as when treated by other methods, some statistics even making it longer.

On the other hand, it was shown that in the great majority of cases it rapidly relieved the symptoms of pain and fever.

There has lately sprung up a wave of skepticism as regards the value of the salicylates. The general practitioner soon finds that in acute rheumatism the hardest and most annoying thing to treat is not the pyrexia, the severe pains, the swollen and tender joints, which belong to the acute stage, but the obstinate relics of the disease which linger in the system, crippling the patient just enough to make, with health apparently so near, his helplessness exasperating.

The salicylate treatment has lately been attacked with much earnestness by Dr. Alexander Harkin, in a series of articles which appeared in the *Dublin Journal of Medical Science* and quite recently in the *British Medical Journal*. This author, however, not only cites objections, but proposes an efficient substitute. He reports fourteen cases of acute articular rheumatism successfully treated simply by the application of a large blister over the region of the heart. No internal medicine was given, and we are told that pain and fever subsided within twenty-four hours after the application of the vesicant. The author states that he has had a number of other cases with which he had been equally successful in almost every instance.

Dr. Harkin attempts to explain the action of his remedy by assuming that acute rheumatism is "a specific form of endocarditis of neuropathic origin, generally allied with myocarditis." The local disease, he thinks, speedily affects the blood and heat-centres.

Dr. Harkin's pathology is absurd, and would cause some doubts as to his competency as an observer, were it not that on other points he writes lucidly and well.

His view as to the efficacy of blisters is also supported by other observers. Indeed, the blister treatment introduced by Dr. Dechilly, of Vancouleurs, in 1850, has had occasional defenders ever since. Dr. Harkin differs from others in asserting the importance of placing the blister over the heart.

It is known that rheumatic fever often terminates with an early defervescence, even where no medicine is given. For this reason no remedy can be accepted as of assured value upon the limited evidence given by Dr. Harkin and a few others. We are inclined to think also that the profession will be slow in giving up the use of the salicylates. It is pleasant to feel that one can almost surely relieve acute symptoms within twenty-four hours. The sufferer's gratitude and confidence thus earned will generally survive the dolorous period that follows, however long. It is quite possible that the natural salicylate, the oil of wintergreen, which Dr. Kinnicutt has found so efficacious, will obviate some of the objections heretofore made against the manufactured drug.

LIABILITIES FOR INJURY TO PATIENTS DURING OPERATION.

The decision of Judge McAdam, in a recent suit before the Marine Court of this city, brought by Thomas J. Kelly against the dentist Colton, to recover for injuries caused by allowing a piece of tooth, which was being extracted, to drop down the plaintiff's throat while he was under the influence of laughing-gas, is one full of importance, not only to dentists but to general surgeons as well. It is alleged that the piece of tooth slipped from the forceps, and for four weeks thereafter the plaintiff was troubled with a cough until he finally expectorated the piece. The court held that while a patient was under the influence of an anæsthetic which deprived him of the use of his faculties the operator was bound to exercise the highest professional skill and diligence to avoid every possible danger, and in this case it was the opinion of the

court that the circumstances shown were sufficient to carry the case to the jury on the question of negligence.

The judgment appealed from was in favor of the plaintiff for $500 damages, and this judgment was affirmed by the present decision.

The whole question evidently turns on the fact whether or no the plaintiff is guilty of negligence. It is fair to presume, in view of the circumstances of the case, the patient being at the time unable to protect himself, that the full onus of any supposed negligence must be borne by the defendant. In view of this it behooves the operator to exercise extraordinary care to prevent accidents.

It is hardly necessary to say that this is a rule very generally observed by surgeons, and accidents inflicting injury upon patients are in consequence comparatively rare. No reasonable excuse can be offered for neglect to exercise even more than ordinary skill in guarding against such mishaps. The law holds that no person should assume extra responsibility in the management of any case without bringing to the same a corresponding amount of skill to meet emergencies. During anæsthesia there is an implied guarantee to the patient that no known precaution which can be taken shall be omitted to guard against every possible accident. The same holds true regarding every step in any operation, the surgeon being bound to exercise his best judgment, his most watchful care and greatest skill for the benefit of his helpless and trusting patient.

That accidents will happen, despite all precautions to the contrary, is well known and the case under consideration appears to form a striking illustration of the fact. The result of the suit may, however, establish a precedent which is full of danger to any operator who is forced to take extra risks for his patient.

THE INDEX CATALOGUE.[1]

To such as may only know of the "Index Catalogue of the Surgeon-General's Office" by what may be written of successive volumes as they appear, can form no adequate idea of the immensity of labor involved in its preparation, nor of the amount of material upon which such labor is based. For instance, the third volume, just issued, which in size and make-up corresponds with its predecessors, includes over nine thousand author-titles, representing over ten thousand volumes and more than seven thousand pamphlets. Besides these enumerated, there are eight thousand five hundred and seventy-two subject-titles of separate books and pamphlets and nearly twenty-nine thousand titles of articles in periodicals. Thus far the three catalogues include over thirty thousand subject-titles, represent twenty-three thousand volumes, as many pamphlets, over twenty-nine thousand book titles, and over one hundred thousand journal articles. And yet the third volume of the "Index Catalogue" has not advanced beyond D.

The profession of the country who have watched the growth of this grand library at Washington, are becoming more and more alive to its value, and, we are happy to say, are appreciating more and more the genuis and labors of the indefatigable librarian, Dr. J. S. Billings.

These catalogues are making available to the wants of the working medical men an amount and variety of medical literature which has never been collected together in any similar library in the world, nor probably ever will be. We are not surprised to hear that the use of the library is increasing with medical men over the country. Its direct influence in encouraging research must in the end exert its influence upon our medical literature and through it elevate the tone of medical education. We have repeatedly said that the American medical man is as much a worker as the physician of any other country if the opportunities are offered him for so doing. The different volumes of the "Index Catalogue" of this great library are some of the essential means to that end in directing his studies and in indicating to him the proper lines to follow.

In looking through this volume, which is a wonder of work in itself, we are struck with the vastness of the storehouse some of the secrets of which are therein disclosed.

For instance, in it are detailed the works on cholera, climate, croup, diphtheria, diarrhœa, dyspepsia, and dysentery, sufficient in number to make a good-sized library for each disease. In all this, however, but the commencement has been made of what is to be in forthcoming volumes. It is gratifying to know that the fourth volume of this invaluable series including the letter E and part of F is nearly ready and that the first part is going to press.

ACUTE AMERICANITIS.

An ingenious writer in *Knowledge*, an English periodical, relates several cases illustrating the "desiccating" effect of the American climate upon Englishmen who come here. If the visitor be young, and if he settle into hard work, he is very likely to suffer from a train of symptoms which the writer facetiously classifies under the name of "acute Americanitis."

An illustrative case was that of a young man who came over from England and began at once some scientific work at Washington, D. C. He soon got into a condition of nervous excitability, with rapid pulse and a general intensification of mental and bodily activity. He grew thinner, and, finally, symptoms of cerebral congestion, etc., set in. He

[1] Index Catalogue of the Library of the Surgeon-General's Office, U. S. Army, Washington, D. C. By J. S. Billings. Vol. III. Washington, 1882.

was obliged to return to England, where he soon regained his strength.

This is asserted to be an exaggerated, yet typical, case of what often occurs to Englishmen when they cross the Atlantic. New York physicians will doubtless, many of them, recall instances in which English visitors have complained about the peculiar effects of the climate here.

"Nervousness" is a frequent symptom, as is also loss of flesh. Professor R. A. Proctor loses thirty pounds in weight every time he comes to the United States; but regains this flesh very soon, upon his return to England.

The author quoted thinks that the causes acting thus acutely upon Englishmen have been steadily at work upon Americans, producing a development of "constitutional intensification" whose topmost wave is disease, *e. g.*, neurasthenia, American nervousness, or "Americanitis." And the prophecy is made "that American physicians will presently discover this, and recommend their well-to-do patients —those who have worked as only Americans in the pursuit of wealth do work—to turn to the land of their fathers, to breathe the soothing humidities of its anodyne atmosphere, and thereby double the remaining years of their lives."

It may be said regarding this writer's speculations that they betray a lurking attachment to British fogs, which has probably caused some exaggeration regarding the banefulness of our climate and the healthfulness of England. There is, however, a foundation for the view that Englishmen are affected acutely and Americans changed organically by the dryness and other qualities of our climate. This subject has been already noticed by many and has been studied from a larger standpoint by Beard in his work on "American Nervousness."

It is somewhat interesting to see that Englishmen are now themselves discovering and acknowledging this "Americanitis," whose existence they have heretofore been somewhat inclined to ridicule.

THE AMERICAN ACADEMY OF MEDICINE.

THE American Academy of Medicine is an organization having peculiar difficulties in the way of its work and success. It aims to promote preliminary education and to elevate the standing of medicine as a learned profession. These aims are acknowledged to be praiseworthy, but American Academicians, in pursuing them, necessarily enter into a little self-glorification, and excite some feelings of antagonism, if not jealousy. Less than ten per cent. of the profession are qualified to become members. The other ninety scrutinize very closely, therefore, the pretensions of those who claim to have had the proper kind of educational start.

But, despite all obstacles, the American Academy has made a position for itself, and has proved to the profession that its views of the necessity of preliminary training are right. The members have judiciously kept their cause, and not themselves, in the foreground.

These are days when doctors need most of all the capacity to utilize what mental gifts they possess, to judge correctly, and to act with the tact and good sense which a broad education helps to secure. Nothing is so likely to narrow a man as exclusively technical or scientific studies. They make one an artisan, not an artist. To those intending to study medicine, we say, therefore, learn something else well first. And this, we believe, is the gospel which the Academy preaches.

The recent meeting of this Society, of which an account is given elsewhere, was by far the most successful one that has yet been held. About fifty new members were elected, a considerable number of excellent papers were read, and much enthusiasm was shown on the part of everyone. The Society was able to take some retrospective glances and speak of things already done. The reports of the committees showed that much active work is being accomplished by the energetic secretary, Dr. Dunglison.

Altogether the Academy deserves congratulations upon having so securely established its existence and demonstrated its usefulness. As long as there is felt any ambition to have the medical profession a learned body in the true sense, a field for its work will exist.

"A PRIOR CLAIM FOR THE DISCOVERY OF THE BACILLUS OF TUBERCLE."—Dr. J. M. Blaisdell, of Bangor, Me., writes: "Under the above heading in the September 30th number of your journal, you state: 'The only objection to Dr. Blaisdell's claim is that when his article was published he did not say how he discovered his bacilli, nor did he figure them or in any way prove that they were not ordinary bacteria.' Now, I would like to ask the question, if failing to name the bacteria 'bacilli,' or something else, or to give the process by which I discovered them, really invalidates the discovery?

"I distinctly stated in my article on the 'Cause of Consumption,' that 'we were enabled to demonstrate that the "little bodies" seen by Virchow in miliary tubercles, were in reality the minute germs of fungi, which having been inhaled into the tubes with atmospheric air, become imbedded in the mucous membrane, incubating and developing into living parasites.'

"My article was hastily written for a popular journal, and consequently clothed in language that the public could understand. Had it been written for scientific eyes only, I should have used 'bacteria' and other terms, known only to the learned, instead of 'vegetable parasites.' But as the whole family of bacteria and bacilli are included in the general term of parasites—and were first discovered in pulmonary tubercle by myself, and announced (in my opinion) as the cause of consumption, I see not why, in all justice, I should not be accorded the priority in the discovery."

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Annual Meeting, October 23, 1882.

F. R. STURGIS, M.D., PRESIDENT, IN THE CHAIR.

REPORT OF THE BOARD OF CENSORS.

DR. DANIEL LEWIS, Secretary of the Board, read the report, of which the following is an abstract. The registry on May 1, 1882, contained the names of 2,772 practitioners, 476 having been added since the report at the annual meeting in 1881.

About fifty complaints had been received during the year, several of which were for non-registration. In some instances the name of the supposed delinquent had been recorded since the original list was published. All other complaints had been referred to the Counsel for the Board, who had promptly taken the requisite legal action, and the results were given in his report hereunto annexed.

In his inaugural address the President had called attention to some of the defects of the present law, especially the difficulty in procuring evidence sufficient to convict, and also the facility with which offenders could procure diplomas from a certain medical college in the City of New York.

The report of the Counsel showed that the law of 1880 was one under which convictions could be more readily secured than at first seemed probable, and steps had been taken to shut off the supply of diplomas just referred to, which seemed to be ready for delivery as soon as the culprit had paid his fine in the District Attorney's office.

As the result of the suggestion made by the President, and the unanimous opinion of the Board of Censors, a new law was carefully drafted and introduced into the Legislature in the early part of the session of 1882, which more clearly defined the limits of illegal practice, and rendered fraudulent diplomas worthless by requiring the graduates of all medical schools to pass a State examination before beginning to practice. Of course it encountered the active opposition of the college above referred to, and, as the Board regretted to say, received only a lukewarm support from some schools which need have no fear of allowing their work to be inspected by the Regents of the University of the State of New York, or any other tribunal. The bill failed to become a law.

The Censors were firmly of the opinion that such an examination as the bill proposed, was an educational reform, which each member of the Society should advocate until its complete realization. Unless medical men themselves were willing to sacrifice time and money to uphold the character of their calling, the public at large could not be expected to undertake the task. We were not engaged in a crusade against quackery and the suppression of its disciples, but all endeavors to enforce medical laws and punish offenders were the fruitage of a growing sentiment in favor of better methods of medical education. Unqualified practitioners would soon lose what influence they had in the community, if it was demonstrated that a thorough preliminary training and medical attainments equal to those required by the best universities here or abroad were demanded for admission into our ranks.

The report was signed by all the members of the Board: Drs. David Webster, A. Jacobi, Edwin F. Ward, Edward B. Bronson, and Daniel Lewis.

The Report of the Counsel, Edward C. Ripley, Attorney, showed that during the year just expiring, the prosecution of illegal practitioners had been much more extensive than in the year 1881. Of the cases mentioned in his last report, and which had since been terminated, there were *ten*. In five of these the prosecution was successful, and fines to the amount of five hundred dollars were imposed. Two of the number, Edward B. Lighthill and John Wesley Grindle, had since been graduated by the Eclectic Medical College of the City of New York. In two instances the prisoners were acquitted, because of the weakening of witnesses; two were discharged by the justice, because of ignorance concerning the law; and one case was awaiting trial at the Special Sessions.

During the year just expiring, Richard C. Flower was arrested, indicted, tried and fined two hundred dollars; proceedings were discontinued against Abraham E. Cox, who promised to take down his sign and to cease practising; James Bryan had been held for action of the grand jury (and subsequently had been graduated by the Eclectic College of the City of New York), case still pending; Henry Cooper had pleaded guilty and been fined fifty dollars; F. W. Johnson had been held in five hundred dollars bail; Richard Johnson had pleaded guilty, and been fined fifty dollars; Adam Claesson had been held in three hundred dollars bail; Dr. Bond (Dr. Humphrey) had been held in five hundred dollars bail; August Frech in three hundred dollars bail; Moses Jacoby held to bail; F. Eliseo Marini held to bail on a second and third complaint; Richard Johnson held to bail on a second and third complaint, and Nicola Re held for trial.

An important case was that of The People, etc., *vs.* Robert A. Gunn and others. This was an action brought by the Attorney-General to annul the alleged certificate of incorporation of "The United States Medical College." The organizers of that institution attempted to form a medical college under a law that did not authorize it, and claiming to be such had been issuing diplomas and conferring the degree of doctor of medicine. A similar institution in Buffalo had its charter annulled last year by a Special Term decision of the Supreme Court, from which it appealed to the General Term. Pending this appeal, and after this suit against Gunn and others was brought, a bill was passed by the Legislature, by which it was attempted to patch up these illegal institutions by a retroactive act. In the Buffalo case the court decided before the bill became a law. In the case of Gunn and others the question was yet to be decided by our courts whether this "United States Medical College" (admitting that it was never legally constituted), had been made legal by the retroactive effect claimed for the act of 1882. Of the whole number, twenty-seven, of prosecutions instituted and continued, only two had proved unsuccessful. In this work the Counsel had been efficiently aided and supported by the Board of Censors and the President, the several judicial officers before whom the cases had been heard, and last, but not least, the press of New York.

The report closed by directing attention to the fact that there was still a lack of interest in matters pertaining to the medical profession, as evidenced, for example, by the passage at the last session of the Legislature of Chapter 367 at the very closing

hours of the session, without a protest from those who ought to have represented and protected the interests of this Society, the interests of the whole profession, the interests and welfare of the whole people. This bill, couched in obscure language, in which the words "medical college" did not appear at all, and pressed forward for passage only at the last moment, had for its effect nothing more nor less than legalizing a number of unconscionable, illegitimate concerns calling themselves "medical colleges," that were yearly grinding out the Grindles, the Bryans, the Coxs, and men of that ilk, licensed to poison, maim, and kill promiscuously, and pollute the medical profession generally. By some legitimate and well-directed means the medical profession of this State should see to it that proper laws were framed and passed and enforced, and that at each session of the Legislature all bills be scrutinized by some competent authority, and thus prevent a recurrence of the fraud attempted by the act of 1882.

REPORT OF THE COMMITTEE ON HYGIENE.

The Committee on Hygiene, through its Chairman, Dr. E. G. Janeway, presented its annual report, of which the following is an abstract:

The Committee presented first the mortality statistics for the three-fourths of the present year, and for the facts upon that part of the report they were indebted to Dr. J. T. Nagle, Assistant Register of Vital Statistics. The total mortality during this period had been 30,255, an excess of 653 over the mortality for the corresponding period in 1881. The increase in population between 1875 and 1880, according to the census, was 164,691. The excess of mortality in children under five years of age, in 1882 over 1881, was 826. The mortality from small-pox in 1882 was 258; in 1881, 364; in 1880, 6; in 1879, 24; in 1878, 2; in 1877, 14; in 1876, 308; in 1875, 1,098. In the autumn of 1874, and spring of 1875, was initiated systematic vaccination by the Board of Health, and the facts recited spoke more forcibly of the value of the system than could any long dissertation. From January 1, 1882, to September 30, 1882, the number of primary vaccinations performed by the Board of Health was 14,067; re-vaccination, 77,466; total, 91,533. The report continued with statistics concerning measles, scarlet fever, diphtheria and croup, typhoid fever, typhus fever, diarrhœal diseases, pneumonia, bronchitis and phthisis. The statistics showed that there had been a marked increase in the mortality.

While it was only 653 greater than last year, it was 10,041 greater than in 1877, and 6,386 greater than in 1880. The comparison of absolute figures, however, was incorrect, and the rate of mortality should be contrasted with the increase of population. The annual increase from the year 1875 to 1880, which was made the basis of calculation by the Board of Health, was 2.98; and, according to that, the present population of the city of New York was 1,279,560. The increase of mortality had been mainly referred to under the diseases already classified, namely: scarlet fever, diphtheria, small-pox, typhus fever, pneumonia, and phthisis. There were six more deaths from diarrhœal diseases in 1880 than in 1882. These combined diseases caused a little less than one-half of the mortality, but were responsible for sixty-three per cent. of the increase. It was probable that the mortality statistics for next year, and for the remainder of this year, would be much more favorable. The diseases already mentioned exhibited, in the tables accompanying the report, periods of activity and decline. These were by no means so marked as in Philadelphia, where, in periods of four and five years, the disease trebles or quadruples its ordinary victims. This difference had been noticed in all large cities, and probably depended upon the epidemic years, so to speak, having consumed so much of available material.

It was noticed that typhus fever occurred this year the same as last year. The same measures employed last year were again used by the Board of Health with success. The changes brought about by last year's outbreak, as regards the rules concerning lodging-houses, together with a knowledge of those most likely to be affected, assisted in reducing the number of those attacked by the disease; so that the deaths numbered 63 this year, as compared with 154 last year. This winter promised to be a cold one, and if the poison should lurk somewhere, or be again introduced, the disease might spread with greater virulence. The committee therefore advised the physicians of this society to report doubtful and confirmed cases promptly to the Board of Health, should such fall under their observation.

Typhoid fever had occasioned fewer deaths than during last year, and than in 1872 and 1875. Thanks to the purity of the Croton, the application of disinfection to the discharges, the rules adopted by the Board of Health requiring privies to be emptied and disinfected at places where typhoid occurs, the disease showed, according to statistics, less absolute fatality than in the periods between 1860 and 1870. The chairman of the committee suspected that a part of the large mortality from this cause during those years was due to the confusing typhus with typhoid fever.

The figures for diphtheria showed a decrease of 411 deaths as contrasted with last year, and an increase of 504 and 794 as compared with 1880 and 1879. The committee believed this disease to be contagious to a greater extent than many physicians had entertained, and also that the poison adhered at times with tenacity to articles of clothing. When faulty sewerage existed, its intensity and spread were increased. Each case demanded isolation, disinfection of excreta and of the room occupied by the sick, as well as of the clothing, etc., etc., in the room.

Those who believed that pneumonia was only due to exposure to cold must be struck by having the mortality seventy-one greater during the first quarter of 1882 as compared with the last. They might, perhaps, derive more comfort from a comparison of the second quarter, during which 240 more deaths occurred than in last year. Bronchitis had also occasioned 87 more deaths in the first and 50 in the second quarter of this year than during the same periods in 1881. On the other hand, it could not be denied that our streets were dirtier to a marked degree last year than during the present. Any one who would study this problem carefully must be struck by the difficulty of explaining this fact, if isolated, in relation to the etiology of the disease.

With reference to the adulteration of milk, each year the Legislature had passed a bill permitting the watering of milk, which, but for the action of the Governor, would have become a law, seriously interfering with the activity of the Board of Health in that respect. The chairman of the committee had felt called upon to aid the Board of Health in preventing the passage of an act permitting the sale

of skimmed milk. The existence of such an act, no matter how carefully guarded, would open the door to great evil. Skimmed milk meant the sale of milk liable to become sour, if not already so; it meant milk from which much of the nutriment had been removed. The few persons who needed it could skim it for themselves, and find uses in the household for the cream. The committee hoped that the incoming Legislature would not dabble in this matter. If they should, it was asked that the president of the Society and the chairman of the Committee of Hygiene be empowered to act in their best discretion in aiding the Board of Health in opposing any measure which increases the liability of the sale of poor or adulterated milk in this city.

The Committee also included plumbing and tenement-house laws in the suggestion above made, with reference to legislative interference.

The Committee summed up the sanitary needs of the city under the following heads:

First.—An increased supply of Croton water. The want was appreciated by all except those who had the high-pressure service. The city needed a new aqueduct upon the following conditions, which should be placed upon a sure basis by a legislative act authorizing the construction of the work: (*a*) Every dollar spent should represent a dollar's worth of work; (*b*) a rigid inspection by competent men who should prevent bad work; (*c*) continuous and equal employment of men in the service from the inception until the completion. It was not desirable to have a large force employed about election time, as had been too frequently the case with public improvements. The responsibility for and the sole charge of this work should be vested in a man or men of such character as to insure honesty in conception, in execution, efficiency, and promptness.

Second.—A better system for the disposal of refuse.

Third.—A change in the sewers so that the present accumulation in the slips would be prevented. The proof that this accumulation is the cause of wide-spread or specific sickness was not obtainable, if it existed. The germs which the sewage might contain were as a general rule prevented, by its dilution with water and its emanations with air, from performing their specific work. The evil, however, was one which would increase with the growth of the city, and might in the future become of vital importance. That the accumulation of refuse matter was a nuisance, both from its effect upon the sense of smell and on account of the necessity for frequent dredging, was a matter easy of demonstration. The Committee suggested that the Society request through a communication to the present and incoming mayor that this subject should receive thoughtful consideration and proper action.

Fourth.—Adequate measures for dealing with districts which had become too densely populated, or in which evils existed which could not be remedied by proceedings against individual owners and houses.

Fifth.—Proper hospitals for the isolation of contagious diseases, which, from their acuteness and the risk attending them, were not adapted for transportation to Blackwell's Island or to North Brothers Island.

Sixth.—Should the new district require parks, as was proposed last year, it seemed to the Committee essential that we should advocate several rather than one large park, inaccessible to many of the future residents. A great need existed in the crowded portions of our city for such parks, and the Central Park did not meet the necessity.

THE PRACTITIONERS' SOCIETY.

Stated Meeting, October 6, 1882.

DR. JAMES B. HUNTER, PRESIDENT, IN THE CHAIR.

A PAPER was read by DR. FRANK P. KINNICUTT, entitled,

THE OIL OF WINTERGREEN AS AN EFFICIENT SALICYLATE IN ACUTE RHEUMATISM.

[The paper is published in full elsewhere in THE RECORD.]

The discussion was opened by DR. T. A. MCBRIDE, who said that he had not used the oil of wintergreen in acute rheumatism, but he had employed it in

MUSCULAR RHEUMATISM,

and also in some cases of subacute articular rheumatism. In these conditions it had answered better in his hands than any other remedy. In lumbago he had before been accustomed to use chloride of ammonium, in combination with perchloride of iron, but he had found the wintergreen would act even better. It promptly relieved acute lumbago in a day or two, and even chronic lumbago was improved in a short time. It was the best remedy, he thought, for pure rheumatic lumbago. He could endorse the remark of Dr. Kinnicutt that the drug should be continued for some time.

The method which he found best for administration of the drug was in capsules with magnesia. The dose was ten minims, usually every four hours. He had never seen any unpleasant results from its use. A dose of twenty minims taken by mistake caused no harm. A case of rheumatic headache—one of the very few he had ever seen—was relieved by the same drug.

DR. BEVERLEY ROBINSON had had no experience with wintergreen. He referred to the subject of the endocardial murmurs described by Dr. Kinnicutt. Such murmurs more often indicate anæmia or a relaxation of the heart-fibre (acute dilatation) than any endocardial disease. He thought that earlier writers had inferred endocarditis too frequently from these murmurs. It probably does not accompany acute inflammatory rheumatism so often as has been supposed.

With regard to the anæmic bruits, he was inclined to think that some were heard just as well at the apex as at the base of the heart.

DR. KINNICUTT quite agreed with the last speaker as to the pathology of the murmurs. In his opinion the murmurs heard in four of his cases were due to an anæmia, brought on by the disease or by salicylic acid. There was always some anæmia associated with acute rheumatism. He thought that hæmic murmurs were quite as frequently heard at the apex as at the base.

He had no reason to believe that the oil of wintergreen protects the heart any more than other salicylates. It is the general opinion now that the salicylates do not lessen the frequency of heart complications.

He began treatment by giving the oil in doses of ten minims every two hours. The capsules, when taken frequently, are apt to nauseate, and so he preferred giving it floating on water or milk. An advantage to be much prized was its pleasant flavor, in contrast with the nauseousness of the salicylates. Its cost was less by almost one-half also, if bought pure and not put in large mixtures.

As to its elimination, in one hour after it is taken

it can be discovered in the urine. As to its antiseptic effects, urine passed within an hour after a dose of twenty minims will remain free from decomposition for twelve days. Ordinary urine will decompose in two or three days. It would seem that the drug might be of some value in

CYSTITIS,

and there are already reports of trials in this direction.

The speaker had used the oil in a number of other diseases than rheumatism, and got the same effects as were obtained by salicylic acid. He had seen no toxic effects from it.

The urine had been examined in all his cases, but no trace of albumen was found. The statistics of results which he had given made a little better showing than those usually given for the salicylates. He knew of no element of error in his reports, though the cases were very carefully nursed and watched.

DR. H. F. WALKER said that a great deal of the oil in the market was made from petroleum, and not from the herb itself—a fact to be remembered.

DR. R. F. WEIR said he had had no experience with the oil of wintergreen—except in candy.

DR. WM. M. POLK said, with regard to the toxic effects, that a boy, nine years old, took by mistake half an ounce of the oil. It caused severe vomiting, and purging, hot skin, rapid pulse, slow respiration, and dulness of hearing. After a dangerous illness of two or three days, he recovered.

DR. GEORGE F. SHRADY reported a case of

SUCCESSFUL TRACHEOTOMY FOR DIPHTHERIA IN AN INFANT ELEVEN MONTHS OLD.

[The case is reported in full on p. 512.]

The paper being open for discussion,

DR. ROBERT F. WEIR said that he had done the operation several times in children under two years of age, but never had had any recoveries. But a very few of such recoveries were on record.

DR. WM M. POLK referred, in connection with the after-treatment of these cases, to the trouble and danger caused by

INSPISSATED MUCUS.

He had operated on a child about two years old suffering from catarrhal croup. The conditions were as favorable as possible, but the child suffered from repeated exhausting attacks of obstructive dyspnœa due to the mucus. These were relieved as completely as possible by removing the mucus, but the patient died, evidently from exhaustion.

DR. WEIR said that removal of the inner tube did not always clear out the outer tube. It was a good plan to pass something through the latter, or even to swab it out, and to let saline solutions trickle down from time to time.

DR. SHRADY said that in the case reported there was no trouble from occlusion until the seventh day, when it was necessary to take out both tubes. This was done again two days later.

DR. SHRADY had tried to keep a moist sponge over the trachea, but to no purpose.

DR. KINNICUTT had been accustomed to use an alkaline spray, and he thought it beneficial, although he recalled a case where nothing seemed to prevent the inspissation of mucus and obstruction except the use of a syringe with a catheter attached. This was passed into the trachea and the mucus sucked out.

DR. WEIR said that he had applied his mouth to the trachea once, and had gotten diphtheria. Now he used a syringe for the purpose.

DR. HUNTER had employed the long syringe used for removing secretions from the cervix. This had answered well.

DR. WEIR referred to the present tendency to do away with the trachea-tube, and mentioned the fact that in opening the trachea and drawing its sides apart there was a protrusion of the posterior wall which had a very deceptive appearance, and had even led surgeons to cut into it. It had been suggested that a portion of the tracheal wall be snipped out. This procedure was asserted to lead to stenosis, however.

DR. POLK referred to a statement that children who have been operated on for tracheotomy do not live beyond the age of sixteen or seventeen, on account of

TRACHEAL STENOSIS

and consecutive lung trouble.

DR. WEIR recalled two cases that had safely passed that age.

DR. BEVERLEY ROBINSON said that he had successfully performed tracheotomy in a child twenty-two months old.

With regard to the use of the spray, he said that he had been in the children's hospital in Paris during an epidemic of diphtheria, when tracheotomy was frequently performed. He never used a sponge, or inhalations, or spray. Subsequently, he was at the London Hospital, where all these appurtenances were employed, but he had not been able to see any difference in the results.

DR. KINNICUTT remarked that the statistics of the London Hospital were the best, as regards recovery, of any published.

AMERICAN ACADEMY OF MEDICINE.

Seventh Annual Meeting, held at Philadelphia, Pa., October 26 and 27, 1882.

TRAILL GREEN, A.M., M.D., PRESIDENT, IN THE CHAIR.

BETWEEN thirty and forty members of the Association were present, including Drs. C. R. Agnew, George M. Beard, L. Duncan Bulkeley, F. D. Lente, Henry O. Marcy, John B. Roberts, Howard Pinkney, Edward G. Bermingham, E. H. M. Sell, Benjamin Lee, R. L. Sibbett, and others.

About fifty new members from various parts of the country were elected.

DR. ELISHA HARRIS, of New York, read a paper entitled

PUBLIC HEALTH SERVICE IN ITS RELATION TO THOROUGH PREPARATION OF THE PHYSICIAN.

The speaker said: The rapid increase of public interest in health questions and local sanitary government has put to the test the best talents and educational equipment of medical men as the officers and counsellors of Boards of Health, as well as the physicians to families and individuals. The experience of numerous committees is continually demonstrating that the majority of practising physicians so fail to prepare and outfit themselves in the natural sciences, in habits of accurate and studious observation and medical logic, and in mastering the stores of knowledge, that they are not adequately educated for the highest duties of public sanitary service.

It is creditable to the best of our local medical officers and others, who are called to advise in communities for the prevention and control of disease, that they faithfully examine their own stores of scientific and professional knowledge in various branches and make use of its resources, and it is creditable to local and State boards of health that the best of them require and encourage the uses of such knowledge, and are also found aiding its increase and development.

The time and cost of the disciplinary course of study are never a waste, and the acquisition of science and of the essential habits of scientific study will become the wealth which the sanitary counsellor and health officer must need, for, as the writer remarked when inducted into the American Academy of Medicine, the faithful physician soon finds that science turns to duty, and that the toiler in science becomes the saver of men.

Much observation and experience in the wants of boards of health and of sanitary government generally leads the writer to urge the duty of thorough preparation for public health service by the most complete general preparation for undertaking the final medical curriculum. Observation warrants the conclusion that nothing less than this will lay foundation for the complete outfitting of the successful officer of public health.

NECROLOGY.

Dr. Richard J. Dunglison reported that, since the organization of the Academy, three of the Fellows had died—Dr. Lenox Hodge, James M. Shearer, and William Henry Allen—and appropriate action was taken to honor their memory by placing on the minutes a record of their literary, professional, and scientific attainments.

Dr. Benjamin Lee then read a paper, the title of which was "Advantages of a Liberal Education Preliminary to the Study of Medicine, as Illustrated in the Early History of Medicine of the Commonwealth of Pennsylvania."

The paper was largely historical and contained many facts of interest to the student of local history, as well as to medical teachers. The prominence taken in Pennsylvania by physicians who had had a preliminary educational training was illustrated.

Dr. H. O. Marcy, of Boston, read a paper on the

BEST METHODS OF TREATING OPERATIVE WOUNDS.

The paper contained the results of a study of the various antiseptics and of the value of antiseptic dressings.

Dr. Lewis H. Steiner, of Frederick City, Md., then read a paper in defence of the purposes of the American Academy of Medicine, it being a reply to a recent criticism by a college professor. Dr. Steiner's paper was admitted to be an admirable answer to an uncalled-for attack.

Dr. George M. Beard, of New York, read a paper on

MEDICAL EDUCATION AND THE MEDICAL PROFESSION IN EUROPE.

The following are some of the speaker's conclusions, reached after considerable study during several visits abroad:

First.—The best system of education in Europe, including both preliminary and medical, is found in Germany. The German physicians are the best educated physicians in the world, both in general and special training.

Second.—Next to Germany comes France, where, as in Germany, it is impossible to get a medical without a more or less thorough preliminary education. In Great Britain less preliminary education is required for medical students than in any of the great European nations. The special defects in the English system are, in addition to deficient preliminary education, these two: First, too little instruction; second, too much examination. It is estimated that only a small per cent. of the English physicians are graduates of Oxford and Cambridge.

If a student must economize in time or means, let it be in the professional and not the academical training. Lengthened terms of medical study will not alone very greatly raise the character of our profession.

Medical books, especially recent cyclopædias and monographs that are not needed by medical students, have a much smaller sale and are less read in America. "Ziemssen's Cyclopædia," which in this country sold by thousands, in England only by a few hundreds. German and French monographs have comparatively a limited circulation in England as compared with this country.

The Staats Examen (state examination) is one of the glories of Germany. Its chief temptation is to be just.

Whence comes now this enormous and towering superiority of Germany in medical education that draws unto itself all nations from afar?

First of all, the Germans are thinkers, philosophers, men of abstract ideas, with inherited genius for theory and for language. In Germany nothing counts but originality. Unless a man say something or do something different from what has been said or done before, he may as well be silent and quiet.

Germany is a great medical centre, because it is a great thought centre.

The defects of Germany are mainly on the side of practical application of science and philosophy to daily wants. In medicine the special great defect is in the treatment of disease; the Germans are nontherapeutists.

The sceptre of science and ideas first appeared in Italy, thence passed to England, then to France, and from France to Germany, and from Germany is destined to pass, partly in the Germans themselves, to our own country.

In comparing the psychology of races and nations Mr. Arnold finds the English wanting in lucidity—another phrase for abounding in timidity.

The social state of the profession in Europe is a reflex and reward of its education and character. The profession as a profession has slight honor, the position of its individual members come from individual character despite the calling.

The practical applications of this inquiry to the future of medical education and the medical profession in this country are these:

First.—In every way and at all times encourage young men, aiming for medicine, to acquire university education in the very best of our universities.

Years since, when I was a student of medicine, I prepared statistics comparing the three professions in regard to preliminary education; these were, I believe, the first statistics on this subject that were published in this country. They appeared in the *New York Medical Times* and the *Yale College Courant*. By these statistics, out of every ten clergymen of every denomination seven were college graduates; the proportion being less with the Methodists than in any other denomination. Out of ten lawyers five were

college graduates. Out of ten physicians one was a college graduate. There is at present, I judge, some improvement, at least in the Eastern part of the country, in the preliminary education of physicians.

Second.—Encourage young men to study and travel in Germany.

Outside of a small circle of German-taught experts the medical literature and the medical practice of England is from five to fifteen years behind Germany and America.

Third.—Encourage young men to do original creative pioneering, both in medical philosophy and medical experiments.

America within two decades has pushed forward, largely under German inspiration and encouragement, at least a century.

At the evening session the members listened to the

ANNUAL ADDRESS

by the President, Traill Green, A.M., M.D., LL.D., of Easton, Pa. After some retrospective remarks he said: Early in our work we showed that there was a decided belief in the mind of the profession that a better preliminary education was needed. Every youth, previous to his having been engaged in a course of medical studies, should be properly qualified by a suitable preliminary education in classical and mathematical learning. One of the greatest obstacles to the improvement of medical education in this country is the deficiency of sufficient preliminary education in those who enter the profession. It is well known that but a very small proportion have had such previous training as is absolutely necessary in order to begin with advantage the study of a science. Many have barely had the common education of our public schools, and some even this in an imperfect manner. Such men have not yet learned how to learn, and yet they start at precisely the same point, and are required to go through the same course of study as those who have undergone the discipline of a college education. In our utilitarian age the study of the classics is discouraged, because they do not obviously tend to increase the amount of "daily bread" in any given community. That they conduce to mental vigor, and prepare the mind for professional pursuits, and lead to those refinements of thought and delicacies in sentiment and action, so essential to the physician, is not a matter of sufficient importance to counterbalance the loss of time expended in their pursuit. The education of physicians has not kept pace with that of theologians, or even lawyers, and our profession has so far lost caste as scarcely to deserve to rank among the learned.

Referring to the

PROGRESS OF THE ACADEMY,

he said: Our society has made constant advance. From year to year we have associated with us in the Academy distinguished practitioners and eminent teachers—men who are moved by love to their profession to carry on this reform—men who are not disposed to retrace their steps. Abundant evidence can be furnished to show that the Academy occupies a position which is approved as the only ground on which we can hope for progress as a profession.

In 1876, the year of our organization, we believe the medical school of Harvard was the only school in the country which required a preliminary examination of intending medical students; now there are thirteen colleges which require the diplomas of a literary institution as a preliminary examination—one of the thirteen is not a regular school.

It would be well for the profession and for the people if none were accepted as students of medicine who had not graduated from a reputable college, or at least from a good high school.

There should be a thorough preliminary examination before a board of examiners prior to matriculation, or the student should be required to possess the diploma of A.B. It is well known that the proportion of the graduates of medical schools who pass the army board is one-fourth of the number who apply.

We think it is safe to say that since the organization of the Academy there have been such advances made in public and professional sentiment as encourage all who are interested in the progress desired. May it be our purpose so to impress the minds of young men who are looking to the medical profession as the field of their labor, that their experience may be that of cultured scholars and skilful physicians, whose lives may be useful and adorned by the liberal culture to which we invite them.

SECOND DAY'S SESSION.

After various reports, the following officers were elected for the ensuing year: *President*—Dr. Henry O. Marcy, Massachusetts; *Vice-Presidents*—Drs. George M. Beard, New York; William Elmer, Bridgeton, N. J.; Cornelius R. Agnew, New York; Thomas M. Drysdale, Philadelphia; *Secretary and Treasurer*—Dr. R. J. Dunglison, Philadelphia; *Assistant Secretary*—Dr. Charles McIntire, Jr., Easton, Pa. Drs. James M. Barton and Thomas B. Reed, of Philadelphia, were elected Fellows of the Academy. Drs. Henry Frazer Campbell, of Georgia, and Austin Flint, Sr., of New York, were elected to honorary membership.

DR. NATHAN ALLEN, of Lowell, Mass., read a paper on

THE INFLUENCE OF MEDICAL MEN.

Dr. Allen showed how earnestly medical men were now striving to investigate the causes of disease. They ought to follow up this branch of work. They could prevent by careful education, training, and watching what could never be cured with drugs. The influence of medical men should be exerted in this direction now.

DR. R. L. SIBBETT, of Carlisle, Pa., read a paper on the

PERCENTAGE OF COLLEGE-BRED MEN IN THE MEDICAL PROFESSION.

The reader had collected a very large number of statistics on this subject.

Among the 222 members of nine County Medical Societies, in New Jersey (6) and Pennsylvania (3), the per cent. of A.B.'s was 12.6; the per cent. of those having had no college training at all was 80.2.

Among the 58 American colleges he had collected records of graduates extending back in many cases to 1820 or 1825. The total number of graduates was 38,054. Of these, 9.2 per cent. studied medicine; 21 per cent. theology; 19.7 per cent. law. Some of the figures are as follows:

No.	Name of College.	Classes.	Whole No.	Medicine.		Theology.		Law.		Remarks.
				No.	Per ct.	No.	Per ct.	No.	Per ct.	
1	Harvard	1636-75	3,913	449	11.5	349	9.0	537	13.7	Law LL.B.'s only.
2	Yale	1836-75	4,575	398	8.7	1,012	22.1	474	12.3	LL.B.'s only.
3	Brown	1826-75	1,476	112	7.6	460	31.2	73	5.0	LL.B.'s only.
4	Bowdoin	1826-75	1,489	155	10.4	294	20.0	...	...	
5	Amherst	1822-75	2,168	179	8.2	923	42.6	293	13.5	
6	University of Vermont	1836-71	665	43	6.5	149	22.4	323	48.6	
7	Tufts	1857-80	254	19	7.5	30	11.8	...	...	
8	Williams	1836-75	1,513	168	9.2	556	30.7	430	23.7	
9	Union	1836-67	3,148	338	10.6	711	22.3	963	30.3	
10	University of City N. Y.	1853-78	599	65	10.9	47	8.0	148	24.7	
11	University of Rochester	1851-78	638	37	5.8	216	33.7	126	20.0	
12	St. Francis Xavier (N. Y.)	1855-77	270	15	5.5	101	37.4	41	15.2	

Two tables compiled from Reports of the Commissioners of Education show the comparative proportions of college-bred men in medicine, law, and theology.

TABLE I.

Professional Schools.	Report for 1879.		Report for 1880.	
	No. Reported.	Per ct. of those who have a degree in Arts and Science.	No. Reported.	Per ct. of those who have a degree in Arts and Science.
Medicine	9,522	8.2	9,876	7.9
Theology	4,362	30.6	5,093	26.4
Law	3,018	25.2	3,134	24.1

Ratio in Table II	1	3	2.15	1	3.1	1.9

In a discussion on

REGISTRATION OF PHYSICIANS,

Dr. Sibbett said that Philadelphia was the home of quackery, and the city of Philadelphia had done a great deal to disgrace them. Over six thousand physicians have registered, eight hundred and thirty-eight without diplomas. He then read a supplement to the registration act to be passed by the Legislature in case of the establishment of a State Board of Health. It gives the Board of Health the power of receiving the registration of all practitioners of medicine and surgery.

DR. CORNELIUS R. AGNEW, of New York, said there was some discouragement in his State with regard to laws for the prevention of irregular practice.

The Society adjourned to meet in New York in September, 1883.

Correspondence.

THE ELECTRIC BATH.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: In an editorial article of your issue of October 7, 1882, headed "The Electric Bath," I find the following words: "What is needed, however, is further careful clinical records which shall tell the failures, as well as successes, from this treatment. The former, we fear, as in electro-therapeutics generally, will not be rare." Apparently in response to your remarks, Dr. Hutchinson, of Providence, sends you a communication, which you publish in your issue of October 21st. His opinion of the bath does not appear to be the most exalted. He candidly admits, however, that "it is quite possible that some details of operating may have been neglected which longer perseverance would have taught." Now, while I hold with you that failures are not rare, I insist that, cases being chosen where proper indications exist, this treatment will compare more than favorably with any and every other non-specific remedy. The chief difficulties encountered by Dr. Hutchinson were: (1) *Frequent systemic depression following immersion of the entire body in water for, say, fifteen minutes, from which enfeebled persons would sometimes not rally for hours.* With respect hereto I will simply say that an ordinary warm bath will in such persons be followed by similar results, and that therefore the treatment is, for the very reason stated, contraindicated in such cases. (2) *The fatigue from completely undressing and dressing was often considerable, and often objected to.* I can scarcely look upon this as a valid objection. The same would apply, with equal force, to any and every other kind of baths. (3) *A sensation of chilliness is common, followed by a stroke of cold.* This is a difficulty I myself experienced in the beginning, but soon learned to overcome. It is due to the lying perfectly still for from ten to twenty minutes in a medium that is of considerably lower temperature than the human body. When persons take an ordinary bath, they are, as a rule, constantly on the move, washing themselves, etc. Were they to lie still for fifteen minutes in a bath of 80° F. (the temperature used by Dr. Hutchinson), the results would be such as the doctor obtained. After a brief experience I had the bath-water prepared of a temperature of 92° F.—a few degrees more or less in in-

dividual cases. I also had the patient stir about some in the tub for about a minute before leaving it, and finally applied a more or less cool douche before submitting the patient to the drying process. Then a good rubbing down with a moderately coarse towel, and chilliness was a thing of the rarest occurrence.

There were administered from October, 1873, to April, 1878, either by me or under my immediate supervision about four thousand electric baths, whereof 3,311 are recorded. In local electrical treatment my experience has been still larger. I have therefore had ample opportunities to make comparisons and draw deductions, and can conscientiously say that, in my estimation at least, there is no one other particular method of applying either the galvanic or faradic current that has so wide a range of application or so few therapeutic failures to record as the electric bath. Failures that have their cause in imperfect administration should not, in justice, be admitted to the statistics of any therapeutic plan or method.

Respectfully yours,

GEORGE M. SCHWEIG, M.D.

315 EAST FIFTY-EIGHTH STREET, NEW YORK.

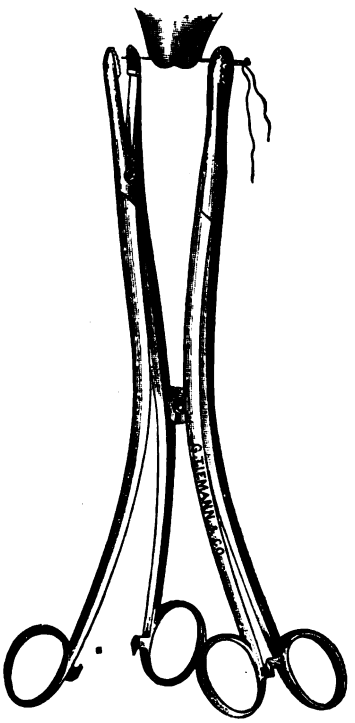
New Instruments.

COMBINED NEEDLE-FORCEPS.

BY C. A. VON RAMDOHR, M.D.,

INSTRUCTOR IN GYNECOLOGY AND OPERATIVE MIDWIFERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

IN operating for lacerated cervix a great deal of time is occupied in passing the sutures. Usually the



needle is first passed through one lip, extracted, introduced into the other one, and extracted again. The reason for this manœuvre is that it is the harder to catch the point of the needle with the extracting forceps the more it is imbedded in the surrounding tissues; and in passing the needle through both lips at the same time, it will always leave the point more or less deeply imbedded.

Any simple contrivance enabling the operator to pass a needle through both lips at the same time, and extracting it without difficulty, thereby shortening the time of the operation, is well worthy of consideration.

The above combined needle-forceps answers such a purpose. It consists of a pair of needle-forceps which may be united or separated by a pivot and notch lock at their middle.

The *modus operandi* is as follows: A straight needle (Pallen's trocar, pointed by preference, longer or shorter according to the thickness of the denuded cervix) is clasped at a right angle in the right-hand (pivot) forceps. It is pushed through both lips, then the open left-hand forceps (notch) is hooked on the pivot and the open branches are pressed against the cervix until the point of the needle lies, as it always must lie according to the construction of the forceps, between the branches. The left-hand forceps is then closed and the right one opened and withdrawn, and the point of the needle grasped by the left forceps is extracted.

In this way I have been able to pass four sutures in a unilateral laceration inside of four minutes, certainly not very slow time.

The instrument is manufactured under the above name by Messrs. George Tiemann & Co., of 67 Chatham Street.

105 SEVENTH STREET.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from October 21, 1882, *to October* 28, 1882.

TURRILL, HENRY S., Captain and Assistant Surgeon. Assigned to duty at Fort Omaha, Neb. S. O. 112, par. 3, Department of the Platte, October 23, 1882.

WYETH, M. C., First Lieutenant and Assistant Surgeon. Will be relieved from duty at Fort Meade, D. T., upon his return from detached service and will proceed to Fort Yates, D. T., and report to the Commanding Officer of that post for duty. S. O. 172, Department of Dakota, October 19, 1882.

KANE, JOHN J., Assistant Surgeon. Leave of absence granted October 9, 1882, Department of the Missouri, is extended two months. S. O. 247, par. 3, A. G. O., October 23, 1882.

BANISTER, JOHN M., First Lieutenant and Assistant Surgeon. The leave of absence granted by par. 5, S. O. 203, Department of the Missouri, October 10, 1882, is extended one month. S. O. 113, par. 2, Military Division of the Missouri, October 23, 1882.

WILSON, GEORGE F., Assistant Surgeon. Is relieved from duty at Vancouver Barracks, W. T., and assigned to duty at Fort Townsend, W. T. S. O. 148, par. 1, Department of the Columbia, October 6, 1882.

OWEN, WM. O., JR., Assistant Surgeon. Is relieved from duty at Fort Townsend, W. T., and assigned to duty at Vancouver Barracks, W. T. S. O. 148, par. 1, Department of the Columbia, October 6, 1882.

BUSHNELL, GEORGE E., First Lieutenant and Assistant Surgeon. Extension of one month's leave of absence is revoked. S. O. 247, par. 2, A. G. O., October 23, 1882.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending October 28, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Oct. 21, 1882.	0	44	33	3	9	40	0	0
Oct. 28, 1882.	0	31	20	3	9	42	1*	0

* This man was picked up in the street. Came from Cornwall, N. Y., W. S. R. R.

THE YELLOW FEVER.—A very remarkable decrease in the number of yellow fever cases at Pensacola, Fla., was reported on October 29th. The number was only nine, with one death. On October 30th the number was nineteen. It is hoped that the force of the epidemic is spent.

Official reports from Pensacola have been received, showing that 2,079 cases of yellow fever and 172 deaths occurred up to and including October 25th.

At Brownsville, Tex., there are 26 cases and no deaths reported for the week ended October 28th, making the total number of cases during the prevalence of the epidemic, 1,977, with 114 deaths. The epidemic is considered practically at an end in this place.

DR. EZRA B. BENNETT, who died at Danbury, Conn., on October 27th, was one of the oldest physicians in Connecticut, having been in active practice for nearly fifty-five years. During his whole career he had been especially interested in surgery. He was the pioneer in Connecticut in operating for ovarian tumor, vesico-vaginal fistula, and club-foot.

DR. EDMUND GRINDAL RAWSON, an old and highly respected physician, died last week at his residence, in this city, at the age of seventy-eight.

THE LATE DR. JAMES B. REYNOLDS.—At the stated meeting of the New York Pathological Society, held October 25, 1882, the committee appointed to prepare resolutions on the death of Dr. James B. Reynolds made the following report:

"The Pathological Society of New York, having heard with unfeigned regret of the death of Dr. James B. Reynolds, for twenty-four years one of its most valued members, directs this minute to be entered upon its records:

"In the death of Dr. Reynolds we recognize the loss of one who was endeared to the profession by his courteous deportment, his high professional attainments, and the zeal which he displayed in the cause of medical education and progress.

"By his clinics in pædiatrics, which were given weekly as long as his health permitted, he supplied a want long felt in the curriculum of medical teaching, and the loss of instruction given by him in this important branch will be keenly felt by students and practitioners.

"The Society extends to the bereaved family of Dr. Reynolds the assurance of its profound sympathy, and directs this notice to be published in the medical journals of New York.

"CHAS. C. LEE,
"J. L. SMITH,
"J. J. HULL,
} Committee."

INVESTIGATING AN ASYLUM.—The Grand Jury has begun an investigation of the management of the Lunatic Asylum on Ward's Island. In view of the number of persons recently pronounced sane and released from the asylum, it was decided to investigate the institution, and especially the case of William J. Hamilton, who was released a short time ago, after having been incarcerated for six years. Hamilton states that he was sent to the asylum after having been arrested for breaking a pane of glass, and was perfectly sane.

MURDER OF A PHYSICIAN.—Dr. Edward Evans, a young physician of Nicholasville, Ky., was shot and killed on October 26th, by a young lawyer, in a dispute over a fee.

WARM BLOOD BATHS.—Among the modern novelties of medical practice, I noticed, a few days ago, an advertisement, in the Rue de Flandre, of warm blood baths, after a new patented system, in the immediate vicinity of the abattoir. From the wording of the advertisement I infer that hereafter there will be "no more anæmia, no more paralysis, gout, rheumatism, chest affections, or rickets." The blood is said to be perfectly liquid, being defibrinated and preserved at the natural temperature. — *Cor. of College and Clinical Record.*

UNION OF WOMEN.—An organization, called the Union of Women of France, is in existence, having for its object the aid of the wounded in time of war, and of those who have been injured by public disasters. In the annual report of this association, recently presented at a general reunion, the services rendered by this useful body in Algiers, Tunis, Boulogne, and other places, were alluded to. Practical courses have been organized for the pupils of the Union.

A QUARANTINE QUARREL.—The Southern health authorities do not get along very amicably. The State Health Officer of Texas announced to the President of the Louisiana Board of Health that, owing to continuance of yellow fever, the Governor would extend the quarantine until cold weather set in. As Louisiana intended to raise its quarantine November 1st, Texas would, after that date, quarantine against New Orleans.

To this the President of the Louisiana Board of Health replied sharply, intimating that the Governor of Texas did not understand his business, and that there could be no danger from yellow fever after November 1st, with quarantine raised.

BAD SHOEING AMONG THE POOR.—Every one has noticed how frequent deformities of the feet and toes are among the poor. That this is due to bad shoes, and not tight shoes, is apparent.

Some light upon this matter was recently given at the Geneva Hygienic Congress by Colonel Ziegler,

Chief-Surgeon of the Swiss Army. He read a paper on the evil effects of badly made shoes, with special reference to hygiene and the marching powers of soldiers. Colonel Ziegler mentioned that the Swiss examining surgeons are compelled to reject every year eight hundred recruits—the strength of a battalion—for malformation of the feet resulting from badly fitting shoes. The foot is in reality a bow, so elastic that at every step it contracts and expands, lengthens and shortens, and a line drawn through the centre of the great toe intersects the heel. But shoemakers, who are generally utterly ignorant of the anatomy of the foot, do not give room enough for the lateral extension of the great toe. They crib, cabin, and confine it until it is forced against the other toes. Hence arise frequent inflammations of the great toe, corns, ulcerations, and sometimes veritable articular inflammation. Another evil, which Colonel Ziegler ascribes in great measure to bad shoeing, is flat-footedness, whereby the arch is converted into a straight line, and prolonged walking and marching rendered impossible. Another cause of this defect is the habit of carrying heavy weights at an early age; but in most instances, Colonel Ziegler contends, perfect shoes would restore the foot to its normal condition. The first obstacle to a reform in the shape of shoes lies in the fact that it would involve a great expense in the shape of new lasts, an expense that shoemakers are naturally loth to incur. Fashion has also its lasts, and shoemakers consider themselves bound to conform to the prevailing mode. A test of a perfect pair of shoes is that, when placed together, they should touch only at the toes and the heels; the soles should follow the sinuosities of the feet, and to give room for their expansion should exceed them in length by fifteen to twenty millimetres.

The Chemical Composition of the Milk of Cows Fed on Distillery Refuse.—Dr. Ellis, at the last meeting of the Canadian Medical Association, read a paper upon this subject. He had made an analysis of the milk of cows fed with different kinds of food. The mean of the solids in the milk of distillery cows was 14.64; of other cows 11.82. The amount of fat in distillery cows' milk was greater than in the milk of others, the minimum of the former being equal to the average of the latter. The casein, sugar, and ash ingredients were much the same in both. The principal difference was the greater amount of fat in the milk of distillery cows. The distillery refuse when examined was found to consist of grain, with the sugar and saccharine matter removed. The fat and albumen remained, together with a small quantity of alcohol, as small as distillers can make it. He could not say whether the use of this food produced any morbid condition in cows.

An Iron Bolt Removed from the Rectum.—Dr. W. W. Horton, of Unionville, Conn., recently removed from the rectum of an imbecile and dumb male patient a bolt fully eight inches long, and with a flanged head three-quarters of an inch in diameter. The man was about forty years of age. The bolt had been in the rectum about nine days, and though the patient knew evidently that the piece of iron, which he himself had probably introduced, was the cause of his trouble, he could not make this understood by others. The threaded end of the bolt, which was either in or had passed through the sigmoid flexure, could be felt from without, over the great sacro-sciatic foramen, and had been considered by the man's friends to be a hernia. A truss had been improvised and placed over this.

Dr. Horton, upon being called, explored the rectum and discovered the head of the bolt. Passing an oiled tape over this, he made traction with one hand, while with the inserted fingers of the other he gave a rotary motion to the foreign body, and in this way, after the expenditure of considerable force, succeeded in working it back into the world. The man had been able to evacuate his bowels regularly, and to this undoubtedly is due the fact that no serious symptoms of inflammation supervened. It seems remarkable, from the roughness of the bolt, and the considerable pressure of the pad upon the supposed hernial tumor, that a perforation did not occur.

The Author of the Zymotic Theory of Disease.—In Sir John Pringle's work on "Diseases of the Army," which is now about one hundred and forty years old, the idea was most distinctly enunciated that disease-germs of certain classes of disease introduced themselves into the blood, and produced a fermentation of the blood, which was the cause of a particular type of disease. Sir John Pringle gave further the results of some observations which showed that he believed in the convertibility of certain forms of zymotic disease to other forms—diseases which they were accustomed to regard as of a different type.

The Sunflower Again.—We referred, some time ago, to the medical uses of the sunflower. A writer in a London journal still further discourses upon the value of this interesting plant. He says: "There would, indeed, appear to be but few purposes to which the sunflower cannot be turned with advantage to mankind. Scientifically dealt with, it will supply us alike with our morning roll and our evening cigar. It is equally susceptible of conversion into a cake of soap, surpassingly emollient, or into a rich and lustrous silk dress. As oil it may be consumed no less freely in the salad-bowl than in the table-lamp. Cattle will fatten sooner on sunflower-cake than upon linseed-cake. The little busy bee improves each shining hour more profitably in connection with the girasol than with any other opening flower. In fact, so numerous are its excellences and so beneficial its virtues that the sunflower may with great propriety be designated the friend of man.

"The Improvement of Climate at a Slight Elevation," was the title of a paper read by the Hon. A. F. Russell at a recent meeting of the English Sanitary Congress at Newcastle.

Mr. Russell would upset the long-received view that temperature regularly decreases with elevation from the ground, and, as the result of a series of experiments, concludes that at a moderate height there is constantly experienced an equable and healthful zone of atmosphere peculiarly adapted for invalids and delicate persons, while it is eminently more suited for all individuals than the air immediately above the surface. Mr. Russell even goes so far as to assert that the upper chambers of all houses are favorably situated in this respect, and that in towns such an altitude offers advantages in respect to atmosphere not inferior to those obtainable at seaside watering-places, the air being drier and more equable.

Mr. Russell's statements will hardly apply in this city. The air of upper stories is doubtless freer from dust and breezier, but that it is much drier or more equable may be doubted.

That the New York Tenement-Houses are still the source of much disease and crime is shown in the recent annual report of the N. Y. Association for Improving the Condition of the Poor. The special object of the Association has been to secure tenement-house reform, and so procure healthy houses for the poor. The abolition in great measure of the Hunter's Point nuisances has resulted in an improved condition of affairs in the tenement-houses on the East side. For the Health Department they have not quite so much to say in praise, though it is acknowledged that while many defects in drainage, ventilation, etc., have been remedied, many culpable violators of the law have not been compelled to comply with its terms. During the past year 1,304 tenement-houses have been inspected, and the condition of 443 of these has been remedied in whole or in part.

The Conversazione given to the International Medical Congress at London last year, cost the city $10,495.

Divorced on Account of a Persistent Hiccough.—Dr. Pollak, at a recent meeting of the St. Louis Medical Society related a case of persistent hiccough which lasted for twenty years and resisted all treatment. The patient was a lady, and her husband was compelled to get a divorce from her. He could not sleep with her, and it was most unpleasant. The woman was apparently strong and healthy.

Friction Sounds from Dilatation of the Heart.—M. Lepine has found friction sounds in patients having no lesion of the pericardium. Upon post-mortem examination, dilatation of the heart was found.

M. Siredey has lately observed a complication of typhoid fever, not alluded to in the books in general use. It is periostitis, generally of the tibia, appearing during convalescence. — *St. Louis Medical and Surgical Journal.*

Lunacy Commissions. — The November issue of *The Century* has an interesting editorial in which the need of a responsible Board of Lunacy Commissioners is pointed out.

Dr. D. A. Cleaveland, of Middletown, argues ably to the same effect in the *N. E. Medical Monthly* for October.

The Milk Crusade.—In the quarter ending September 30, 1882, the City Board of Health has made 5,011 special examinations, 73 analyses, and has seized 9,560 quarts of milk unfit to sell.

Mr. George E. Waring, Jr., has been appointed member of the National Board of Health, vice Dr. Charles F. Folsom, resigned.

The Presbyterian Hospital held its fourteenth anniversary on October 26th. According to the report for the past year, 1,202 patients were treated in the hospital, the number being largely in excess of previous years. Of this number 87½ per cent. were free patients. Six hundred persons received assistance through the ambulance ser ice, and the capabilities of the institution were at times taxed to their utmost extent for want of room.

Columbus Medical College. — The discussion about this college has been kept up very actively in our various exchanges. There seems to be but one opinion as to the character of the college—that it was but little better than Buchanan's diploma mill.

Small-Pox and Scarlet Fever are prevailing extensively in Cincinnati. Much complaint is made against the city government, "the filthy streets and reeking gutters."

A New Anatomy Law in Maryland. — Up to within a few months Maryland has been among those American States whose laws were silent regarding the practical study of anatomy and the desecration of graves. A law has recently been passed, however, which authorizes the use of bodies requiring burial at the public expense, except in cases where the deceased have requested burial, or are strangers or travellers, "for the advancement of medical science" *within the State*, and provides that officials of Baltimore city and county shall permit any physician or surgeon of the same city or county to take such bodies, upon his making a request for them within forty-eight hours after death.

Dr. J. J. Woodward, U. S. Army, has returned from Europe, and the profession will regret to learn that his health has not been improved by his trip.

Woman's Work and Standing in the University of London.—In the mathematical honor list the names of women do not appear, nor in that for zoology. In science generally the female students can hardly be said to be pre-eminently successful, while in modern languages other than English they have secured far more than the average proportion of the honors due to their numbers.

The Johns Hopkins Medical School.—It is announced with some show of authority that the trustees of the Johns Hopkins Hospital design opening that institution, and the medical school to be established in connection with it, in the fall of 1883. This announcement is somewhat surprising, says the *Maryland Medical Journal*, in view of the repeated statement that the hospital would not be ready for inauguration for five or six years at least. The authorities, however, have decided not to wait for the full completion of the extensive buildings, but to commence work as soon as the accommodations already provided can be rendered available. These consist of an administrative building, a male and a female pay ward, a kitchen, a nurses' home, an apothecary building, octagonal wards, an isolating ward, an autopsy building, a free dispensary, an amphitheatre, and a laundry. These, with the exception of the last, are already under roof, but no inside work has yet been done upon them. About $1,300,000, including cost of ground, has so far been spent on the buildings, which, when completed, will have a capacity for four hundred patients. A site for a building for the medical school has been purchased in the vicinity of the hospital.

Frequency of Rheumatism.—Among adult civilians the proportion of persons having rheumatism (chronic, muscular, or articular) is about one per cent., as shown by the U. S. Provost-Marshal's reports.

Our esteemed contemporary, *The Louisville Medical News*, is showing some of its old-time piquancy under its new editorship. It denies the versatility which we were disposed to attribute to the teachers in its local schools.

The New Medical College at Chicago, the College of Physicians and Surgeons, opens with a large class. Its fees are said to be only about one-half as great as those of the other two regular colleges, to which fact is imputed some part of its prosperity.

Our excellent contemporary, *The Sanitarian*, is to be published weekly after the first of January next.

Crural Neuralgia among Dentists.—Crural neuralgia is said to be somewhat frequent among dentists, owing to the position they have to assume during their work.

An Improbable Interview with Mrs. Langtry.—It is rumored that Mrs. Langtry, the English beauty, has been interviewed by a medical reporter. She said that she was not a homœopathist, as had been stated; she believed in the New York code, however. Her impressions of American medical men had so far been very favorable, and confirmed previous anticipations formed by a constant reading of The Medical Record. The branch of medicine in which she had been chiefly interested was dermatology; in this America easily led the world, and she was sorry she could not have got over in time for the Newport meeting of the Association. She attributed the beauty of her complexion to a constant study of American dermatological literature.

Mrs. Langtry was hardly prepared to give her opinion of Post-Graduate Schools, but thought they were very nice. She would send tickets, she said, to any doctors not connected with some medical school—it seemed such a pity. The reporter told her, however, that there were none such. Mrs. Langtry preferred to take her medicines in pill form. She liked the oval-shaped, sugar-coated ones best.

Mrs. Langtry asked about our insane asylums, and strongly urged the use of the tight-fitting jacket known as the "Jersey," as a substitute for camisoles and strait-jackets.

Sweet Peace.—Two New York neurologists were recently seen to shake hands with each other in a cordial manner. It is thought now that it will not be necessary to organize a third neurological society.

Night Medical Service of Paris.—In this service there occur about five hundred midwifery cases per year. It is proposed to raise the fee for this class of cases from ten to twenty francs.

Guaiac, for the Cutting Short of Acute Tonsillitis.—Dr. Morell Mackenzie says that guaiac given early will rarely fail to cut short an acute tonsillitis. The formula is as follows:

℞. Resin guaiac ..... 70 grammes.
Gum tragacanth..... 43 "
Sacchar. alb..... 17 "
Black currant paste ... . q. s.

M. Div. in trochischi No. 350. Sig.: One every two hours.

One can also give aconite, as recommended by Ringer. If the disease is not checked, give small pellets of ice.

Nitric Acid for Chilblains.—Dr. Lapatin who had a large experience with soldiers during the Turco-Russian war, recommends nitric acid as an application in chilblains. Equal parts of dilute nitric acid and aqua menth. pip. are pencilled on the toes, at first daily, then twice a day. After three or four days a brownish scurf is formed, which is thrown off.

Decrease of Blindness in Prussia.—It is very satisfactory to note that one of humanity's afflictions is not on the increase—at least not in Prussia. In 1870 there were 22,978 blind persons in that country; in 1880 there were only 22,677. The population had meanwhile increased 10.6 per cent., so that while in 1870 there were 9.3 cases of blindness to every 10,000 inhabitants, in 1880 the ratio was only 8.3. Only about 25 per cent. of blind persons were born so. It is believed that the diminution is largely due to improvement in medical care and treatment.

Frozen People.—It has been a mooted question what would be the best way to resuscitate those frozen. Laptschinski seems to have settled the question. Of twenty animals gradually brought to in a cold room, fourteen died; of twenty introduced at once into a warm room, eight died; of twenty placed immediately in a hot bath, all recovered.

The Poison of the Borgias.—Perret makes the statement that the base of this infamous poison was oil of ergot.

Domesticity as a Cause of Insanity.—Mrs. M——, aged forty-four, mother of eight children, acute mania. The husband, when asked if he could suggest any cause for her illness, exclaimed with much animation that he could not conceive any reason. "She is a most domestic woman; is always doing something for her children, is *always* at work for us all; *never* goes out of the house, even to church on Sunday; never goes gadding about at the neighbors' houses, or talking from one to another; has been one of the best of wives and mothers, and was *always* at home." The superintendent, in commenting on this case, says: "This appreciative husband could hardly have furnished a more graphic delineation of the causes of his wife's insanity, had he understood them never so thoroughly."—*Report of Hartford Retreat for Insane.*

Sulphur and Malaria.—At a recent meeting of the Paris Academy, M. d'Abbadie called attention to some facts regarding marsh fever. Some African elephant hunters from plateaus with comparatively cool climate brave the hottest and most deleterious Ethiopian regions with impunity, which they attribute to their habit of daily fumigation of the naked body with sulphur. It is interesting to know whether sulphurous emanations, received involuntarily, have a like effect. From inquiries made by M. Fouque, it appears that in Sicily, while most of the sulphur mines are in high districts and free from malaria, a few are at a low level, where intermittent fever prevails. In the latter districts, while the population of the neighboring villages is attacked by fever in the proportion of ninety per cent., the workmen in the sulphur mines suffer much less, not more than eight or nine per cent. being attacked. Some other facts, tending to show the anti-malarial influence of sulphur, are given.

It will be a great comfort for some to know that though the bottomless pit is feverish, there can be no real malaria.

"The History of Great Epidemics as Shown in Coins and Medals," is the title of a curious work by Drs. L. Pfeiffer and C. Ruhland of Tübingen. It describes the medals commemorating great famines, floods, comets, the disappearance of yellow fever, cholera, the discovery of vaccination, etc.

Abscesses in Elephants.—Abscesses are often formed under the hard epidermis plates in the skin of the elephant. They are generally small, ranging in size from that of a pea to that of a hazelnut. Being covered by the fixed skin, they cannot readily find an opening on the surface. They are usually

discovered accidentally by the painful movements of the animal while it is being cleaned, whenever the sore spots are touched.

In several instances elephants have been known to carry, by means of their trunks, the hands of their keepers to the painful place. These abscesses are principally caused by the penetration into the skin of filth and foreign matter, such as grains of sand, slivers of wood, etc. The treatment consists simply in thinning down the epidermis until the small pus sac is opened.—*Journal of Comparative Medicine.*

PESSARY IN THE RECTUM.—Dr. H. L. Turney relates (*Nashville Journal of Medicine and Surgery*) the history of a lady patient who had been treated by a homœopath for retroverted uterus. Dr. Turney was summoned to her one night in haste and found the patient in great pain. He examined her and found a large size Hodge pessary skilfully lodged in the rectum.

THE FREQUENCY OF FLOATING KIDNEY is greater than is supposed, according to Dr. Skorczewski. Among 1,422 persons examined he found 35 subjects (32 females, 3 males). In 5 of these both kidneys were movable.

The causes are, pendulous abdomen, disappearance of circumrenal fat, atony of tissues, subsequent to febrile diseases, and the pressure of some hypertrophied abdominal viscera. In Dr. Skorczewski's cases there was very often observed coexistence of floating kidneys with malarial hypertrophy of the spleen.

A NEW REMEDY FOR SPASMS.—The *Medicinische Central-Zeitung*, of July 15, 1882, publishes the result of experiments instituted by Dr. Schiffer, of Berlin, for the purpose of determining the therapeutic value of the *extract of guachamaca*, a tree indigenous on the Apuche mountains. As a specific for all spastic conditions of the motor apparatus we so far possess, in reality, one remedy only, curare, which, however, on account of its danger, and the uncertainty of its action, as well as of the remedy itself, has mostly been used for physiological experiments alone.

Guachamaca extract, prepared from the bark of the quebracho plant, which belongs to the same class as the oleander (Nerium ol., L.), and of which latter the skin between tree and bark is also poisonous, is a remedy which, while not so dangerous in its effects, is far more reliable and uniform in its action and can besides easily be procured pure and genuine, and of always equal strength, as it is by no means rare.

Schiffer experimented with this drug, and made his observations in the clinic of Professor Frerichs. He employed the remedy in solution, in the dose of one-sixth of a grain, and by the hypodermic method, in cases of tonic and clonic spasms of the muscular system, and always with a very good effect. He noted also that, administered internally, no matter in what solution, the drug was as little absorbed by the mucous membrane of the alimentary canal as curare is.—*Philadelphia Reporter.*

PROFESSOR VIRCHOW once said in some of his lectures that of ten students to whom he would show a pathological specimen, nine could not see it.

A NEW DISEASE.—A California physician who discovered a new disease—love madness—has been experimenting with the person afflicted therewith and has produced the "love parasite," or bacillus micrococcus. This he cultivated up to the twentieth generation, and with the parasites of that generation he inoculated a number of subjects. The inoculation was invariably successful, symptoms of the disease appearing a very short time after the operation. A bachelor, aged fifty, on the first day after the inoculation had his whiskers dyed, ordered a new suit of clothes and a set of false teeth, bought a top buggy, a bottle of hair restorer, a diamond ring, and a guitar, and began reading Byron's poems. The inoculation produced symptoms of the same nature in a young lady of forty-five. She spent five dollars at a drug store for cosmetics, bought a lot of new hair and a croquet set, sang "Empty is the Cradle," sent out invitations for a party, and complained that the Chico young men do not go into society. An inoculated youth of seventeen, employed in a country store, did up a gallon of molasses in a paper-bag, and also, in a fit of absent-mindedness, put the cat in the butter-tub and threw some fresh butter out of the window. Finally, he sat in a basket of eggs while looking at a photograph of a pretty girl, and was discharged for his carelessness. The Chico doctor is still experimenting, and will soon lay the results of his observations before the medical world.

MEDICAL TROUBLES IN MAINE.—A correspondent of the *Boston Medical and Surgical Journal* writes concerning the state of medical affairs in Maine, and affirms them to be quite inharmonious. The constitution of the State Medical Society is unsatisfactory, he says, because it gives plenary power in the matter of membership and discipline to a board of five censors. It is desired, therefore, by some to reform it. The Maine General Hospital is said to have been foisted upon the State Association. The country physicians find that it attracts their paying patients, who go there to be operated upon, when they could perhaps be treated equally well at home. The advantages of the hospital are widely advertised throughout the State. The medical school of Maine is also acting in a way unsatisfactory to many. We are told that another attempt at change will be made when the Society meets again.

THE CALAMITY IN THE SEGUIN FAMILY.—On Wednesday morning the public were startled with the dreadful announcement that the lovely wife of Dr. E. C. Seguin, of this city, had, in a fit of temporary insanity, shot all of her little children—three in number—and afterward herself. She had taken them to an upper room, tied their hands behind their backs, and then, under the pretext of playing "blind man's buff," first killed the eldest, a beautiful boy of six years, then two sweet little girls, aged respectively five and four years, and evidently in an instant afterward took her own life. When found in the evening, some time after the commission of the deed, all were dead. The lady was of a most lovable disposition, had been devoted to her husband and family, and had shown no symptoms of insanity except occasional attacks of melancholia, for which she could not account, and which she bravely endeavored to overcome. Her devoted husband, with an affectionate concern for her condition, had arranged to have her accompany him on a pleasure trip the next day; but he came home in the evening to find himself suddenly deprived of his entire family. A greater calamity could not befal any one, and coming thus upon Dr. Seguin, calls forth the deepest and most heartfelt sympathy of his many friends. May he have the strength to bear this terrible affliction.

Original Lectures.

MEDICAL NEW YORK—OLD AND NEW.

AN ADDRESS DELIVERED AT THE INAUGURATION OF THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

BY D. B. ST. JOHN ROOSA, M.D., LL.D.,
NEW YORK.

THE recollection of the oldest inhabitant of Paris or London does not run back to the time when each of those cities was not a great metropolis. The traditions of these great centres are those that belong to vast populations. From time immemorial they have contained crowded streets, long lines of shops, grand cathedrals and the other attributes of great towns. New York may well claim to be a metropolis; her vast commerce and her million and more of people are sufficient to justify her claim. She is certainly a mother city now. But she is a modern metropolis. Her traditions are those of a provincial town, vying with Boston and Philadelphia and Newport for the honor of being a chief city in a frontier country. There are probably New Yorkers in this assemblage, who remember the time when the pigs ran about Broadway, and when every family that kept a carriage was known by name and by sight by the average citizen.

The rapid growth of New York offers an explanation, if not an apology, for many of the imperfections that exist in the management of public affairs. We can hardly expect of an overgrown and awkward boy the culture and understanding of a man. It is difficult for one who has seen with his own eyes the wondrous change that has converted New York into one of the centres of the world, to realize that the things and methods that were suitable for a small town, will no longer fulfil the requirements of a great city. The changes that are so marked in the commercial and social life of New York, are none the less decided in the position of that profession which, through some of its representatives, has solicited and secured your presence to-night.

New York as a town containing a few doctors, one small medical college, with a hundred medical students, offers a great contrast to the medical metropolis that we live in to-day. If the consideration of such a theme before this audience needs any apology, it may be found in the fact that much of the good health of the city and the nation may depend upon the character and wisdom of a resident profession that annually sends out five hundred or more new doctors to practise with drugs and cutting instruments.

At one time, a little before 1841, the one medical college of New York was so little known or was so obscurely situated that an aspiring student, now a distinguished professor, could not be directed to it by the gentleman to whose office he went to begin his medical studies. Yet this was the day of Mott, of Kearney Rogers, of Griscom the elder, and of Alexander H. Stevens, of Hosack and of Francis. The New York Hospital was upon Broadway, in front of Pearl Street, its grounds covered by green grass and studded with ancient trees. This hospital and not the college was the surgical and medical centre of the city.

A great change was about to come upon the existing system of medical education, but the college hardly knew it. The men at the hospital did. They knew that the learned essays, the eloquent harangues must give way to colloquial instruction in the presence of the patient. In these days the colleges have learned that medicine and surgery cannot be taught like law and theology. They are fast becoming vast dispensaries, dissecting-rooms, and laboratories. The science and practice of medicine are taught by facts and not by theories. In these quiet times in the medical New York of some fifty years ago, there was but one dispensary, and that was scarcely ever used by students. There was an occasional invitation to an operation in the small amphitheatre in the hospital. There were, however, brilliant triumphs in surgery; triumphs that made American surgery famous, and which will make doctors talk of the surgeons of those days as long as they talk of anything.

There were also excellent and wise general practitioners. They had no thermometer, but the *tactus eruditus* stood them in good stead, and they often made prognoses that we who are reliant upon instruments of precision might envy. Unambitious beyond the ambition to serve their patients, they reverently consulted the treatises of the fathers, or the essays and cases of their contemporaries across the sea.

> "Far from the madding crowd's ignoble strife
> Their sober wishes never learned to stray."

In those days a New York doctor had no idea of writing a book, perhaps not even of reporting cases in print. At the very most, he might contribute reports of his cases to one of the few journals, but if of a literary turn of mind he contented himself with editing the works of an Englishman or of a Scotchman, or perhaps he translated some French writer. Almost with bated breath did these men, some of whom are worthy to be compared with the best of our time, speak of the medical men of the old world, separated from them as they were by not only miles of sea, but more than all, by lack of opportunity for mutual intercourse, for self-instruction, such as London and Paris gave in good measure. Little did they think of the day of the Flints and Dalton, Sims and Thomas, of Emmet, Hammond, Jacobi, Hamilton and Barker and Sayre, and many others, when American text-books are on every table in trans-atlantic medical libraries, and are quoted at every lecture in European clinics.

In those times the doctors knew each other not only by name, but so well as to enjoy a joke at the expense of one another's personal characteristics. They stopped each other on the street and talked of the weather and the politics of the day. Indeed Hosack and Francis interested themselves in all the social and literary affairs of the time. At No. 1 Bond Street was a drawing-room whose Saturday evenings attracted the wits of the town, as well as those who might be temporarily in New York. That age was not all golden, however. There was opportunity for envy and cabals, for gossip and slander. The medical profession then as now was somewhat belligerent, and not always in a good cause. There was too much reliance upon foreign opinions, too little upon the great authority, the exact and intelligent study of the patient himself. While we have necessarily lost some of the restful attributes of life in a small town, the life among medical men is on the whole broader and better than it was fifty years ago. In these changes for the better New York easily takes the lead as a metropolitan city should. Even in her code of ethics she has during the last year, unlike her sister medical cities, taken a step which shows that she believes the conduct of a gentleman cannot be

defined by a set of rules. The steamship, the railway, the telegraph, and the telephone have made changes in medical as well as commercial New York. *Depau Row* is no longer up town, nor is Chambers Street the centre. All the surgical wisdom of the city is not to be found in the New York Hospital. The consulting-rooms of our physicians are now filled with patients from San Francisco as well as from Bound Brook and Newtown, and all are anxious to get away by the first afternoon or evening train. There is no longer a *rus in urbe* on Manhattan Island, since Harlem Lane has given place to St. Nicholas Avenue.

It is unfortunate for New York that the business men have been the chief ones to recognize this change in the city. They are quick to exchange their cargoes from sailing ships to steamers, to build immense warehouses, and to connect this market with the others of the world by the most expeditious means. They at least know that New York is no longer a rival of Newport. But New Yorkers have been slow to learn that their city has become an educational as well as a commercial metropolis.

Some years ago I attended a public dinner in this city, at which one of the speakers was the mayor. The dinner was given by the alumni of one of our medical schools, and the chief subject of discussion was the advantages offered by the metropolis in the way of professional study. In the mayor's speech, he expressed some surprise that New York should be thought to be anything more than a commercial town. This mayor was one who stands high among his predecessors and successors in character and intelligence. He had taken an especial interest in educational matters, and yet it was a new idea to him that New York perhaps might be, or already was, a university centre.

But it is not strange that the chief official of this city took such a view. Our public men have not been educated to take any other. In Boston, when President Eliot wants a hundred thousand dollars for Harvard College, he walks down Beacon Street, and, without pulling a door-bell, he finds the son of a Puritan who will give it. In Philadelphia, the new provost of the university calls together the best representatives of the city to aid him in the management of his great charge, and he finds everywhere sympathy and support. In Boston, no rich man can be properly buried who has not left some money to Harvard College, the Medical School, a hospital, or the Institute of Technology. In New York, half a dozen men, with money enough to endow Columbia College and the University, besides creating a thousand free beds in a hospital, die in one year and do not mention New York in their wills. It is the great stamping-ground, however, for the man who wishes to plant a new denomination in a parish already having five or six to each fifty people. Peripatetic presidents of Tuscaloosa and Oshkosh Universities wander about from one banking-house and private house to another and try to enlist the sympathies of every moneyed man in the community. And at public dinners of the academic institutions, where there are a hundred men who have acquired their professional education, and have made fame and wealth in New York, the collection-box is passed about again, till New York charities and professional schools are in despair at any recognition of their claims.

I have heard New York accused of a want of civic pride. Be this accusation just or not, she has certainly not appreciated her great position as a place for extra academic, for professional, or, as I prefer to say, for university study. For example, the University of the city, founded with a broad and comprehensive charter by men whose ideas were far ahead of their time, now that her opportunity has come, chooses to hug her feeble little college rather than lift on her strong arms the University that rightfully belongs to her. In her professional schools of law and medicine, in the addition of others, is her great work, for New York parents have long since resolved that college boys are better off in New Haven, Princeton, and Williamstown than in a vast city.

Columbia College was very loth to begin her scientific school, now one of her chief glories, and she is very slow indeed to use her enormous advantages of wealth and renown for that which is her great future. The medical school of that College contains, perhaps, twice as many students as does the academic department, and yet it remains unconnected with it except in name. The school of law also out-numbers the undergraduate department, while its fame is as wide as the limits of the nation.

New York has not kept pace with the small towns in the number of her undergraduate students, or in the reputation of her colleges, but her professional schools have been for fifty years growing in magnitude and importance.

New York now has more than two thousand medical students. Her hospitals and dispensaries have increased until they can scarcely be named off-hand. Yet the medical colleges continue to be private and proprietary institutions. Their teachers are, I believe, among the best of our country and worthy of any country. But while Boston and Philadelphia are making vast strides in improving the methods of instruction, New York is obliged, from lack of endowments, to hold on to the old plan. Those who have studied one, two, and three years sit upon the same benches, hear the same lectures, and crowd the same wards and amphitheatres. There is no matriculation examination, and, unless in exceptional cases, but one final one at the end of three years, of what is in some cases merely nominal study. Graduates in medicine, who came here for special study, so far as they heard lectures at all, heard the same that were given to undergraduates under the conditions I have described. In fact, the changes of the time have not been appreciated by the educated and wealthy people of New York. Immersed in their own affairs, untaught by those who should have taught them, so far as they have taken an interest in educational matters, it has been chiefly in public schools and colleges, while professional institutions have scarcely been observed by them. Medical men have been remiss in not educating their fellow-citizens upon these subjects. Although medical teachers have been enlarging their curriculum and increasing the number of their teachers in the colleges, the growth has been chiefly at the top and not at the foundation of the structure. No fundamental changes have as yet been made in New York medical colleges.

What relation has our present enterprise with a reform in medical instruction in our city? Certainly it has nothing to do with undergraduate reforms. However much as individuals we may be interested in such changes as shall cause a New York medical diploma to be evidence of fitness to practise, the school which we inaugurate to-night has nothing to do with this subject. Our object is not to make more doctors, but to improve those we have. We propose to make a centre in which it will be possible for a gradu-

ate in medicine to fit himself for the detection and treatment of the diseases that are not fully discussed in the studies and lectures of the ordinary course of three years in a New York medical college. It is true that the various subjects upon which our lectures and demonstrations are given are treated upon in these schools. There is a weekly lecture upon most of the subjects, besides, in the course upon medicine, surgery, obstetrics, anatomy, there are incidental allusions, more or less full, which, if availed of, give the graduate a general knowledge of what have come, rather unfortunately as it seems to me, to be called specialties. But, and it is this *but* which furnishes a reason for our existence, there is no such knowledge furnished as will enable a man to recognize and successfully treat many of the common ailments of men and women. Even a hospital training of from one to two years, which unfortunately but a small proportion of our graduates are able to secure, leaves many subjects practically untouched. Honest practitioners confess at once, with much embarrassment, their lack of knowledge, much more of experience, in many cases, and, if possible, ignore their existence when they cannot send them to men whose opportunities in these departments have been sufficient. Many others, equally honest, living in places remote from large towns, seek by means of text-books, and their knowledge of the general action of disease, to do what they can, but even these must leave much untouched. If proof of this statement is desired it is easily furnished in the crowded clinics of the medical colleges of small towns. There patients are furnished by the score or even hundreds, who await from year to year the arrival of special professors who have been chosen to supplement the regular faculty.

Many practitioners come to New York every year to acquire the practical knowledge of diseases called special, but which they find to be very general, and of which they were taught very little in their fifteen months of attendance upon lectures. What can they do? They may matriculate at any of our colleges and in the dissecting-rooms; if it be anatomical knowledge they desire to supplement, the facilities are ample and excellent. Of late years, too, the dead-houses have also done much to instruct the general practitioner. He can, besides, with some trouble of inquiry and running about, find special courses in diagnosis, where experts will furnish excellent practical teaching. If, however, he seeks in the lectures upon special subjects in the colleges that which he must acquire in a short time or not at all, he finds himself baffled and disappointed. He soon finds that these weekly lectures and demonstrations are for those who have no practice behind them, whatever may be before, for those who have the whole five months of the session at their disposal. Besides, the classes are so large that only the early and persistent men on the front benches have an opportunity to study the cases with the teacher. Even for those who find the courses they desire in the dispensaries and hospitals, the difficulties are by no means insignificant. There is no central place where they may find what they desire. This centre we hope the New York Post-Graduate Medical School may furnish. But it may be said that existing medical schools should furnish these facilities. This we fully admit. At least the corporation, which should be at the back of the teachers, should have a post-graduate as well as an undergraduate school, or the course should be lengthened so as to include it. This is the ideal medical department of a university. But ideals are not always to be obtained. Certainly this ideal is not yet to be obtained in New York. A man who quarrels with the inevitable is not wise, but he may flank a difficulty. He may not be able to get out of the wet, but he may wear a Macintosh and carry an umbrella. I think the colleges would be greatly the gainers by this enlargement of their scope. But as proprietary institutions, without an interested corporation to sustain, and without invested endowments, they believe that undergraduate instruction is all they can properly undertake. It would be easy to show that Berlin and Vienna have acquired their pre-eminence as medical centres, not by the teaching of undergraduates, but by the instruction furnished to medical men. The practitioners who have spread the fame of Helmholz and Virchow, Traube and Ludwig, Langenbeck, Arlt, Graefe, Skoda, Braun, Oppolzer, Politzer, and Gruber have been in large measure graduated physicians, who have sat at the feet of these great teachers after the fundamental studies have been finished.

A few weeks ago your speaker had the opportunity of looking over the new building of the famous school of medicine of the University of Edinburgh. Nothing can exceed the excellence and grandeur of the arrangements for the study of anatomy, physiology, and so forth, as exemplified in the new structure of this renowned and in some respects model university. My guide, one of the instructors, said to me, "What we need now in Edinburgh to attract the men who go to Germany, are better provisions for graduates. In that we are deficient. For that cause we are losing, and have lost some of our proper fame." If this be true of Edinburgh, how much more true of New York. This city of ours stands without a successful rival in the country in the opportunities she can furnish to the medical student. This statement may seem a trifle strong to our neighbors in Boston and Philadelphia. I will, however, leave the students who have seen the advantages offered respectively by these cities to justify my statement. New York is now, unless some great disaster overtake her, destined to continue to be the commercial metropolis of the Western world. If common wisdom direct the beneficence of her citizens, if her civic pride can be aroused, in spite of Baltimore and the Johns Hopkins, New York will be the university centre of America. In devotion to this chief city of my native Empire State, I have felt for years that it was my duty, which nothing can deter me from, to cry aloud as to the importance of the effort which shall one day accomplish this end.

> "May I never
> To this good purpose that so fairly shows
> Dream of impediment."

The elements which are yet to be fused to this form are all about us. That our school may be one of the agencies in continuing and securing our intellectual pre-eminence is the earnest desire of those whom I have the honor to represent. We cannot believe that it will always continue in its present detached condition. Our aspirations are far beyond those of a school whose affairs are controlled by those who should be busied chiefly with teaching. It will yet be a part of a great university.

Circumstances over which we have no control have compelled us to add another unendowed school of medicine to those that now exist. But we have no idea that it will remain so. When we have demonstrated our usefulness and the necessity,

we shall seek an endowment at the hands of our fellow-citizens. We believe that we shall see the day when New York will first nourish her own children before she is generous to others. We also believe that the governing bodies of our universities will yet make them so in fact as well as name, that medical colleges will become an actual part of them, and that then the post-graduate medical school will have its appropriate place in the third and fourth years of study. Not division, not separation, but unity in university instruction is what we seek, and what we believe our institution will ultimately promote. We shall belittle our power and fail to exert our proper influence if we do not all, merchants, lawyers, clergymen, and physicians, soon recognize the fact that not even Prague in the thirteenth century, when thousands of students came to her halls on the banks of the Moldau, had a better claim to be a university town than New York has in the nineteenth.

London has not been wise in dividing her medical profession into a large number of medical schools. Some of her influence has been lost on this very account, and I speak, not from the superficial opinion of Americans who have visited and studied in the metropolis, but I give the deliberate judgment of one of her most successful and eminent practitioners who has lately visited New York.

Paris, Berlin, and Vienna have obtained their enormous power over medical action and thought, in part, at least, because the faculties of their great universities have comprehended nearly all the men in the cities who have been competent and willing to teach medicine. There has been concentration of effort at one centre. That consummation I earnestly hope for New York.

Within the memory of many of us, Italy, dissevered and separated into petty kingdoms, has been united by the patient genius of Cavour, and now she is a united and powerful country.

Germany, also, by "blood and iron," has again become a nation, and her power in the councils of the world greatly increased.

I trust there will arise for our beloved city of New York, not a Cavour or Bismarck, but such a wise understanding on the part of her citizens that they shall with one accord strive for a unity of plan and action which shall unite all her scattered, unknown, and undeveloped energies, and cause her to be everywhere recognized and resorted to as the great universtiy centre of our side of the Atlantic.

SOLUBILITY OF OFFICINAL MORPHIA SALTS IN WATER AND ALCOHOL.—Some recent experiments by J. U. Lloyd (*New Remedies*) show that some of the statements of our text-books in regard to the solubility of morphia salts require modification. The solubilities, as determined by Mr. Lloyd, are as follows: Acetate of morphia: one part requires of water at 60° F., 11.7 parts; at 212° F., 1.34 part; of alcohol, sp. gr. .820, at 60° F., 68.3; at the boiling point, 13.3. Hydrochlorate of morphia: one part requires of water at 60° F., 23.4 parts; at 212° F., 0.51 part; of alcohol at 60° F., 62.7 parts; at the boiling point, 30.8 parts. Sulphate of morphia: one part requires of water at 60° F., 21.6 parts; at 212° F., 0.75 part; of alcohol at 60° F., 701.5; at the boiling point, 144 parts. The most important fact to be observed is that morphia sulph. is almost insoluble in cold alcohol, and that water will not hold at 60° F. more than about three grains to the fluid drachm.

INTERNAL ŒSOPHAGOTOMY.[1]

THE DIVISION OF MEMBRANOUS OR CICATRICIAL CONSTRICTIONS OR OBSTRUCTIONS IN THE ŒSOPHAGUS BY INTERNAL SECTION.

BY J. O. ROE, M.D.,

[ROCHESTER, N. Y.,]

FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION, MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK, OF THE CENTRAL NEW YORK MEDICAL ASSOCIATION, ETC.

THE few operations of internal œsophagotomy that have been performed have given results that are very gratifying, when compared with the unsatisfactory results in most cases of dilatation, as well as of external œsophagotomy and gastrotomy, and notwithstanding accidental complications which sometimes unavoidably arise, the operation must take its deserved place among the operations in the œsophagus.

The published statistics of the operation show that it has been performed fifteen times. Eight times in France: first, by Maisonneuve, three times; after, by Lanelongue, once; Dolbeau, twice; Trélat, once; and Tillaux, once. Three times in Germany: Schiltz, twice, and Czerny, once. Once in Denmark by Studsgaard. Once in England by Mackenzie, and twice in the United States in the following cases.

Mrs. F. C. Robinson, of Spencerport, N. Y., aged twenty-four years, the wife of a druggist, was brought to me by Dr. P. G. Udell, her family physician, October 27, 1881, for consultation concerning a stricture of the œsophagus, from which she was suffering. The cause of the stricture was unknown. She first felt an uncomfortable sensation or obstruction in the lower part of her throat in February, 1874, after a violent paroxysm of laughter, but at that time had no difficulty in deglutition.

The dysphagia occurred quite suddenly one day during the following June. She first experienced difficulty in swallowing liquids and solids; semi-solids could be swallowed more readily. Soon it became almost impossible for her to swallow any substance but chocolate. This she could get down very slowly, and on this she sustained herself, though in quite a weakened condition. All solids and all other liquids would be returned shortly after taken.

In January, 1878, a severe form of stomach trouble came on, attended with vomiting of more or less blood, being due, it was thought, to ulcer of the stomach. Soon it became impossible for her to swallow any substances whatever, necessitating the employment of nutritive enemata to sustain her. This condition continued until the following June, when she was again able to resume her chocolate. At the beginning of the difficulty all substances which she could not swallow would be returned at once, but after a time they began to be regurgitated less quickly, until she could take half a glass of water or other substance and retain it for several minutes. This indicated the formation of a sac above the stricture, and from the walls of this sac undoubtedly much nutriment was absorbed—chocolate being the

[1] A portion of this paper was read before the Medical Society of the State of New York at Albany, February 8, 1882.]

only substance which appeared to pass into the stomach, though very slowly and with difficulty. This condition continued until she passed to the care of Dr. Udell, May, 1881, who diagnosticated the stricture of the œsophagus.

I should remark here that no previous diagnosis of stricture of the œsophagus had been made. The apparent gastric irritation was ascribed to indigestion or dyspepsia, hysteria, gastric ulcer, etc.

Dr. Udell at once began systematic dilatation of the stricture with flexible conical œsophageal bougies, and pursued it assiduously, but with very discouraging results. The tissue composing the stricture seemed to be of an elastic character, so that no matter how widely the opening was dilated it would return again almost immediately to its previous calibre, and no improvement in swallowing would follow. On exploration with a bulbous sound the stricture was found to be in the superior portion of the tube, about three inches (75 mm.) below its upper orifice. It was about half an inch (13 mm.) in extent, evidently a ring of elastic tissue. The opening was so small that only one of the smallest olive points (4 mm. in diameter) could be passed without using considerable force. Just above the stricture on the left side of the œsophagus was found a saculated dilatation into which the sound readily slipped, if it was not strongly directed toward the right side.

I advised Dr. Udell that this was a case very favorable for the operation of internal œsophagotomy. Accordingly, at the request of the patient, the operation was decided on.

Through the kindness of Dr. Morell Mackenzie, I procured of Mayer & Meltzer, London, an internal œsophagotome, made after Dr. Mackenzie's improved plan, having but a single cutting blade, as shown in Fig. 1. The shaft of the instrument is fifteen inches (38 ctm.) long, made of gum elastic and flexible. Through the centre of the shaft runs a stem, which is attached to the blade at the lower end of the instrument. When the instrument is introduced the blade is concealed in the metallic shield, which is firmly attached to the lower end of the shaft.

The distance which the blade is thrown out is regulated as desired by a screw in the handle.

Fig. 1.—Internal Œsophagotome, after Mackenzie.

December 7, 1881.—I divided the stricture by making a single incision through the posterior side. I was at once able to pass very easily a bulbous bougie, No. 18, English scale. There was very little hemorrhage at the time, but some slight bleeding followed during the afternoon, and clots of blood were vomited. The pain from the operation was very slight. The sensation, the patient said, was like a sharp sting or the scratch of a pin. The patient was ordered to abstain from taking any food by the mouth for two days, in order to exclude the irritation which the passage of the food and the *débris* lodging in the wound might cause. She returned to her home, and the next day after the operation, Dr. Udell began the use of bougies to keep the opening free, and to prevent the recontraction of the stricture.

For a day or two after the operation she suffered considerable pain in the chest and in the region of the stricture, and some soreness followed for three or four days on the introduction of the dilating bougies.

On the fifth day after the operation I received a note from Dr. Udell, stating that the patient was doing finely, and that he had passed without difficulty the bougie of the third size (14 mm. diameter). Liquid food passed readily into the stomach and was retained; and this had not occurred before in seven and a half years.

The stricture was then dilated three and four times each day with No. 2 (17 mm. in diameter), the next to the largest size of the bulbous bougies; but notwithstanding this, after a time the stricture began to give indication of recontraction, it becoming difficult to pass the No. 2 bougie which had passed easily before; and the swallowing of liquids became more difficult.

Accordingly, January, 1882, I repeated the operation, making two incisions, one in each side, laterally, but not quite as deep as the previous incision. There was no hemorrhage of consequence this time, and but very little pain or soreness on passing the dilators. The stricture now appeared to yield entirely, and in three or four days it was dilated to the full size of the normal calibre of the œsophagus without difficulty, and the patient began to take solid food.

At the time of the second operation, I became convinced of the inefficiency of the ordinary bulbous bougie for dilating purposes. In addition to this, difficulty is often encountered, after they have passed the stricture, in withdrawing them, because of their shape, being like an egg, conical at the distal end, and quite blunt at the posterior end. I therefore had some dilators made in six different graduated sizes, of hard rubber, cylindrical, tapering at both ends alike, and securely fastened to a whalebone stem (see Fig. 2). These I found to be an admirable improvement, as they could now be held in the stricture for a short time at each introduction, giving the benefit of pressure, with the advantages of which in overcoming such conditions all are familiar. The tolerance of these bougies by the œsophagus gradually increased, though their pressure against the larynx interfered with respiration and prevented their long retention within the stricture; while conical rubber or gum-elastic dilators of the same size cause such obstruction to respiration, by closing the laryngeal opening, as to necessitate their withdrawal at once.

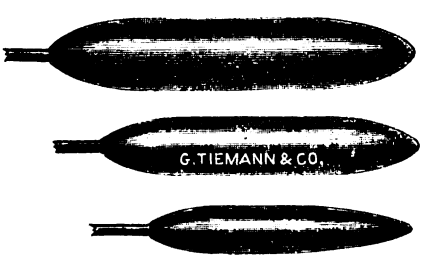

Fig 2.—Cylindrical Œsophageal Dilators.

With a stricture in the lower or middle portion of the œsophagus, this obstruction to respiration would not be encountered, and the instrument could soon be retained for a considerable length of time. The tolerance of an instrument by the œsophagus

is shown by Krishaber[1] in cases of disease of the œsophagus, where a stomach or feeding tube was retained continuously in different cases, from forty-six to three hundred and sixty-five days.

This plan of keeping the opening free and preventing a reunion of the cut surface, has worked admirably, as there is now no perceptible tendency to reclosure or narrowing of the passage, and the patient takes all kinds of food freely. At first considerable food would lodge in the sac, and when this was full it would be regurgitated, as before the operation, giving the appearance of vomiting from gastric irritation; but now the sac is gradually decreasing in size, and there is a corresponding decrease in this vomiting.

Case II.—Carlton A——, aged eight years, son of a lumber dealer of Rochester, was brought to me, January 25, 1882, for advice concerning a stricture of the œsophagus.

Sixteen months before, in mistake for water, he drank some washing fluid of the following composition:

Babbit's potash	lb. j.
Sal ammoniac	℥ ss.
Salts of tartar	℥ ss.
Water	qts. iv.

A physician was immediately called, who administered olive oil. For three or four days after his throat and stomach were irritable and painful, particularly on swallowing. This soon subsided, and for two weeks he had no difficulty in swallowing, and was considered well. He then began to have more or less dysphagia, which increased until about November 1st, when he could only swallow liquids, and these with some difficulty.

Dilatation of the stricture was now begun with a very small gum elastic bougie, a much larger one could soon be passed, and swallowing was so much improved that liquids could be taken readily and some solids for a short time.

The dilatation was now continued, though only once in two weeks, but in the fall of 1881 marked dysphagia came on, and at times it was almost impossible to swallow anything, even milk.

This condition continued until I saw him. He was then much emaciated and very weak.

Examination revealed an obstruction, as had been stated by the father, in the lower end of the œsophagus, through which I was unable to find any opening, even to pass the finest filiform bougie, with the patient under ether.

Every second or third day I repeated these unsuccessful attempts at finding a passage, until it seemed useless to continue them longer, but, remembering how others had succeeded in similar cases when about to abandon them, I concluded to try just once more, and, March 26th, was successful in getting through a fine filiform bougie, tipped with a metallic point. This I followed with slightly larger ones until the opening would admit a bulbous-pointed bougie, No. 18, English scale. With a flexible, conical bougie I could stretch the opening much wider, but it would contract again to the above size. Continued attempts at enlarging the opening by dilatation proved futile; therefore, June 2d, I performed internal œsophagotomy by making a single incision in the posterior side, that shown by the one-sided bulbous bougie, in Fig. 3, to be the deepest. There was no bleeding, the saliva being scarcely tinged with blood. Soon after the incision I began dilating again. The third day after I made a second incision in the right side as before. I repeated these incisions at intervals of four or five days, until I had made six in all, and

Fig. 3.

continued the dilatations. The opening is now permanently free, sufficient to admit a bougie 15 mm. in diameter, and swallowing is unobstructed. With improved deglutition the little fellow began to gain rapidly in flesh and strength, and to grow fast, and is now a stout and healthy boy.

The last operation previous to these just reported was done by Dr. Morell Mackenzie, of London, July 12, 1881.

I am able, through his courtesy, to present the record of the case as reported by him on the presentation of the patient at the clinical demonstrations before the Laryngological Section of the International Medical Congress, London, August 4, 1881.[1]

"Henry Alexander, aged thirty-six; ship-rigger, while engaged at work, September 17, 1880, drank, in mistake for water, some of a clear solution of potash (used for removing paint, etc.). He was at once admitted into the London Hospital. For three weeks he had ice to suck, and was fed by nutritive enemata. At the end of nine weeks a fine bougie (No. 1 or 2) was passed. After the lapse of thirteen weeks, with progressive dilatation of the stricture, he was enabled to eat fish. About the middle of February, 1881, he somehow caught small-pox, and was transferred from the London to the Small-pox Hospital, where he remained under treatment for four weeks, during which time no special attention was directed to the throat. On convalescence he returned as an out-patient to the London Hospital, but by that time had retrogressed in regard to swallowing, being able only to take jelly. He was admitted into the Throat Hospital, April 7, 1881, in a very debilitated condition.

"About the beginning of May, after use of ice, No. 4 bougie was passed. The stricture was found to commence at a level rather below the cricoid cartilage, the bougie then passing through a slightly tortuous track, deviating from right to left.

"Progressive dilatation was made, so that, by June 2d, a No. 8 could be got through the stricture; from this time progress became increasingly difficult. A graduated bougie was used, but by July 8th an advance of one size only had been made.

"Internal œsophagotomy was performed by Dr. Mackenzie on July 12th, the stricture being divided from below upward, in middle line, behind. No anæsthetic was administered. No. 14 bougie was passed without difficulty a few hours afterward. There was little pain after the operation, but this increased considerably toward the evening; it was referred to the stomach and to the back, and became severe enough to need a hypodermic injection of morphia to relieve it.

"On auscultation of the region to which pain was referred in the back (corresponding to the base of the right lung), fine crepitation on expiration and inspiration, with diminished breath-sounds, was found. Temperature, 100°; respiration, 40.

[1] De la sonde œsophagienne a Demeure. Ann. des Mal de l'oreille, du larynx, p. 265. Paris, November, 1881. Also, Transactions of the International Medical Congress, London, 1881, vol. ii., p. 392.

[1] For notice of the case, *vide* Transactions of the International Medical Congress, London, 1881, vol. iii., p. 332.

"July 13th.—Patient complains of very sharp pain on swallowing. Crepitation extending from right base to angle of scapula; diminished percussion resonance at lower part; slight, colorless, viscid expectoration. During the next few days the pulmonary signs became more marked; expectoration more profuse, but retaining the same characters. Patient has milk, eggs, beef-tea, and port (3 oz.), taking these well; some diarrhœa. Pains in stomach and right side more or less constant, increasing toward evening; obvious dyspnœa on slight exertion; spongio-piline, sprinkled with spts. tereb., for relief of pain, together with hypodermic injection occasionally at night.

"July 22d.—General condition fairly good; bougies 7, 8, and 9 passed.

"July 23d.—8, 9, and 10 passed. An expectorant mixture ordered. On successive days bougies were passed, similarly progressive in size.

"August 1st.—No. 15 passed easily; pain as before, but coming on only toward evening; less expectoration; crepitation still audible at right base. Temperature from time of operation has averaged in the evening a little above 101°, and in the morning a little below 100°. The patient died in the London Hospital about the middle of October.

"*Post-mortem.*—Both lungs were found considerably congested, and presented patches of pneumonia. The right pleural cavity contained a large quantity of sero-purulent fluid. Commencing about one inch below the cricoid cartilage, and extending downward for three inches, the walls of the œsophagus were found to be slightly thickened, hard and uneven on the inner surface, the lumen of the gullet being considerably narrowed for that extent. At the lower part of the stricture an incision of about an inch long was found extending through all the coats of the tube below, and through the mucous and part of the muscular tunic for the upper half of its length. The wound showed but little sign of cicatrization."

The unfortunate termination of this case Dr. Mackenzie largely attributes to the patient being a confirmed drunkard, as it was found impossible to keep him from taking spirits in large quantities.

Considering the slight attention which the operation of internal œsophagotomy has received at the hands of our surgical authors and the absence of any article on the subject in English that I am aware of, a review of all the cases, in which the operation has been performed, cannot but be of interest as well as profit. By studying its past record, its successes and failures, we can judge correctly, and without prejudice, its merits and demerits—facts rather than theories should govern our judgment.

Case I. (By Maisonneuve).—A young girl, in a fit of despair, swallowed a quantity of sulphuric acid, which produced an inodular stricture in the vicinity of the cardia, 3 ctm. long. Œsophageal bougies were introduced, and the patient nourished for a time by nutriment injected through them into the stomach. Notwithstanding the introduction of the bougies, the stricture continued to contract until it became impossible to introduce the bougies and for the patient to swallow even liquids in sufficient quantities to sustain her. She was greatly reduced in flesh and strength, and in immediate danger of starvation. Maisonneuve having just read a paper before the academy on internal urethrotomy, conceived the plan of dividing strictures in the œsophagus in the same manner. Accordingly he had an œsophagotome made by Charrière after the plan of his well-known urethrotome, only adapted to the œsophagus by being longer and thicker. It has two independent blades, sliding each in a groove on the outside of the stem, the point of which is tipped with a slender, flexible guide. The length of the instrument is 50 ctm. The blades are each 12 mm. wide, their cutting edge occupying only the anterior third, the other two-thirds being entirely blunt. To each of the blades is attached a long steel stem, provided with a button for working it, either alone or together with the other blade.

In using the instrument it is first carefully introduced through the stricture guided by the flexible point. Then one of the blades is introduced into the groove and gently pushed downward, severing the stricture. The second blade is introduced if required.[1] July 16, 1861, he made a double incision through the stricture from above downward, unattended by pain or hemorrhage. On the following day the patient could swallow bread, eggs, and meat freely. On the eighth day subacute peritonitis supervened, and death occurred on July 31st.

At the autopsy there was absolutely no inflammation of the œsophagus or of the surrounding cellular tissue. The stricture showed a perfectly clean mark of the scarification, confined entirely to the morbid tissue, which had been but incompletely severed. There was no lesion of the stomach, but there was an intense peritonitis, the origin and source of which was entirely unknown, though the cause seemed to be in the pelvis.

Case II. (By Maisonneuve).—That of a young woman with stricture in the œsophagus, just below the thyroid cartilage, caused by tuberculous infiltration. For three months the patient had been unable to swallow sufficient liquid food to sustain her, and she was almost moribund. It was impossible to pass the smallest sound. On July 20, 1861, with much difficulty and the exercise of considerable force, a fine whalebone bougie was passed. This was followed by a flexible bougie screwed to the stem of the œsophagotome, which was introduced through the stricture, and section of the stricture was made from above, downward. After the operation a large sound could be passed easily, and the patient could swallow food readily. Four days afterward she was attacked with acute peritonitis, and died August 1st.

The conditions revealed at the autopsy were almost identical with those of the former case. A slight mark of the incision through the tumor was found, but no inflammation in or about the œsophagus. Intense inflammation, with exudation, in the abdominal cavity. In both cases the stomach was examined to ascertain if a perforation had been produced, but none was found. Braun[2] suggests that there might have been one, too small to be seen on simple inspection, that caused the inflammation, but this seems highly improbable.

Case III. (By Maisonneuve).—M. C——, a man fifty-eight years old, had experienced for two years great difficulty in deglutition. The cause of the stricture was unknown. It was located at the junction of the upper and middle third of the œsophagus, and had gradually contracted to such an extent that only soup and thin broth could be swallowed.

April 3, 1862.—Two incisions were made through the stricture, when immediately afterward an ivory ball, 1½ ctm. in diameter, could be passed without difficulty. The pain attending the operation was very

[1] For illustration of this instrument, vide Lehrbuch der Chirurg von Dr. Eduard Albert, 1881, p. 542.

[2] Czerny's Beiträge zur Operativen Chirurgie, 1878, p. 86, note.

slight, and there was very little loss of blood. The same evening the patient could eat bread and meat. Eight days after, no accident having occurred and deglutition remaining good, the patient departed for the province and nothing more was heard from him.[1]

A fourth case of stricture of the œsophagus is reported by Lanelongue to have been given by Maisonneuve in connection with the above three cases, but on an examination of Maisonneuve's original article, the case is not to be found reported there.

As the case is undoubtedly authentic, and the reference wrong, I will cite it from Lanelongue. It is to be excluded, however, from the operations of internal œsophagotomy, as the operation was only attempted, but never performed.

"Besson, fifty-seven years of age, was admitted to the hospital, May 1, 1865, with a cancerous stricture near the cardia. Food was regurgitated immediately after taken. Internal œsophagotomy was proposed, but after many fruitless attempts at introducing the œsophagotome the operation was abandoned.

"May 20th.—An œsophageal sound was introduced, it was believed, into the stomach, and broth and herb decoction was injected, which passed without difficulty. Immediately after, there was anxiety, sharp pain in back, cold sweats, extreme lividity, pulse small and frequent, and death followed next day.

"At the autopsy emphysema and liquid was found in the posterior mediastinum. Perforation of the œsophagus four or five centimetres above the cardia, at the junction of the œsophagus with the cancerous tumor. This perforation was caused by the penetration of the sound. There was a cancerous tumor at the inferior extremity of the œsophagus, with infiltration along the lesser curvature of the stomach."

Case IV. (By Lanelongue).[2]—Patient twenty-three years of age; farmer; admitted at Hospital St. André, October 22, 1864. In November, 1853, in mistake for white wine, drank from a bottle some sulphuric acid. Excruciating pain in neck, breast, and stomach followed, and continued with fever and inability to swallow for eleven days. On the twelfth day a sound was introduced into the œsophagus, and broth was injected into the stomach. This was repeated for twelve consecutive days, when he was again able to swallow milk, broth, and even soup, and, after a time, solid food. For two years he experienced no other symptoms than slight pains after eating, but he now began to lose his teeth, and being unable to masticate his food, deglutition became difficult and painful. He now applied at the Hospital St. André, and for one month an œsophageal sound was introduced, with improvement. He then left, and was told to have the sound passed frequently, which he failed to do. After a time the dysphagia returned, and he was again admitted to the hospital in a greatly debilitated condition, spending most of his time in attempting to swallow. On examination, an impassable stricture was found just below the cricoid cartilage. After repeated unsuccessful attempts, a whalebone bougie, 1 mm. in diameter, was passed. The stricture was ascertained to be a cicatricial band 2 ctm. in length. Owing to the hardness and unyielding character of the stricture, progressive dilatation failed to give relief.

Not knowing of Maisonneuve's previous operations, Lanelongue conceived the plan of dividing the stricture as in internal urethrotomy, and had a urethrotome modified to the œsophagus. It consists of a metallic stem, hollow and curved, armed with a concealed blade near its inferior extremity. This blade is half elliptical, and can be thrown out 1½ ctm. It is hidden in the "opercule" when introduced, and can be thrown out either above or below it. To the lower extremity of the instrument is attached a conducting bougie to facilitate its introduction. This is made of whalebone, and has an olive point 1 mm. in diameter. On November 8, 1864, Lanelongue performed the operation by passing the stem of the instrument through the opening and sliding the cutting blade from above downward through the stricture. The instrument was then turned and two other incisions made. The operation was painless and almost bloodless. No reaction and but little pain on deglutition followed for two or three days. There was immediate improvement in deglutition, and the patient was enabled and continued to take solid food freely. Dilatation soon restored the œsophagus to its normal calibre, which continued at the end of a year, when he was last seen.

Case V. (By Dolbeau).—A young girl had, eighteen months before (in October, 1868), tried to commit suicide by swallowing sulphuric acid. Dysphagia was so great that she could only swallow broth and milk. After many unsuccessful attempts, Dolbeau succeeded, at the end of eight days, in passing the smallest of the graduated series of olive bougies, mounted on a whalebone stem made by Charrière. By progressive dilatation, the stricture could only be enlarged to five or six millimetres. Division of the stricture was then decided on by Dolbeau, and performed with an œsophagotome made by Messrs. Robert & Colin. It consists of a ball 6 mm. at the base, terminating conically, containing two concealed blades, which are regulated by a mechanism in the handle of the instrument. The divergence of the blades is exactly limited to the diameter of the ball, so as to prevent them from passing beyond the limits of the cicatricial tissue. The operation was made by passing the olive beyond the stricture, when the blades were thrown out and the stricture divided as the instrument was withdrawn. The operation was painless and bloodless. Dilatation was then resumed, and 1 ctm. was soon reached, when deglutition was rendered normal.

Case VI. (By Dolbeau).—In the year previous (1869) Dolbeau had another patient, on whom he operated for internal œsophagotomy in the Hospital Beaujon. In this case the dysphagia dated back two years, and was also the result of swallowing sulphuric acid. After progressive catheterization and dilatation, five or six millimetres only could be attained, which decided him to perform internal œsophagotomy, as in the previous case, and it was done with the same result. A dilatation of 1 ctm. was rapidly reached after the incision, allowing complete alimentation. There was no pain or hemorrhage in this case, as in the previous one, and, on being dismissed from the hospital, she was advised to make daily use of the sound.

The above two cases were reported to the Société Impériale de Chirurgie, March 16, 1870.[1]

[1] Dolbeau: Gazette des Hôpitaux, Avril 5, 1870, p. 159.

Case VII. (By Trélat).—A man, thirty-one years of age, came under the charge of Trélat, at La Pitié, October, 1869, with stricture of the œsophagus, caused by drinking, May 26, 1867, in mistake for water, a glass of dilute nitric acid ("un verre d'eau second"). Violent pain followed immediately, with vomiting of black and pure blood. The next day he was relieved. Three weeks later, solid food began to be swallowed with difficulty and sometimes regurgitated. Dysphagia increased; soon liquids only could be taken with great difficulty, sometimes not for twenty-four or thirty hours.

October, 1867.—The patient sought admission at the Hospital Lariboisière, under the care of M. Verneuil. After eight months of continuous dilatation of the stricture with an ivory ball bougie, he was able to swallow very well, even some solid food, and he left the hospital; being advised, however, to use the sound very often, which he failed to do.

Dysphagia soon reappeared and he sought re admission at the hospital, July, 1869. Dilatation was again renewed, but without ameliorating the condition of the patient. An operation being evidently necessary, the patient was sent to M. Trélat. All substances taken would be retained for a few moments and then regurgitated, indicating a sac above the stricture. Very little would pass through the opening, which would only admit an olive 8 mm. in diameter. The stricture was 35 ctm. from the incisors and 1 ctm. in length. It was of an elastic, movable character, as the distance to the upper side, on passing the olive downward, was greater than to the lower side, when the olive was withdrawn. The patient's condition now became extreme, requiring active operative interference—either divulsion of the stricture, external œsophagotomy, gastrotomy, or internal œsophagotomy. The latter Trélat decided on, as the stricture was too low for external œsophagotomy. The instrument used was made by Robert & Colin, and has a total length of 60 ctm. It consisted of a graduated stem 42 ctm. long, a handle 12 ctm. long, and a terminal stem or guide 6 ctm. long, having an olive point 4 mm. in diameter. At the junction of the stem with the shaft is a half-flat bulb. Below this bulb are two blades concealed, which are thrown out, by a screw in the handle, after the instrument has penetrated through the stricture to the bulb, and the incision is made by withdrawing the instrument.

On December 2, 1869, Trélat made the first incision with the blades separated 15 mm. There were but a few tinges of blood and only a light sensation of pain in the region of the xiphoid appendix for two days after. The next day the patient could take finely chewed, solid food. Six days after, an olive, 9 mm., could be passed, and on the seventh, 10 mm.; beyond this the stricture could not be dilated.

December 16th.—A second incision was made with the blades separated 18 mm. Result as after the first incision. But little improvement followed this incision, owing, Trélat thought, to the dulness of the point of the blades.

December 31st.—A third incision was made with the blades separated 2 ctm., and sharpened to the point. No pain attended this operation, but almost immediately after the patient vomited a glassful of blood, and next day the stools were darkened with blood. With absolute rest and very cold drinks, the hemorrhage was arrested and the patient was very comfortable, excepting a soreness at the seat of the stricture on the passage of food.

January 11th.—Hemorrhage recurred, caused by straining in defecation, and again, the next day, losing about four hundred grammes. This was again checked, but the xiphoid pain continued and the patient was very weak.

January 17th.—Another slight hemorrhage without cause. Shortly after this, on taking wine or alcoholic potions, there occurred violent paroxysms of coughing, with expulsion of food and a prolonged burning pain in the region of the incision, indicating œsophagitis in this portion of the tube. On the withdrawal of wine and alcoholic potions and all irritating substances, the cough and pain subsided, and with a nutritious diet of milk, broth, and thickened potage, he regained strength and color.

February 15th.—Dilatation was resumed and an olive, 11 mm., then 12 mm., was passed. Now, instead of an annular obstacle on passing the olive, a sensation of a series of nodosities is felt.

February 28th.—No more regurgitations of mucus or food, and the patient takes all kinds of food freely and normally. Improvement continued, and, March 25th, an olive, 13 mm. in diameter, could be passed, and the patient was feeling extremely well.

(The above case by Trélat was reported to l'Académie de Médecine, March 8, 1870.[1])

(To be continued.)

ON THE

RADICAL CURE OF HERNIA BY HEATON'S OPERATION.[2]

By WILLIAM T. BULL, M.D.,

SURGEON TO ST. LUKE'S AND THE CHAMBERS STREET HOSPITALS, NEW YORK.

Dr. George Heaton, of Boston, was known to have effected many cures of hernia by a method of treatment which he did not make public till a few years before his death, when he published a book on the subject.[3] This method, which he calls that of "tendinous irritation," consists in a "mild irritation of those portions of fibrous tissue lying directly in contact with the neck of the hernial sac, thickening and consolidating their substance, and effecting a contraction of the openings." It is insisted upon that only a moderate "irritation" shall be produced, and that such an amount of inflammatory reaction as is shown by suppuration, or constitutional disturbance, or redness, heat, pain, or swelling for more than a few hours is to be avoided. The irritant used is a fluid made up of the solid alcoholic extract of quercus alba, fourteen grains; Thayer's fluid extract of quercus alba (prepared in vacuo), half an ounce, triturated with heat till as perfect a solution as possible is made. To this, sulphate of morphia, gr. j. to the ounce, is added. (For hernia with very large openings, he recommends a semi-fluid mixture of the solid and fluid extracts.) The operation consists in injecting the fluid, by means of a metallic syringe with solid piston, and short, strong needles (which I now show you), into the fibrous tissues overlying the sac and forming the walls of the inguinal canal. The sac is reduced, if possible, but it

[1] Trélat, U.: Sur l'œsophagotomie interne dans les rétrécissements cicatriciels de l'œsophage. Bulletin Général de Thérapetique Médicale et Chirurgicale, Paris, 1870, tome 78, p. 252. This article also contains an illustration of Trélat's œsophagotome.

[2] Read before the New York Surgical Society, October 10, 1882.

[3] The Cure of Rupture, Reducible and Irreducible, also of Varicocele and Hydrocele, by New Methods. By George Heaton, M.D. Edited by Dr. J. Henry Davenport. Boston: H. O. Houghton & Co. 1877.

is admitted that in the majority of cases this cannot be done. After invaginating the scrotum into the external abdominal ring with the right forefinger, the left is pressed perpendicularly over, and into the ring, forcing the spermatic cord to the inside, so as to feel the edge of the external pillar of the ring, separated from the finger only by the skin and subcutaneous fat. The needle, with the syringe attached, is then thrust perpendicularly through the integument, and after passing, but not touching the external pillar, is carried upward in the direction of the canal (the finger being withdrawn) as far as its uppermost limit. Ten to twenty minims of the fluid are injected, the point of the needle being swept about over as large an area as possible, and the instrument rapidly withdrawn, so as to leave no fluid in the subcutaneous tissue. A compress and bandage are applied at once, and the patient kept recumbent for eight or ten days (or till the local tenderness has disappeared), and then allowed gradually to resume his usual avocation, wearing the bandage or a truss for six or eight weeks or three months. If the hernia has not reappeared at the end of this time, the support may be discontinued. If it recurs, a second operation is to be performed. This, in Heaton's words, happens in from one-third to one-half of all the cases. The same method, with slight modifications, he applied to umbilical and femoral herniæ with good results.

My own experience with the operation began in 1879, when Dr. Knight and Dr. Gibney, of the Hospital for Ruptured and Crippled, kindly referred some patients to me. I first satisfied myself that it was possible to deposit the fluid in the proper place without entering the peritoneal cavity, by four operations on cadavers with large inguinal canals, and then operated on every patient who would submit, repeating the injection, when possible, in case of failure. In all, I have performed the operation on forty patients, but I can report the ultimate result in only twenty-one of them, since the remaining nineteen have not been seen since leaving the hospital, and extended search has failed to find them. Counting in repetitions of the operation, and operations on both sides, there have been forty-nine operations in these forty patients without any serious disturbance. It is, hence, to be considered perfectly safe, and furthermore, unlikely to be attended with more than trifling local, and no constitutional reaction. In only one case was there enough local inflammation to warrant the application of a cooling lotion for a few days. No swelling has been perceptible externally, but a plug of induration has generally been felt over the site of the canal, which has disappeared within two weeks. Tenderness has persisted for periods varying from four days to two weeks. The pain at the time of injection has been considerable, but has seemed to me to depend largely upon the temperament of the patient. In only three cases has ether been used. General abdominal pain, mostly a dull aching, has required for a day or two one or two hypodermics of morphine. A very light epididymitis has followed the operation in six cases, which subsided in two or three days. One patient had retention of urine for five days, and in another the rupture (an omental one) came down the day after the operation, and was irreducible for a month. Once the needle broke off at its shoulder, but was easily extracted through a slight skin incision. The diet has been moderated only in quantity, and no effort has been made to confine the bowels, which have generally moved spontaneously after two or three days, or, if longer confined, have been moved by enema. In most cases, I have had no idea whether the sac has been returned or not. Probably, in herniæ that have existed for more than a few weeks, the sac is adherent, and is merely invaginated, and the fluid is deposited between it and the internal surface of the fibrous walls of the canal. In the cured cases, according to Heaton, it gradually atrophies. I do not think it is likely to be penetrated by the needle, for on the introduction of the latter, it is pushed aside, together with the spermatic cord, by the finger, and as the needle traverses the canal, its point can be directed away from the sac and against its fibrous envelope. I have never had any reason to think that fluid has been deposited in the peritoneal cavity.

The operation is easy, except in fat subjects with small openings, and in these, I confess, I should have no very definite idea as to the position of the needle. I have not always found it easy to feel the external ring by thrusting the left forefinger *vertically* into it, and have generally preferred to incline it slightly and to flex the terminal phalanx so as to make it partly enter the ring and serve as a guide for the needle when it is about to be passed up the canal. Heaton's syringe has been found satisfactory, but it is more easily manipulated when furnished with a collar of roughened metal about its middle, as was suggested by Dr. Weir. I find a needle a trifle longer than that used by Heaton the most convenient. These, made by Schmidt, are two and a half inches long. In the after-treatment the bandage has answered every expectation, but when the patient walks about I think a truss, which does away with a perineal strap, is preferable. I have preferred to use a pad made of rubber adhesive plaster, owing to the difficulty of keeping a cloth pad in place.

I am sure that it is of the utmost importance to keep the pad and bandage carefully adjusted while the patient is in bed, and constant watchfulness is necessary for this end. An intelligent patient can help his own cause materially after being instructed, and is more to be relied upon than the average interne or nurse. Especially is this the case when he begins to move about, for it is imperative to avoid all severe efforts at the outset, and to very gradually resume ordinary occupations. Bad judgment, or inattention to details which have been given, will very often imperil, if not destroy, the efficiency of the operation. I am so much impressed with the importance of this factor in effecting a cure, that of two patients with similar herniæ, I would give twice the number of chances of success to the one who had intelligence enough to comprehend what was being done for him, and self-control and "gumption" enough to carry out instructions faithfully.

I pass now to a brief statement of the twenty-one cases, the result of whose treatment I have been able to learn.

CURED.

Case I.—A clerk, aged eighteen, has right oblique inguinal hernia (incomplete) of uncertain duration. Mass, equal to one joint of little finger, descends into canal. Easily reduced, no truss. Bandage discarded five months after operation. Examined one year and nine months later and no sign of return. Ring as patent as on other side.

Case II.—A gardner, aged twenty-one, with right oblique inguinal hernia, congenital and com-

plete. Projects into scrotum as large as horse-chestnut, apparently intestinal, once irreducible for several hours. No truss. Now easily replaced, and ring admits tip of index finger. After operation a truss for three months, then bandage for three more. Nine months after the operation I could find no sign of the rupture, and the ring was smaller. Two months later Dr. Jayne, of Cold Spring, who recommended the operation to him, wrote me that he had examined him and that he considered him cured. He does hard manual work.

CASE III. — A banker, aged thirty-one, with right oblique inguinal hernia (complete) of nine months' duration. Mass, like elongated horse-chestnut, projects into scrotum. Easily replaced. Has worn truss, on removing which rupture descends. Tip of index finger admitted into internal ring. After the operation a *lighter* truss (made by DeGarmo & Co.) was worn for four months. No descent when it was removed at odd times. Shortly after the operation he developed caries of the spine. In order to wear a spinal brace the truss was discarded. A month later he died ; but in the interval there was no return of the hernia, although he was walking about and constantly troubled with violent cough. Patient of Dr. Andrew J. McCosh.

CASE IV. — A bookkeeper, aged twenty-six, a patient of Dr. L. Bolton Bangs, has had a hernia nineteen years. It is a right oblique inguinal hernia, and forms in the scrotum a tumor the size of a small orange, apparently intestinal and omental. Easily reduced. Opening admits index finger. Has worn truss irregularly. Two operations in seventeen days, after which truss was worn for five months, but with very much less pressure than before. For three months past it has been discarded the greater part of the time. There has been no descent ; though the canal and ring are but a trifle smaller than before.

CASE V.—A waiter, aged thirty, has had an oblique inguinal hernia for five weeks. Has worn truss, but it comes down five or six times a day, as large as a horse-chestnut. Ring admits index finger. Fourteen days after operation there was a slight descent. Second operation, after which he returned to work. A year later the patient stated that he had discarded the bandage six months previously, and that there had been no relapse.

In all of these five cases there was no descent of the hernia from the time of the final operation. Although the time which elapsed since all support was discarded is somewhat short in Case III., I consider it a cure, because of the unusual strain from coughing, which the abdominal walls withstood. Case V. I have not been able to examine, but have every confidence in the intelligence of the patient. That truss or bandage was worn for so long a time after operation in these cases is due to the patients, rather than myself. They were indisposed to lay them aside, because they felt that they were cured, but that if there was a relapse their condition would be worse than before. This I can say has *never* been the case, as will be seen from a consideration of the cases that I think it fair to call improved. They are seven in number. Cases VI. and VII. seem to be practically cured, but I have ventured to call them only improved, since they are still wearing a support.

IMPROVED.

CASE VI.—Printer, aged twenty-three, with oblique inguinal hernia (incomplete) of nine months' existence, the size of a small sausage in canal. Has worn truss, but it descends readily on removing it. Little finger only can be passed into canal. After operation a bandage only was worn. A year and three months later he persisted in wearing bandage, and was under the impression that the hernia had been down "once or twice," but it could not be made to descend and the ring was apparently closed.

CASE VII.—Lawyer, aged thirty-three, a patient of Dr. V. P. Gibney, had a direct inguinal hernia of two years' standing, which filled one-half of the scrotum. It could be easily reduced, but truss would not control it. Opening admits index-finger. Two operations in fourteen days, and bandage only applied. While wearing this a small indistinct protrusion would occur beneath the pad, and he was referred to Dr. G. for a truss. One similar to that worn before the operation was applied, with the addition of a perineal strap. Thirteen months later Dr. Gibney reports, "No appearance of tumor even on coughing. Not as much impulse as on the sound side. Can not get tip of little finger into ring."

CASE VIII.—Porter, aged thirty-three, with double oblique inguinal hernia, for which he has worn double truss ten years. On right side the protrusion descends as large as a hen's egg beyond the external ring, on the left it merely "pouts" through the internal ring. Truss does not control the right one satisfactorily. Operation on both sides at once. Two weeks later resumed work with the same truss. Nine months later he reports that he is much more comfortable. The left rupture has not materially changed, but the right has descended only two or three times, and then only when truss was off. On coughing it does not come outside of canal.

CASE IX.—Surveyor, aged eighteen. Has noticed for eight days a protrusion which distends the left inguinal canal on coughing. No truss. Ring admits tip of index finger. Truss after operation. Nine months later hernia could not be made to descend, and the ring seemed to be closed. A rupture now exists on the right side, and a double truss has been worn for three months. Operation on the right side. At present, eighteen months after the first operation, he still wears truss. The left hernia came down a year, the right two months after the operation. Both are controlled by truss and can not be made to do more than just protrude through the internal ring, which feels smaller than before.

CASE X.—Laborer, aged forty-seven, with oblique scrotal hernia and hydrocele. After tapping hydrocele, hernia as large as goose-egg. Ring admits index finger. Descent after first operation. Second operation a month later. Truss. No relapse. Hydrocele tapped again and injected with tinct. iodine. Six months later hydrocele tapped again. Ring smaller, and a mass only as large as horse-chestnut could be forced out. One year after the operation, after tapping the hydrocele again, the hernia was found in the same condition. A third operation was proposed, together with antiseptic drainage of the tunica vaginalis.

CASE XI.—Laborer, aged fifty-six, with right oblique inguinal hernia, existing eighteen months, and descending into scrotum as large as a hen's egg. Opening admits index finger. Has worn truss, but suffered much from feeling of weakness, and rupture has come out on coughing in spite of truss. After operation, same truss. Nine months later he reported that the rupture had descended but once, and was then only half as large as before, and that he was perfectly comfortable with the truss. On

coughing a protrusion somewhat smaller than a horse-chestnut filled the canal but did not emerge from it, and the ring would admit only the tip of the index finger.

Case XII.—Clerk, aged thirty-two, with oblique inguinal hernia of four years' standing. Ring admits index finger and hernia is of the size of small banana, reaching into scrotum. Worn truss irregularly. Admitted to hospital for strangulation, which was relieved by taxis. Operation four days later. Bandage. Descent six weeks afterward on lifting a heavy package, and incarceration, relieved by taxis. Second operation after five days. Discharged wearing bandage. Two years and a half from date of last operation patient wrote that he had had no further trouble from the rupture in any way, but wore a truss on account of a rupture on the other side.

The improvement in these cases is shown in their being made more controllable by a truss, in the diminution of size of the hernial orifices, and that of the hernial protrusion. A repetition of the operation might be expected to effect a cure in cases VIII., IX. and XI.

It is because the operation has not been repeated in the following four cases, and because there was a decided improvement for a while that I am tempted to report them as temporarily improved, rather than as absolute failures.

TEMPORARILY IMPROVED.

Case XIII. — Errand-boy, aged fourteen, with right oblique inguinal hernia reaching into scrotum, the size of hen's egg. (Intestinal?) No truss. Came down two months after operation, half as large as before. Induration exists in tissues of cord outside of external ring. (Operation probably imperfectly performed.)

Case XIV.—Shoemaker, aged thirty-six, with right inguinal hernia of fourteen years' duration. Truss. Size of goose egg. Ring admits tip of index finger. Relapse at end of a year while wearing bandage.

Case XV.—Clerk, aged twenty-five, with left oblique inguinal hernia, existing five years, as large as the thumb and projecting beyond external ring. Descends under truss on making exertion. Has been larger. Ring admits tip of index-finger. Bandage for six months. Relapse shortly after removing it.

Case XVI.—Dressmaker, aged eighteen, with double femoral hernia on one side, of six years' standing, and as large as a small orange when down, on the other of two years' duration, and of the size of a hickory-nut. Wears a double truss, in spite of which ruptures give great annoyance, and is unable to do house-work. Operation under ether on one side, followed in three weeks by operation on the other side, without ether. Considerable induration in femoral canal. Four months later the truss would control both herniæ, and the larger one descends only on coughing. Six months after operation rupture as large as before but controlled by truss, except on making severe muscular efforts. Induration has disappeared from canal, and rings are about as before.

FAILURES.

In the five cases which follow, the rupture descended on the patient's getting up, or within ten days later.

Case XVII.—M——, aged seventy-three, with large scrotal hernia retained by truss only when he moves about very quietly. Ring admitting two fingers.

Case XVIII.—M——, aged four and one-half. Congenital scrotal hernia down most of the time, size of small orange. Ring admits tip of index-finger. Ether.

Case XIX.—Laborer, aged fifty-one, with scrotal hernia size of fist, existing eighteen years. Truss uncertain. Opening admits two fingers.

Case XX.—Farmer, aged fifty-three, with scrotal hernia size of two fists, existing ten years. Opening admits middle finger. Truss fails to control it. [Operation repeated by Dr. Weir a month later, with no better result.]

Case XXI.—Porter, aged thirty-four. Right inguinal hernia (direct) of six years' duration, large as fist, omental. Opening admits one-half of index-finger. The day after operation the hernia came down and could not be replaced. No strangulation. Efforts under ether unsuccessful. In bed for a month; poultices followed by elastic compression. Tumor gradually reduced in size till it formed a firm adherent "plug" as large as a hen's egg, over which a truss could be worn with comfort.

SUMMARY.

Forty-nine operations have been performed on forty patients, only twenty-one of whom have been followed long enough to learn the result. Five have been cured, seven improved, four temporarily improved, five have not been improved at all.

It will be seen that all the cases have been inguinal hernia with one exception. I can hence only speak of the applicability of the operation to this form of rupture. The number of cases is too few to enable me to draw any but the most general conclusions; and I find these so tersely formulated by Dr. George W. Gay, of Boston, as the result of his own experience with fifteen cases ("23 operations, 4 cured, 8 relieved, 3 unrelieved"), that I can not do better than quote them, and express my coincidence with them. He says, at the close of a paper read before the Suffolk District Medical Society, November 19, 1881,[1] "I know nothing of the merits of the operation in other kinds of hernia, but in the one under consideration I can but conclude that it is safe. It is not very painful; it is not very difficult to perform; it does little harm, even if it does no good; it will cure a certain number and will relieve others." From my own experience I feel justified in recommending the operation, and I am sure that in another series of twenty cases I could greatly improve on this record. I hope that the experience of other members of this society will contribute further to our knowledge of the possibilities of the operation, and incite the profession at large to further study of its advantages.

I have limited this paper to my own experience with Heaton's operation, but before closing, it is proper to call your attention to what has been claimed by other operators with modifications of this method. Dr. Joseph H. Warren, of Boston, in "A Practical Treatise on Hernia"[2] recommends an instrument of his own invention and the following fluid for injection:

℞. Fl. ext. querci albæ.....	ʒ vi.[3]
Alcohol (ninety per cent.).....	ʒ iss.
Ether sulph.....	ʒ ij.
Morph. sulph.....	gr. iv.
Tinct. verat. viridis.....	ʒ ij.

M. Sig.—Inject 15 to 20 drops in small and recent herniæ, but 25 to 50 drops in large or old herniæ.

[1] Boston Medical and Surgical Journal.
[2] Boston: James R. Osgood & Co. 1883. Second edition.
[3] Reduced by distillation to ʒ ij.

He uses a rubber bandage after the operation. He had among his first twenty-nine cases "some failures," but says, "in my last cases, out of more than the same number I have not had a single failure" (p. 385). He also quotes these results reported by Dr. H. S. Greeno, of Kansas City, Mo.: Cases operated on, 97; reported cured, 91; failures, 6; number reported who have abandoned the use of trusses, 56. And he reports from Dr. W. H. Heath, of Buffalo, N. Y., Assistant Surgeon United States Marine Hospital Service, twelve cases operated on, with nine permanent cures. Schwalbe,[1] of Magdeburg, reported to the last Congress of German Surgeons thirty-four cases cured by injections of alcohol.

Progress of Medical Science.

CURE OF HYDATID CYSTS BY CAPILLARY PUNCTURE.—Dr. Allesandro Borgherini reports *in extenso* the histories of four cases of echinococcus cysts treated by capillary puncture and withdrawal of a small quantity of fluid. Of the four cases three were cured, but in the other a second puncture with complete evacuation of the cyst was necessary. The punctures were made with the needle of a hypodermic syringe and the amount of fluid withdrawn was from one-half to two drachms. A slight elevation of temperature followed the operation in every instance, but in one case only did the fever continue for any length of time or rise to any considerable height. Improvement did not follow until from eight to fifteen days after the punctures were made. The author thinks that possibly the cure is brought about by the altered tension caused by the abstraction of a small amount of fluid and the consequent disturbance of osmosis, a process by which the parasite obtains nourishment. Or possibly the slight puncture acts as a traumatic cause to impair the vitality of the parasite.—*Gazzetta Medica Italiana*, August 5 and 12, 1882.

ACUTE CIRCUMSCRIBED ŒDEMA OF THE SKIN.—Dr. Quinke describes (*Monatshefte für praktische Derm.*, No. 5, 1882) under this name, a disease which bears striking resemblance to so-called giant urticaria. The malady manifests itself by the appearance of œdematous swelling of the skin and subcutaneous cellular tissues in circumscribed spots, of from two to ten centimetres in diameter. These tumors show themselves most commonly upon the extremities in the neighborhood of the joints, but may also come upon the body and face, in the latter region more particularly in the lips and eyelids. The swollen portions of skin are not, as a rule, reddened, but are pale, rather translucent in appearance, and not sharply defined. The subjective sensation is that of tension, itching being rarely felt. The mucous membranes of the lips, soft palate, pharynx, and entrance to the larynx may also be invaded by similar swellings, and to such an extent that difficulty in breathing ensues. One case, in which were manifested gastric and intestinal symptoms, suggests that the mucous membranes of these organs may be also affected. In another instance repeated serous effusions into the joints took place. Coming on suddenly, and, as a rule, simultaneously, in different regions, these swellings, after an existence of from several hours to a day, disappear with equal abruptness. By reason of the appearance of successive crops of such lesions, the malady, as a whole, may be prolonged for several days or weeks. The general health is generally undisturbed, but in some cases there was indefinite prodromal indisposition, and during the existence of the eruption heaviness of the head, thirst, and diminution in the quantity of urine. A rise in the temperature of the body was never observed. Once having been attacked, the individual is subject to recurrences of the disease, usually in the same regions of the body, sometimes at regular, sometimes at irregular, intervals of time. The affection appears oftener in men than in women. The patients were, as a rule, healthy in other respects, some of them of nervously irritable temperament. In one instance the malady was inherited by the child of the patient, the disease manifesting itself during the first year of life. This affection is to be classed among the angio-neuroses. Prophylaxis consists in regulation of the general condition, more especially of the digestive functions. Atropine seems to be of some service. In several instances scarification was necessary on account of œdema of the larynx.

[1] Beilage zum Centralblatt für Chirurgie, No. 29, 1882, page 58.

BROMIDE OF POTASSIUM IN VESICAL CATARRH.—Dr. Ciancosi claims excellent results in the treatment of vesical catarrh by bromide of potassium in doses of one-half to three grammes daily. He explains its effects primarily by its depressing action on the vaso-motor nerves and the cardiac plexus, producing a general ischæmia of the entire organism. In addition, a local action is exerted on the vesical mucous membrane from the presence of the salt in the urine. It has been found in this fluid ten minutes after its administration by the mouth.—*La Union Médica de Carácas*, July 16, 1882.

THE PORRO OPERATION IN ITALY.—Dr. Negir has published in the *Annali d'Ostetricia* some statistics concerning Porro's operation in Italy. Up to March, 1882, there had been thirty-eight operations, in fourteen of which recovery ensued and in twenty-four the patients died. Of the fourteen recoveries, six belonged to eight cases operated upon in the Maternità in Milan. These results cannot be said to be very encouraging, though the mortality may be reduced in subsequent operations.—*Racoglitore Medico*, August 20, 1882.

A PERITUBULAR LYMPHATIC SHEATH IN THE TESTICLE.—Professor F. Legge has discovered that the seminiferous tubules are invested with a lymphatic sheath, to which he gives the name of peritubular. It is formed of a continuous endothelial layer surrounding the tubule, whose surface is also covered with a similar layer of endothelium. Between the sheath and the tubule is a free space in which can be seen a number of lymph-corpuscles. This peritubular sheath can be most readily distinguished in the smaller animals, but the author has established its existence also in dogs, sheep, and man.—*Gazzetta Medica di Roma*, August 1, 1882.

THE THERAPEUTICAL EMPLOYMENT OF MAGNETISM.—Dr. D. Luis Barraquer, in *La Gaceta Médica Catalana*, August 15, 1882, favors the therapeutical application of magnetism, asserting that in many cases more speedy and definite results are obtained from its use than from that of electricity. He employs a powerful electro-magnet, capable of sustaining a weight of two hundred and fifty to three hundred pounds. The author relates the histories of two

cases in which definite lesions existed, and in which marked relief followed the application of the magnet. The first case was one of cerebral hemorrhage with consecutive hemiplegic contractures. The hemorrhage had occurred three years previously. One application of the magnet was followed by visible improvement, and after four sessions the forearm and fingers could be fully extended. The second case was that of a boy suffering from deafness, due to middle-ear disease following measles. Galvanism had been employed eight times with the effect of increasing the hearing distance from 0 to 1 foot. Magnetism was then tried, and, after a sitting of half an hour's duration, the hearing distance was increased to three feet. At the fifth session the watch could be distinctly heard at a distance of fifteen feet.

Iodoform in Chronic Broncho-Pulmonary Affections.—Prof. Chiaramelli claims for iodoform an almost specific action in pulmonary phthisis. It should be given in one-tenth-grain doses two or three times a day. The author believes that it lessens the amount of the expectoration and improves its character. At the same time the fever is reduced. The drug is also of value in the chronic bronchitis of the aged and in bronchorrhœa with pulmonary emphysema.—*Gazzetta Medica di Roma*, August 15, 1882.

Extirpation of a Mammary Adenoma with Continuance of the Gland Function.—Dr. José Armangué, in *La Independencia Médica*, August 21, 1882, reports the case of a woman, thirty years of age, who suffered from a large tumor of the breast. The integument covering it was normal, there was but little pain, and the axillary glands were not enlarged. The tumor, an adenoma, measured when removed seven and one-half inches in length and width by two and one-half inches in depth. The nipple was situated in its vertical axis at the level of its upper and middle thirds. This was dissected away from the tumor and left attached to the integument. After the healing of the wound all that remained of the mamma was a small portion of apparently atrophied gland tissue in the upper part. Two years later the woman became pregnant, when the breast began to enlarge, and, after delivery, secreted milk in abundance, the child being suckled indifferently with either breast.

Insanity Cured by Erysipelas.—Dr. Fritsch (*Jahrbücher für Psychiatrie*, vol. iii., 1882) reports two apparent cases of melancholia, which recovered after being attacked by a delirium resulting from erysipelas. The first patient had markedly depressing delusions but no hallucinations. The second patient had both hallucinations of hearing voices through a telephone and depressing delusions. The second case seemed to have systematized hallucinations, and although Fritsch says she was cured, she continued to be "nervous." It is probable that this was a case of monomania, and the supposed recovery a remission due to the erysipelas. He also reports a case of progressive paresis, which was markedly improved by erysipelas. Fritsch's cases, though quite interesting, are not exceptional, as similar ones have been reported by Esquirol, Sponholz, Nasse, and Macleod. That acute febrile disturbances sometimes exert a favorable influence on insanity has long been known.

Progressive Paresis.—Dr. Cullère, after an extended examination of progressive paresis, or, as he prefers to call it, dementia paralytica, in its relations to arterial atheroma and yellow softening, comes to the following conclusions: First, there exists a form of progressive paresis which is characterized at one and the same time by the ordinary lesions of meningo-encephalitis, and by those of cerebral senility, atheroma, miliary aneurisms, and patches of yellow softening. It is developed at an advanced age, follows a more or less slow course, and may rapidly terminate at the end of a congestive attack accompanied by acute maniacal excitement. It may be diagnosed during life by aid of the sphygmograph and aortic auscultation. The psychical and somatic symptoms waver between those of senile dementia and progressive paresis. Secondly, among certain senile dements there occur congestive attacks, which lead to inflammation of the cerebral cortex, and produce lesions, macroscopic at least, of progressive paresis. These fluxionary changes retrocede at times, and the symptoms of progressive paresis disappear, to give free play to those of organic dementia.—*Annales Medico-Psychol.*, 1882.

Action of Piperidin and Coniin.—Dr. Kronecker has made some comparative experiments upon the toxicological relation of piperidin and coniin, and found that between these two drugs a remarkable parallelism existed, as both substances are poisonous to nerves, paralyzing them. A parallelism also exists in their chemical reactions. Piperidin mainly paralyzes the sensory; coniin, like curare, the motor tract. Dr. Fliess has studied this more in detail, with the following results:

First—Piperidin.—In medium doses ($\frac{1}{6}$ of a grain) it removes the reflex irritability in about ten minutes. The reflex time by small doses is at first lengthened, and soon becomes normal. The inhibitory apparatus in the brain is not paralyzed. The central nervous organs are not paralyzed. The motor nerves are not affected. The paralysis is in the peripheral termination of the sensory nerves. Piperidin in large doses arrests respiration in frogs for a minute. The pulse-frequency after small doses of piperidin sinks to about two-thirds of the normal number. When piperidin is directly conducted through the heart it removes the heart-beat, but the muscular substance is not injured.

Second—Coniin.—It paralyzes first the peripheral ends of motor nerves; later, the centre. In the beginning it calls out an excitation of the inhibitory apparatus. The convulsions seen in warm-blooded animals do not appear in frogs, on account of the paralysis of the motor nerves. The frequency of the breathing is first increased and then diminished. The pulse-rate after small doses is also diminished. When coniin is conducted through the heart it does not affect the cardiac muscle.—*DuBois-Reymond's Archiv*, 1882.

Treatment of Gangrene of the Intestine.—At a recent meeting of the New York Medical and Surgical Society, Dr. Weir raised the question of treatment in intestinal gangrene, by relating the following case: About ten days ago a woman, aged thirty-five, was seen by him in consultation. Her physician stated that on the 10th of May last she was seized with colicky pains and vomiting. Passing his hand over her abdomen, he could discover no hernial tumor, but, as there was apparently intestinal obstruction, he gave opium freely, and repeatedly administered enemata. After four or five days a free movement of the bowels took place, and she

felt relieved. He discovered, the day before Dr. Weir saw her, a tumor in the left groin, and the patient then told him that this had first appeared, although temporarily, the preceding August. Dr. Weir found, on examination, that the tumor had all the signs of a stercoraceous abscess just below the femoral opening on the left side. On incising it, fetid pus and fecal matter were discharged. The sphacelated portion of gut, about an inch long, was laid open freely, and, as the fæces had free vent, nothing further was done. The patient was entirely relieved, and the sloughing cellular tissue had since come away, leaving a fistula discharging biliary matter. Dr. Weir thought that an artificial anus in this locality would be more likely to heal than if it had been at the site of an inguinal hernia. He found that the statistics of resection of gangrenous intestine, as done by Czerny and Gussenbauer, gave only about thirty-five per cent. of recoveries. He asked whether it were better simply to slit up the strangulated portion of intestine, hoping that the artificial anus would heal of itself, or, as had more commonly been done of late, to remove the gangrenous portion, and unite the upper and lower healthy segments. He believed that the older method would be preferable in most cases, and that the resection would be suitable for gangrene, either where it was so recent as to be unguarded by adjacent adhesions, or was due to an internal strangulation.—*The New York Medical Journal and Obstetrical Review*, October, 1882.

Muscarin.—Högyes has made experiments upon animals with muscarin and has arrived at the following results:

First.—Muscarin increases the excitability of striped muscle-fibre.

Second.—It depresses very rapidly the functional activity of the central nervous system, and lessens the excitability of the peripheral nerves.

Third.—The dilatation of the blood-vessels after an injection of muscarin is an immediate result of the paralytic action of this poison on the vaso-motor centre. Later, there ensues a depression of the activity of smooth muscle.—*DuBois-Reymond's Archiv*, 1882.

Cerebro-spinal Meningitis in a New-born Infant.—A young woman became affected with cerebro-spinal meningitis at the end of her pregnancy. She died after having given birth to an apparently healthy child, which presented, two hours later, symptoms of meningitis, followed rapidly by death. —Bambas, in *Progrès Médical*, No. 17, 1882.

Rapidity of Nerve-Force.—René has recently made experiments upon the rapidity of the transmission of nerve-force, and found it in man, as a mean, to be twenty metres per second. All the numbers expressing the rapidity of nerve-force in nerves, either sensory or motor, exhibit considerable differences, according to the individual, or the procedure, or the region excited, or even in the same individual. The intensity of the excitation is of great importance, the rate of transmission augmenting with it, especially in sensory nerves. For the motor nerves, when the excitation becomes strong, the rapidity diminishes. In locomotor ataxia there is a considerable retardation of rapidity of transmission of nerve-force, whilst in the beginning of general paralysis the rate is more rapid than normal.—*Gazette des Hôpitaux*, No. 46, 1882.

Noma Pudendi.—In the October number of the *New York Medical Journal and Obstetrical Review*, Dr. Anna Lukens reports a case of noma pudendi, which terminated in recovery. The patient was a female child, mulatto, three years of age, previously healthy, excepting an attack, when two years old, of acute articular rheumatism, complicated with endocarditis, from which she recovered with permanent mitral insufficiency. For six months previous to her last attack of illness the child's general health was remarkably good. On May 10, 1882, it was reported that she had been very restless and feverish, having had a chill the previous night. Attention was directed to the genital organs, which, upon examination, revealed a condition closely resembling aphthous vulvitis. The patches covered nearly the entire mucous surface of the labia majora and surrounding parts. The whole surface was of a grayish color, and covered with a thin gray discharge exhaling an exceedingly fetid odor. Sloughing of the parts occurred soon after, and increased rapidly, involving the perineum and extending back beyond the sphincter ani, and for more than an inch behind the anus. The inguinal glands were not affected.

The general condition of the child at this time was very unfavorable. There was great prostration, with complete loss of appetite, thirst, restlessness, and high fever, the temperature in the rectum ranging from 101.5° F. in the morning to 104° in the evening. The pulse was feeble, small, and frequent. The parts were swollen and extremely sensitive. Micturition was painful. This condition continued for three days, when a detachment of the eschars occurred, leaving a deep furrow on each side of the anus, with sharply defined, irritable edges. The right labium continued swollen and grangrenous for several days later. The constitutional symptoms began to subside soon after the separation of the slough occurred. Healthy granulations sprang up, and the healing process went on quite rapidly. In three weeks from date of attack the entire surface was healed, but not without considerable deformity. The sphincter ani was entirely destroyed, also a portion of the perineum. An irritable ulcer occurred within the rectum.

The local treatment consisted, first, in bathing the parts with carbolized water, afterward dusting them thickly with iodoform, with no other effect than correcting the fetor. Balsam of Peru was next applied, but with no better result. After this a preparation consisting of equal parts of pulverized gum, camphor, and balsam of Peru was applied twice daily, and the parts were covered with carbolized cotton and bandaged. The latter treatment gave apparently excellent results, as the progress of the disease was arrested, and the slough began to separate soon after and was rapidly detached. The constitutional treatment consisted in giving tincture of the chloride of iron and chlorate of potassium with quinine and stimulants.

Noma was not recognized by the older writers, but was, according to Bamberger, first described by Battus, a Dutch physician, in the beginning of the seventeenth century. The disease is one of unfrequent occurrence. West observed but seven cases among thirty thousand sick children, six of which terminated fatally. Vogel remarks that he has seen but five cases, of which only one ended in recovery. He also states that from eighty to ninety per cent. of the patients with noma perish in a few days. Noma pudendi appears to be of even rarer occurrence than noma of the mouth, or cancrum oris.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, November 11, 1882.

HEATON'S OPERATION FOR HERNIA.

We are all familiar with the remark of the renowned preacher, that it was neither right nor proper that Satan should monopolize any of the good tunes. It is consequently said that his choir was celebrated for its choice singing. The quacks, or rather such as we generally view as quacks, are in many ways in the same relation to us as was the Evil One to the candid and practical dominie. Hence, also, we are beginning to inquire into the reasons for the success of men whose ways are apparently dark, and whose tricks are mean. And often we do so with benefit. Several years ago a London surgeon was bold enough, in a little book on bone-setting, to say that he had fathomed some of the secrets practised by one of the professionals in that line; and more, that he had received instruction of the arch-innovator himself. And his book was a readable and instructive one, proving, as science is always capable of doing, that the days of miracle are passed, and that tact and common-sense are at the bottom of every success. The little work may have been read under protest, but still the facts it disclosed were useful all the same.

Whether emboldened by this example or not, it is certain that since then many reputable men have taken occasion to investigate other matters of quackery and give science any advantage which may come of it. For instance, the popular treatment of piles without pain has been rationally explained by the hypodermic injection of carbolic acid. Then, again, the so-called cancer cures have been duly weighed in the balance of experience, and even the anointing oil of the popular Hebrew saint has been subjected to the searching analysis of a distinguished chemist.

Several years ago the surgical world was somewhat surprised to hear it whispered around that a man named Heaton actually cured some cases of hernia by simply injecting a fluid along the inguinal canal, thereby producing an inflammatory exudation which plugged up the said canal. The facts were stubborn, and when opportunity offered the method was conscientiously studied by Davenport, who published a little work on the subject, with the consent of the author, who furnished him the data. It was then discovered that the fluid used was mainly a decoction of white oak-bark, and that the operation for its introduction was comparatively simple.

There were two elements that lent mystery to these cures, viz.: the secrecy of the preparation used and the pretension of special skill in the performance of the operation. Both of these mysteries were solved, and by various articles in the journals the means of cure were placed in the hands of every surgeon who desired to operate by that method. In all frankness it behoves us to say that the operation does sometimes cure; not in any such proportion as claimed by the originator, but certainly enough to claim for it a recognized means to a desirable end. In Dr. Bull's elaborate and practical paper in the present number the general average of good results equals a little less than one-third. This, taking into account the general run of cases, may safely be considered the average experience of other surgeons. The paper in question will tend, however, to increase the statistics of the operation for hernia by directing attention anew to the Heaton method, and popularizing it, so to speak, among surgeons who, not believing in it, were not disposed to try it.

It does not appear to be necessary to use the oak-bark mixture as an injection, as alcohol has answered equally well in the hands of Schwalbe and others, and there seems to be no good reason for supposing that pure carbolic acid may not be utilized in the same way. At least the experience of Levis in his treatment of hydrocele by injection of the latter acid should have considerable weight in weighing the chances. But whatever fluid may be used, the method of injection is fortunately quite simple, and is unattended with danger in the hands of any competent surgeon. It is hardly to be expected that the percentage of cures will be increased, but even as it is the gain is something.

THE HOME PRODUCTION OF QUININE.

The "protective" atmosphere of Philadelphia makes itself felt even in the medical profession. While one journal is ardently advocating the re-establishment of a duty upon quinine, another now starts a propaganda in favor of the home cultivation of quinine-bearing plants. We are an ague-ridden people, according to the Philadelphia *Medical Times*, and were it not for quinine, ten per cent. of the population in some parts of the country would be sick every autumn. Three autumn months without qui-

nine would probably witness, says our contemporary, more deaths from malaria in the United States than yellow fever has caused among us during the century. Over a million of ounces of quinine, on an average, are used every year in the United States, which is very nearly a full anti-periodic dose to every inhabitant. It is a question of much importance, therefore, to have this drug cheap. Furthermore, says the *Times*, in a somewhat startling manner, what should we do if our supplies were cut off by a war?

It is plain that cheap quinine and home-raised quinine would be a very desirable thing. The attempt to cultivate cinchona, however, is quite out of the question, and the possibility of producing quinine in the United States has until lately seemed very slight.

Within a few years large quantities of what is known as the cuprea barks have been introduced into London and this country. They contain from one to two per cent. of quinine and a characteristic alkaloid called cinchonamine. They are quite free from the inferior alkaloids. These barks are obtained from small trees or shrubs belonging to the genus *Remijia*. They grow in two distinct regions, one the basin of the Magdalena River, in the province of Santander, Brazil, the other in the basin of the Orinoco, among the mountains which constitute the eastern branch of the cordilleras of the Andes. They grow in a dry climate and at only a slight elevation above the sea. There is, therefore, a prospect that we may be able to acclimate them in certain portions of the United States, such for example as Southern California or some of the Gulf States. They are said to be rapidly disappearing.

It is very well known that, so far, the attempts of our Government, as represented by the Agricultural Department, to acclimatize foreign plants, have failed, or nearly so. Still, this proceeds, we believe, more from political peculiarities than from any climatic faults. If the statements made regarding the *Remijia* are correct, there is no reason to doubt that it can be grown upon our soil. Certainly the country needs quinine, and a great deal of it. We do not feel any serious alarm over possible wars or anti-periodic blockades, but any measure which will cheapen quinine deserves the strongest encouragement. We would second the suggestion that Congress, or the Agricultural Department, undertake the experiment of raising cuprea bark.

EXPERIMENTING UPON THE ARABS.

The project of utilizing the Arabs for purposes of experimentation has been advocated by M. Bouley before the Académie de Médicine. Some weeks ago M. Peuch announced that by diluting the secretions of the tag sore (claveau) in sheep, and then injecting a small amount subcutaneously into healthy animals, he could give them immunity. Furthermore, this immunity was obtained without producing any actual symptoms of the disease inoculated. The experiment was tried upon seventeen sheep, with success in every case. It was affirmed on the basis of these experiments, and of similar experience with inoculations for bovine pleuro-pneumonia and charbon, that immunity against a contagious disease may be obtained by suitable inoculations, *without the production of any of the ordinary symptoms of the disease.*

Reasoning from this alleged fact, M. Bouley conceives that he can perhaps improve upon the now somewhat old-fashioned practices of Jenner. It is possible, he thinks, to take the virus of small-pox, dilute it and inject it subcutaneously, with the result of giving immunity against variola, without there being any constitutional or cutaneous disturbance whatever. But it would be necessary to make some experiments upon human beings first. M. Bouley, therefore, like Mr. Gladstone, turns his longing gaze toward Africa. The Arabs have, as a rule, been obstinately opposed to vaccination. They recoil from allowing the impure blood of the Giaour to be mingled with the sacred juices of the faithful; consequently there has been a great deal of small-pox among the various Arab tribes. Although this prejudice has disappeared to some extent, there yet remain many who will not submit to vaccination. To accommodate the religious idiosyncrasies of this class, M. Bouley proposes to experiment with dilute inoculations. M. Bouley's project is interesting and deserved a kinder reception than it got at the Académie, since it was not proposed to experiment upon the ignorant or the unwilling. It will no doubt be attempted in course of time. Meanwhile it is apparent that the crying need of pathological science to-day, is a class of martyrs who will submit to scientific experimentation.

KENTUCKY INSANE ASYLUMS.

Much discussion has been going on in the Louisville press, lay and medical, over certain troubles in the Central Insane Asylum at Anchorage, Ky. It appears that this model institution has been retaining as lunatics two persons now alleged to be perfectly insane. The Grand Jury has also indicted one of the attendants for wilful murder, by "ducking" a patient, and the charge of gross malfeasance in office has been brought against the superintendent.

Investigations have shown that the institution in question has been conducted very much as though it were a prison instead of hospital. Some six hundred lunatics and epileptics are kept in promiscuous thraldom within its mismanaged limits. The charge of caring for all these has been intrusted to only two physicians. The whole institution appears to have been organized and conducted largely on the

prison-house methods, at which Pinel revolted ninety years ago. Surely, the world moves slowly in some parts of Kentucky.

There is much evidence, however, that the medical men are not all to blame. Judging from the comments of our Louisville contemporaries, politics is very largely at the bottom. From the testimony given it is clear that the State itself makes very inadequate provision for the care of her insane, and also that what she does is done very badly. Two years ago one of the asylums reported itself as having too much money, and as in a condition generally of smiling surplus and peace. At the same time the Anchorage Asylum was hampered with insufficient funds and overcrowded wards. It had, says the report, a beautiful milk-house, and a new and improved coffee apparatus, but a mortality of nine per cent., and a ratio of cures one-third less than the average in asylums. A year ago the State Society called attention to the bad condition of insane asylum affairs, and it is somewhat strange that, with a medical governor, nothing was done. The investigations and agitation now going on come none too early. It is greatly to be hoped that our Kentucky brethren, who do things well when they really set at work, will not leave the present matter until some very radical improvements are made.

VACCINATION OF IMMIGRANTS.

According to a report of the National Board of Health, there were inspected in the States of Indiana, Illinois, and Missouri during the month of September, 1882, 14,404 immigrants, of which number 2,918 were found imperfectly, or not at all protected against small-pox, hence liable to contract and propagate the disease. Of these 234 had *never* been vaccinated, and many of them were adults. On September 6th Inspector Starkweather notes the following case: Found a case of modified small-pox in the person of a single woman, thirty-nine years of age, coming from a small town near Manchester, and bound for Neenah, Wis. She had been vaccinated only once, and then in infancy. She presented a card stating that she had been vaccinated on the steamship Scythia (Cunard Line), duly signed by the surgeon of said ship.

On the other side was printed the following in English and four other languages: "Keep this card to avoid detention at quarantine and on railroads in the United States." In this instance sixty-five adults were vaccinated who had been exposed on the train. There were three cases of small-pox in Ford County, Ill., referred to in the last report, due to the importation of immigrants. One of these cases terminated fatally. Appended to the report is a long list of vessels which have brought to this country a large number of unprotected immigrants, susceptible to small-pox. To divert this danger, a protective measure—that of vaccinating just before leaving port, or during the passage to America, has been adopted. While the plan is a good one, its prosecution has been attended with gross carelessness in many instances, as shown by the last report. It is found that passengers arriving by vessels of the same line are not equally well protected. One surgeon will have made a careful inspection and have vaccinated and re-vaccinated all unprotected or doubtful cases, while another will have been so indifferent to subsequent results, as to have given "Cards of Protection" to those who were either very superficially inspected and not vaccinated at all, or vaccinated with unreliable virus. Now, if the Steamship Medical Service is to be of any real value in preventing the generation and multiplication of cases of variola in our Western States, it must exercise greater vigilance in the discharge of its duties than it at present manifests. To remedy the evil it would be well to vaccinate *just before*, or immediately after sailing, in order that the surgeon may have time to test the quality of the virus, and the value of the operation, and thus be able to report intelligently and truthfully the condition of each immigrant. It also appears that the inspection service of vessels arriving at Boston is superior to that of the New York lines, the former representing a very desirable standard, for there has been in Illinois but one case (a mild varioloid) attributed to Boston in something over one year. In the three States already referred to, as well as in Chicago and St. Louis, the Immigrant Service is to be commended for the efficient work it has done in providing facilities for the care of those affected with small-pox, and for instituting a rigid inspection, and enforcing a careful vaccination in *each* case requiring attention or operative interference.

THE GROWTH OF CHILDREN.

Some interesting facts in relation to the growth of children are furnished by Geo. W. Peckham in the "Sixth Annual Report of the State Board of Health of Wisconsin." It considers first the laws of growth, recognizing the physiological truth that the size of an organism is modified by waste and repair, and that in proportion as reintegration exceeds waste does the body increase in size up to a certain period. Besides these two general laws, there are external forces which determine the rapidity of reintegration and disintegration, and it is found that these various influences do not act with the same degree of intensity at all periods of growth, or affect equally both sexes. In youth, if the conditions be normal, the process of waste is exceeded by that of reintegration, hence the organism increases in size. If, per contra, the hygienic conditions be unfavorable to normal growth, the body must be sub-normal in bulk. Starting with these as facts, statistics are given to show the results of investigations. They are:

First.—The rate of growth in the two sexes is such that the boys are taller until the twelfth year, and heavier until the thirteenth; between thirteen and fifteen the girls are taller and heavier; after the age of fifteen the boys excel the girls both in weight and stature. Girls nearly cease to grow when about seventeen years old.

Second.—Children of pure American descent are taller than children of foreign parentage, but they are lighter.

Third.—The height of American-born men is shown to be more modified by the conditions accompanying *density* than by all other influences, race excepted.

Fourth.—The body of the girl is shorter than that of the boy, until the tenth year, thereafter greater, until the sixteenth. From fifteen to eighteen, the bodies of the girls grow two inches, the bodies of boys over four. For the lower extremities, at nine years those of the girls are longer, at eleven shorter, and from twelve to fourteen longer. At fourteen the lower extremities of girls almost cease growing, while those of the boys increase by four inches between fourteen and nineteen. In this connection we naturally think of the question, Is development of the brain commensurate with this physical growth of the body, and are the same general principles involved in each instance? Let us recall what development is, and what are the conditions most favorable to such a process of natural evolution. By development we mean a process by which an organ is formed, or by which one already formed is fitted for higher and higher functions, till finally it shall exist in a state of perfection. To this end there must be just enough stimulus applied to maintain the organ in a state of normal activity in its co-operative development with other important organs. When such an equilibrium is interfered with by a stimulus which induces excessive vital action, there must follow a hyper-normal disintegration, resulting finally in permanent impairment of function. During this time there may be a sufficient expansion of the mind to meet the unreasonable demands made upon it, but the high tension must eventually produce a general lowering of the vital forces, because of affecting primarily the organ upon whose integrity the entire organism depends for its highest expression of well-being. Such a condition is the product in many instances of our present public school method of instruction.

THE NATIONAL MUSEUM OF HYGIENE.

SEVERAL years ago, when the Parkes Museum of Hygiene was first opened in London, we advocated editorially the establishment of a similar institution in this country. The subject fell dead at the time. Within the past year, however, much interest has been shown in the matter, and such a museum has been organized under the efficient care of the energetic Surgeon-General of the Navy. Congress, during its last session, gave $7,500 to help the institution. At the recent meeting of the American Public Health Association the subject was brought up by Dr. Gihon, and it was suggested that a permanent committee be appointed to forward the success of the museum. The Association gave the plan a hearty endorsement and will make the museum the depository of its own collections. A library is to be connected with the exhibition, and this will materially add to its value. Altogether there is a promise that, before many years, our country will possess a permanent sanitary exhibition which will be of great practical interest as well as creditable to us as a nation.

Reports of Societies.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, October 10, 1882.

DR. T. M. MARKOE, PRESIDENT, IN THE CHAIR.

DR. W. T. BULL read a paper (*vide* p. 451) on

HEATON'S OPERATION FOR THE RADICAL CURE OF HERNIA.

DR. R. F. WEIR presented a record of forty-one cases in which he had operated, with fourteen cures. The record was more or less imperfect, because of the great difficulty in keeping track of the patients, most of whom were treated in a hospital. The dates of cures varied from four and a half months to over two years; the majority were under one year. The cases were divided chronologically into two series. The first contained twenty-eight cases, of which eight were successful, and the others were marked improved. In the list all the so-called improved cases were classed as failures. He did not place much reliance upon the results obtained in the first twenty-eight cases, because it required some time to properly carry out the technique of the operation, which he had found not an easy one to perform. It was not an easy matter to throw the fluid deep into the canal. The timidity which he experienced in his earlier cases in placing the instruments sufficiently near the internal ring, in using Davenport's needle, he had overcome to a certain extent by the employment of DeGarmo's modification of Heaton's needle. With this instrument, with the needle considerably enlarged and strengthened, and the syringe itself slightly changed, he had been able to reach the deeper portion of the canal and discharge the fluid without as much risk as seemed to attend the use of the other instrument; therefore, he considered more reliable the second series of cases, thirteen in number, in which he had obtained six cures, and in two the condition was so improved that the patient was able to wear a truss, which was impossible previous to the operation. In five cases the operation failed completely. In two of these cases the openings were very large, and the operation was purely experimental, hoping only thereby to reduce the size of the opening so that the patient could wear a truss. Four of the successes,

however, were of too short duration to be fairly used in deductions. The fluid first used was Heaton's, but that employed in the last series was Warren's. In all the cases the hernia was inguinal. His failures he attributed, first, to timidity through lack of experience in introducing the point of the needle deep into the canal; and second, from regurgitation of the fluid along the track of the needle as it was withdrawn. He had found that unless he could get a perceptible impulse of the needle through the deep layer of fascia, a hardened cord which resulted from the injection distinctly followed toward the skin. When this occurred failure frequently took place. He did not at present feel so much encouraged with regard to the beneficial results that might be expected as he did in his earlier operations. He could hardly estimate the good results as high as Gay and others, but thought sufficiently well of the operation to urge its continuance on the members of the Society. Little or no risk was encountered, and he believed that the recent experience of Schwalbe in injecting alcohol frequently (the fluid preferred by him) contained a hint for surgeons to follow in practising Heaton's method. He should himself hereafter resort in difficult cases to repeated injections, instead of the two or three advised.

Dr. L. A. Stimson had operated upon one patient in 1879. The hernia was a large inguinal one, and the external orifice admitted two fingers. Three injections were made. The first two produced no reaction whatever. The operations were performed with Heaton's syringe and solution. The third injection was followed by inflammatory reaction which lasted twenty-four hours, and was attended with considerable local induration. The patient was kept in bed about three weeks longer for other reasons, but within a month following the last injection the hernia came down while he was still in bed, although not so large as before the operation. During the interval between the third injection and the descent of the hernia there was a large mass in the inguinal region which steadily diminished in size. The patient did not wear a truss after the injection. Dr. Stimson regarded the case as a failure.

Dr. James L. Little had performed the operation four times. The first case was that of a child, and the operation was a failure, owing to the fact that the point of the needle did not enter the external ring, and the fluid was thrown into the tissues outside.

In the second case the injection caused a deposit which plugged up the ring. Two weeks after the operation the hernia did not come down, the patient left the hospital and has not been heard of since.

In the third case the patient entered the hospital with a large scrotal hernia in a strangulated condition. This was reduced by prolonged taxis under the influence of an anæsthetic. In this case the external ring was very large, so that the scrotum could be invaginated by the finger some distance into the canal. Ten days after, Heaton's operation was performed, and, as in the first case, the needle failed to enter the ring, and the induration took place in the tissues outside, producing no effect upon the hernia. A second operation was performed about a week after, and was more successful; the fluid was evidently thrown into the hernial sac, the induration extending down to a point just above the testicle and upward into the canal. Five months afterward there had been no return of the hernia, the hardened mass had nearly disappeared, and no opening could be felt in the ring by invaginating the scrotum. The patient has discarded the truss.

The fourth case also entered the hospital in a strangulated condition; was reduced by taxis. This was a very large scrotal hernia, and the external ring was of considerable size. Although the utmost care was exercised the injection was thrown directly into the sac, which became filled with deposit and extended down to some distance below the testicle, and the hard induration was also prolonged upward into the canal. This patient four weeks after the operation was going about without a truss, and the induration was slowly disappearing.

He agreed with Dr. Weir as to the difficulty of introducing the needle so as to throw the injection into the situation advised by Dr. Heaton. These two cases, however, showed that there was very little danger if the injection was thrown directly into the peritoneal sac. In both of these cases there was a slight rise of temperature after the operation, and some local tenderness in the vicinity of the external ring. In all these cases he used Heaton's fluid and Heaton's syringe, except one, when he introduced the hypodermic with the greatest care. He believed the operation to be a safe one, and worthy of further trial. He knew of one case in which Heaton operated some years ago, which has remained cured ever since. He agreed with Dr. Weir in regard to introducing the point of the needle so as to throw the fluid into the proper place and produce tendinous irritation.

Dr. H. B. Sands inquired concerning the *rationale* of cure in cases in which it took place, and as to what was meant by tendinous irritation.

Dr. Bull said it had been claimed that white-oak bark caused contraction of the fibrous tissue and therefore it was deposited in the neighborhood of the fibrous tissue, which undoubtedly existed in the walls of the inguinal canal. That was the pathology which had been given by Dr. Heaton, which Dr. Warren had asserted was the invention of Dr. Davenport, of Boston.

Dr. Sands asked if it was supposed that the cure was brought about by the deposit of plastic lymph.

Dr. Bull replied that he was unable to see how that question could be settled without pathological demonstration. There was a plug of exudation in the inguinal canal after the injection, and it was greater in area than the material injected. It was fair to assume, therefore, that there had been a certain amount of plastic exudation produced. Whether there had been an actual contraction of the rings, he thought it impossible to say. But he thought all who had examined these cases would agree that at a later date the size of the ring, as evidenced by the introduction of the finger, was unquestionably smaller than it was before the operation. In some instances it seemed to be absolutely closed. Whether this result was due to a tonic contraction of the fibrous tissue which lasted indefinitely, or whether it was brought about by a process of inflammation, he was unable to say. In the method proposed by Schwalbe there seemed to be a certain amount of pathological reason, because it was well known that repeated injections of alcohol into fibrous tissue would cause a cirrhosis of that structure. There was a certain amount of alcohol in Heaton's fluid, and perhaps this was sufficient to produce a plastic deposit which has a tendency to contract afterward.

Dr. Weir thought there was an inflammatory deposit which plugged up the canal more or less. He

also regarded the suggestion of repeated injections made by Schwalbe an important one.

Dr. Stimson thought that in old cases of hernia the operation could certainly do no good, and believed that whatever of success had been obtained, had been in those cases in which there was a distinct inguinal canal and the hernia was small.

Dr. Bull remarked that in all his successful cases there was no extensive protrusion, and that there was a distinct canal with two distinct openings.

Dr. Stimson thought that the inflammatory deposit made about the canal would render the descent of the hernia more difficult than before the operation.

Dr. Little thought that the dressing had something to do with the result. When a compress and bandage were applied and considerable pressure made upon the walls of the canal, plastic exudation was thrown out and organization probably took place, and in that manner the canal was closed.

Dr. Briddon's experience had been limited to three cases, all of which resulted in failures. He thought there could not be any contraction of the tendinous structure produced by the fluid. He believed that the diminution in the size of the ring could be explained by the cessation of the dilatation, the result of the constant presence of the hernia.

Dr. V. P. Gibney, on invitation, said his experience consisted simply in observing the progress of the cases operated upon by Dr. Bull and Dr. Weir, and to him it had been rather satisfactory. Any one who had had experience in applying trusses to dispensary patients, he thought would appreciate the assistance given by Heaton's operation. Several cases which he had observed were practically unmanageable in this respect, either that the hernia itself could not be retained by the use of the truss, or else that the patients themselves were of that class which is unmanageable. But after one or two injections these patients had been able to wear the truss with a small pad and a light amount of pressure, and in that way they had been made comfortable. His impression was that the results which had been obtained had been permanent, although he had failed in many cases to ascertain what the final results were. As to the number of positive cures he had no experience to relate. He thought the operation was one which should be performed, even if a cure was not effected.

Dr. L. S. Pilcher said that his knowledge of the operation came through one of his acquaintances, who was operated upon for inguinal hernia by Dr. Heaton between fifteen and twenty years ago. The exact character and extent of the hernia he was unable to give. The result was complete relief, which had been permanent. He had been able to persuade but one of his patients to submit to the operation. A young man, seventeen years of age, who had an inguinal hernia, slight in extent, but which had been present for at least five years, submitted to the operation. He was still using a retaining truss, but there had been no reappearance of the protrusion. Of course, it could not yet be stated what the ultimate result would be. In the course of the observation of that case one or two points presented themselves which he thought were worthy of mention. The first was with reference to the character of the instrument to be used. In Dr. Warren's writings, considerable stress had been laid upon the possibility of penetrating blood-vessels with the sharp edges of the needle. The instruments spoken of were such as were intended to be thrust through the skin, and for that purpose necessarily should be considerably sharp. Then they were pushed forward through the connective tissue of the inguinal canal, and finally reached the point at which the fluid was to be deposited. It was, therefore, not to be wondered at that when pushing a sharp instrument along, one should be somewhat fearful lest the manipulations did damage, for he could readily conceive that an artery might be penetrated, or the instrument might be made to pass into the peritoneal cavity. This difficulty presented itself to him in his own case, and he had his needles blunted to such an extent that it was necessary first to make a small opening in the integument and then he was able to pass his blunt-pointed needle along through the tissues without fear of its penetrating the vessels or passing into the peritoneal cavity. Perhaps this precaution would avoid the accident of going outside of the canal. The second point was with reference to the amount of irritation. Dr. Heaton, in his writings, had cautioned particularly against the production of undue irritation, and claimed that if much irritation followed the operation, so much that there was a distinct inflammatory reaction, damage was done, and a successful result was not to be expected. Dr. Warren, on the other hand, had said that it was necessary to have considerable inflammatory reaction, and that unless such reaction was obtained, no benefit would result from the operation. His fluid for injection, therefore, was more irritating than that recommended by Dr. Heaton. Dr. Pilcher asked for the general experience of the members upon that particular point: Which was produced in those cases where the best results were obtained, a marked or only a slight degree of inflammatory reaction?

Dr. Briddon said that a practitioner with whom he had a conversation two or three years ago, told him that he had been present at quite a number of operations performed by Dr. Heaton, and that uniformly the results had been remarkably good.

Dr. Bull said that in only one instance had he succeeded in provoking an excessive amount of irritation, and by that he meant such a degree of inflammatory reaction as manifested itself by swelling, redness, and great tenderness over the point where the injection had been made. He should say, in general, that the cases did best in which a moderate degree of reaction had been excited. He felt inclined to strictly follow the directions given by Dr. Heaton, and to make a second injection in case there was not sufficient local reaction produced by the first, that is, sufficient to give rise to moderate tenderness. He had repeated the injection on that principle in two out of five cases, in which the operation was successful.

Dr. Weir believed that he had made a mistake in not repeating the injection. In one of his cases, in which there was more than the usual reaction, the result was very good.

The President said he had had only a limited experience in this operation. He had performed it some eight or ten times, and his thoughts were early directed toward the danger accompanying the passage of the instrument and the risk of wounding important parts by the sharp point. This was particularly impressed upon him in his first case, which was one of femoral hernia occurring in a lady who was rather fat. He did not dare to use a sharp instrument by plunging it into the groin, lest he might wound the femoral vein, and had made for

himself an instrument considerably longer and stouter than either of the needles which had been exhibited. It was made of steel, with an olive-shaped point, having a central opening through which to inject the fluid. This instrument he used by introducing it first through a little puncture made with the bistoury. He operated twice upon the patient with great ease and satisfaction, as far as the operative procedure went. He had used the same instrument in cases of inguinal hernia, and thought he should not use any other, because it was stronger and could be readily manipulated, and could be freely passed in all directions without danger of doing damage.

Another suggestion was one founded upon his idea of the rationale of the treatment. He believed that the entire success of the method depended upon the formation of new tissue as a result of the lesion caused by the instrument and by the deposit of an irritating fluid in the wounded parts. If that was the case, then it was desirable that the quantity of effusion should reach a certain amount, and that the quantity thus poured out should remain in the situation for a certain time, where it could organize and subsequently contract. Reasoning from these data, it had seemed to him that pressure applied over the part would have the effect of causing absorption of the new material, and would do away with the very result we wished to accomplish. Commonly the hernia could be prevented from descending by the position of the patient in bed. In most of his cases, therefore, he had left the fibrinous effusion to be organized in the inguinal canal without interference, by pressure, keeping the patient in bed, if possible, two or three weeks. He was unable to state the exact results, as all but one of his patients were hospital patients, and they soon disappeared from under observation. The plastic exudation in none of them extended into the scrotum to any extent. There was nothing more than a finger-like process extending down toward the external ring.

TRAUMATIC PHRENIC HERNIA.

Dr. A. C. Post narrated a case as follows: A female patient, nineteen years of age, fell out of a third story window and received a very complicated injury. There were fracture of the lower jaw, fracture of the left humerus, bleeding from the mouth and nose, and severe shock. These were followed by passage of bloody urine and severe abdominal pains, by very urgent dyspnœa, extreme orthopnœa, with tympanitic resonance on the left side of the chest, and the patient died on the fourth day after the injury. There was found at the autopsy a small opening in the diaphragm, on the left side toward its posterior part, through which a portion of the stomach, a portion of the splenic flexure of the colon, and nineteen feet of the small intestine had passed into the left pleural cavity. Probably the passage had been gradual. The urgent symptoms, except shock, were not observed in the beginning. The left lung was pressed toward the upper and posterior part of the thorax, and weighed only eight ounces. The right lung was hyperæmic and œdematous, and weighed nineteen ounces. Dr. Post regarded it as a remarkable instance of traumatic phrenic hernia.

EXCESSIVE REACTION IN A HYDROCELE TREATED BY INJECTION OF GLYCERINE AND CARBOLIC ACID.

Dr. Post also narrated a case as follows: Four weeks ago a man about fifty years of age called upon him with a large swelling of the scrotum, larger than a single fist, in which there was fluctuation. There was no distinct translucency. It was a case of hydrocele of twenty years' standing. He punctured it with the trocar, drew off a quantity of clear fluid, and then injected the sac with about three drachms of a fluid consisting of equal parts of glycerine and carbolic acid. On the following day the patient came to his office and there was about the usual amount of inflammatory reaction, and the progress of the case seemed to be favorable. On the next day the patient was not well enough to go out, and when Dr. Post visited him he found an enormous distention of the envelopes of the testicle. There was a livid discoloration, and the swelling was painful and heavy. He felt somewhat alarmed about the condition of the patient, but the swelling gradually subsided and now the man was able to go about, wearing a suspensory bandage. There was a greater amount of reaction than he had ever seen in a case of hydrocele treated by injection. In answer to a question Dr. Post said it had been his custom to allow patients to walk home after being thus treated for hydrocele, and with the directions that they should lie down and remain in a recumbent position for a few hours; if then there was no pain or tenderness, that they might get up and walk about, and perhaps apply friction to the part. If there was much tenderness and pain he gave directions that the patient retain the recumbent posture. He had not seen excessive reaction follow the injection of tincture of iodine.

SCIATICA AND CRURAL NEURALGIA.

Dr. Post also reported a case of sciatica of six years' standing. The patient had received the ordinary variety of treatment without benefit, and he came for the purpose of having the sciatic nerve stretched. Dr. Post bandaged a splint to the posterior part of the limb and then flexed the entire limb upon the trunk, but was not satisfied that he stretched the nerve. At least the patient was not benefited by the procedure. About four weeks ago he exposed the nerve by an incision and applied traction in both directions, graduating the force by means of a spring balance. This he did at the suggestion of Dr. McBride. The force applied was forty pounds, and applied very gradually in both directions, first to the proximal end downward, and then to the distal end upward. The patient during most of the time since the operation had remained in bed, although for the last two weeks he had been allowed to take some exercise. There had been no return of the sciatic pain in the upper part of the limb, but there had been a certain amount of paralysis, both motor and sensory, in the lower part of the foot and leg, and traumatic pains in that region. The partial paralysis was gradually disappearing, although a considerable amount remained. It was too early yet to determine what the ultimate result would be.

Dr. Post also referred to a case of anterior crural neuralgia of three years' standing, in a patient of about fifty years of age, in which he advised the application of the actual cautery. It was applied along the course of the nerve from the groin nearly to the knee, and also upon the leg at a few points where it was painful. Thorp's multiple cautery, having six points, was used, and it was applied at eighteen different places, making in all one hundred and eight minute punctures. He saw the patient eight days after the operation and the relief had been complete.

VESICAL CALCULUS—RAPID LITHOTRITY.

Dr. L. A. Stimson presented a stone removed by the rapid operation from the bladder of a man sixty-two years of age. There was nothing specially noteworthy in the clinical history of the case. The stone was composed of urates, weighed 562.5 grains, and measured at the first catch four centimetres. The lithotrite used was one which Dr. Keyes had devised. The beak of the instrument was almost square, the tip being curved as suggested by Dr. Bigelow. The female blade was largely fenestrated, the male blade deeply notched, and it went entirely through the fenestra of the female blade. The catch in the handle was double; the screw was a rapid one, moving one inch in three turns. The evacuating-tube which he used was also devised by Dr. Keyes, was straight, measuring 28 French. It consisted of a straight tube fitted with a staff having a flexible rubber end, an inch and a half long, with a permanent curve like that of an ordinary sound. The flexible rubber end projected beyond the end of the tube, and was intended to facilitate the introduction of the instrument. This evacuating-tube, which was a new device, delivered extremely well, and seemed to overcome the difficulty which had sometimes been experienced, namely, delay caused by fragment of stone becoming lodged in the eye of the instrument. The man was discharged cured on the sixth day.

Dr. Keyes remarked that heretofore he had not been satisfied with any lithotrite except one which had an open beak, as all others were liable to become impacted. There were two additional difficulties occasionally met with in practice—first, the male blade did not catch perfectly well about a smooth stone, and second, it was sometimes difficult to introduce the instrument when the prostatic urethra was rigid. To meet these two difficulties he had devised the instrument exhibited, the male blade of which was really Reliquet's blade, and the female blade was fenestrated and had Bigelow's curve at the beak. With this beak he had been able to pass through a rigid prostate with perfect ease. The straight evacuating-tube he thought was desirable because he had experienced considerable trouble with curved tubes in having pieces of the stone lodge in the eye, necessitating the withdrawal of the instrument, as other fragments could not pass through, and in withdrawing it the urethra was liable to be torn if the fragment projected.

The Society then proceeded to the transaction of miscellaneous business.

Hospital Saturday and Sunday Association.—At a recent meeting of the Hospital Saturday and Sunday Association, important amendments to the constitution were approved by the eleven members of the association present. It was agreed to amend Article II. by substituting an article providing that no hospital with less than twenty beds in its wards shall hereafter be admitted to the association. It is also provided that each hospital shall be entitled to an additional vote for every fifty free beds in its wards. These amendments are inoperative without the written assent of eight more of the members of the association, nineteen votes constituting a majority. The association is preparing to do a greater work this year than ever before, and it is believed that the Hospital Saturday and Sunday subscriptions will be largely augmented this season.

Correspondence.

GYNECOLOGISTS AND VIRGINS.

To my Friend Andrew.

Some time last week I found in the post-office your postal, the book-lists I had asked for, and a pamphlet in dull green covers. The upper right-corner of the pasture-lot was fenced off, and therein I learned that you youself were the parent of the enclosed idea (for, as I have noticed, such literature consists of one idea, more or less new, diluted with old stock, as Marion Harland directs to make new soup by adding some savory article to what was left over from yesterday).

The extreme modesty of the title, thus shrinking up into one corner of the cover, befitted well the pages within, where each little island of verdant text seemed to lose itself moderately in an ocean of margin.

In fact, it was your monograph "On a New Method of Removing the Cervix." Though why this general rage against the cervix, by which every one has a new way of cutting, sewing, or basting the humble part?

However, I congratulate you upon this your first public appearance.

So you are a specialist, a gynecologist! You've seen a flock of sheep circle around, a confused mass of doubt, until one starts to jump the fence, and then the whole flock with marvellous decision of character, so out of keeping with their hesitation of a moment ago, follow. Where? Oh anywhere, anywhere where they all go.

Come now, don't you think the boasted division of labor which, our philosophers tell us, is both a means and a result of our high state of civilization, has in it, at least as it develops itself in the formation of medical specialties, a good deal of that impulse common to gregarious animals?

Why have you so suddenly come out as a specialist? Why, because they all do it; and, old chum, between us, I'll tell you another reason. You think you see your way to have patients sent to you by other doctors, to whom be sure you will from time to time send "the compliments of the author." But be very careful you don't send 'em any of your patients. Well, yes; you might send them some incurables or "malades imaginaires," *to get their opinion*. But the good ones, the paying ones—"Oh there are some of my old families who will insist on having me." That covers them, you see.

You say you have made a special study of it. Oh, of course.

So you are a gynecologist!

Andrew, your daughter is a fine girl. She has the beauty of face and mind and character that careful nurture and training can give her. I doubt not you have trained her to be self-reliant and the defender of her own honor by the force of her own will.

But who are going to be your patients? Have you foreseen the mothers who will bring their daughters to you, the young girls who will come to you?

Factories, sewing-machines, long hours' standing behind counters, hanging out clothes barefoot, hard toil, scant wages, and many sorrows—these are the causes that send them to you; and they all come to you because of some derangement of the generative

organs. And what are you going to do to them? You are a specialist, but before all you are a physician; and let me warn you never to forget it. Not only do they come to you for treatment, but they trust you, and before you make that vaginal examination which you look upon as a necessary preliminary to making your diagnosis, stop and imagine the shock which your own daughter would experience were she to be obliged to submit to it.

"Oh," you say, "but she is of a refined nature." Andrew, the instinct of modesty is not confined to the cultured; such have a double guard in instinctive modesty and a trained will, but the only safeguard of the uneducated is that instinctive feeling which always exists once.

Want, poverty, hardship, often a pretty face or form, and all manner of temptation drive the daughter of the poor toward ruin, and instinctive modesty is the one sole safeguard. Do you think you can venture to first shock, and then, by repeated vaginal examinations, obliterate this instinct with impunity?

But, you say, it is necessary for the recovery of the patient. Are you sure?

In the first place, let me ask you, do you need to see a patient's liver, intestines, stomach, or kidneys in order to form your diagnosis when one or other is ailing?

Do you not rather pride yourself that from the patient's complaints and the altered secretions you can form your diagnosis? Neither do you demand to *feel* of a patient's other internal organs. Certainly palpation aids in a diagnosis where there exists some marked malformation of the *anterior* abdominal organs, but can you by palpation find out a dyspepsia, an enteric, gastric, or cystic catarrh, or a nephritis? Yet these are easily diagnosed.

And when you have looked into the vagina, what do you see? practically little in most cases, never farther than the outermost opening of the uterus.

Has it not often struck you that you find, usually, just what the symptoms led you to expect to find?

But, you reply, you expect the probe to give you valuable information. Were all virgins truly virgins, I could only assent; but how many gynecologists of experience can stand forward and say, "I have never accidentally caused an abortion"?

You say you are obliged to make local applications to the diseased parts. Do you make local applications to a liver, spleen, or kidney, in which is some subacute inflammation? Are not a bronchitis, enteritis, or cystitis cured without the direct application of solid nitrate of silver or iodine? No, no, Andrew, the same blood-vessels and lymphatics supply the uterus or ovaries as supply all the organs. The same blood impoverished or deteriorated flows through them all, and in one or another brings on disease, or the same blood enriched and purified is capable of restoring to healthful function the one as the other. The same sensitive and sympathetic nerves are similarly affected. The same use of judgment in the estimation of symptoms will bring you to an honest diagnosis in uterine diseases, just as certainly as in diseases of organs which lie out of sight and touch, and the same principles of treatment will affect the blood-supply, the nutrition, the innervation of the generative as all other organs.

Far be it from me to imply that there are no cases in which a vaginal examination is not imperative and direct local treatment essential. Indeed, such cases are frequent, although by far less common among virgins than among married women, and he would be guilty of criminal neglect who should refuse to resort to all known measures of cure. But let the vaginal examination be held in reserve as the last and extreme resort, when the same principles applicable to all organs have been faithfully tried and found wanting.

Now, Andrew, one thing more before I close. In your zeal to restore damaged perineums, and to sew up or cut down cervices, remember that it sometimes falls to the lot of the plain doctor to effect a cure of the *patient* by restoring the general functional health, even where a specialist has had full swing and failed to cure the *disease*. So, if you will be a specialist, try not to forget what you used to know as a plain doctor.

CLAUDIUS.

CONVALLARIA MAIALIS AGAIN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: As the home supply of this valuable cardiac remedy is likely to be short till another spring gives us the flowering plant in abundance, it might be well to state that Professor Germain Sée writes me that a reliable extract of the convallaria may be obtained from the principal pharmacies in Paris, France (Pharmacie Mialhe, 8 Rue Tavart; Pharmacie Langlebert, 55 Rue des Petits Champs).

The *Working Bulletin* of Parke, Davis & Co., on the convallaria maialis, states that Dr. Ralph D'Ary, of Romeo, Mich., a Russian physician, was the first to introduce the lily of the valley into this country, having learned its therapeutical uses while on a summer tour in his native country. To Dr. D'Ary, certainly, the priority of credit is due. I find that it is difficult to substantiate my former statement (taken from insufficient authority), that certain eclectics in this country had used this remedy for cardiac dropsy prior to its introduction by Dr. D'Ary.

E. P. HURD, M.D.

NEWBURYPORT, MASS.

ERYSIPELAS AS A CAUSE OF PUERPERAL PERITONITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The *American Journal of Medical Sciences*, for October, contains a review on the "Transactions of the American Gynecological Society," vol. vi., for the year 1881.

In this review, an essay by Dr. H. F. Campbell, of Augusta, Ga., on "Erysipelas in Childbed without Puerperal Peritonitis" is cited. In his essay Dr. Campbell reports the case of a woman delivered while suffering from facial erysipelas, and who escaped "all puerperal complications due to erysipelas." "Dr. Campbell did not touch the woman, and the midwife made no manual contact."

In the discussion which followed, Drs. Goodell and Smith, of Phiadelphia, related two cases of erysipelas in puerperal women without any affection of "the internal organs." Dr. Smith concluding from these cases that "puerperal fever is essentially contagious and not infectious."

Dr. Ellwood Wilson believed in the power of disinfectants to destroy the poisonous influence of erysipelas or scarlatina over puerperal patients, he having attended such cases the same day with but one unhappy result.

Dr. Barker believed, with Dr. Putnam-Jacobi, that the poison of cutaneous erysipelas is often not transmitted to the internal organs. He believes in the

great danger of contagion to puerperal women from erysipelas with purulent discharge.

Soon after the appearance of this review, I had a patient under my care in the Post hospital with phlegmonous erysipelas of the right arm, extending to the chest, and of the right leg. From the history of the case, and from my experience, while interne in the Charity Hospital, I have no doubt of the correctness of the diagnosis. There was deep suppuration and wide-spread destruction of the connective tissue in both situations. Pus, which was abundant and ichorous, appeared some days earlier in the axillary region than in the leg. I incised the former about 7 o'clock P.M. Afterward I simply cleansed my hands with tepid water and common washing soap.

About twelve o'clock the same night I was aroused by a soldier to see his wife who "was sick." Not knowing the nature of the sickness, and flurried by this unusual occurrence, I hastened round to his tent, only to find her in labor. Without thinking I immediately made a vaginal examination, found the membranes ruptured, the head presenting high up in the pelvis, and the os scarcely sufficiently dilated to admit my index finger. Returning to my quarters I, for the first time, bethought of my erysipelatous patient, and was naturally very much alarmed and annoyed by my thoughtlessness.

There then being no other doctor on duty at the post, I determined to change my clothing, thoroughly disinfect myself with carbolic acid, and attend to the confinement, leaving my other patient for a couple of days in charge of the hospital steward.

The patient being a primipara, the labor was, as I had anticipated, a very tedious one. Toward the final stage the patient became so irritable and exhausted that I deemed it prudent to deliver the head by instruments. The perineum was slightly ruptured, the placenta delivered, and the uterus forced to contract by Crede's method with but slight hemorrhage.

Another soldier's wife undertook to nurse the patient. By my directions, to which she adhered religiously, the vagina was syringed with a hot carbolized solution, twice a day. Having to attend to my erysipelatous patient I never went farther than the tent door after her delivery. Yet, under the watchful care of her companion, this patient never had the slightest bad symptom; never any rise of temperature. On the ninth day she was quite clamorous to be allowed to sit up a "little while," and I granted permission. Throughout her convalescence was exceptionally favorable.

By all who discussed Dr. Campbell's paper it was agreed that erysipelas was "essentially contagious and not infectious," and especially dangerous when the erysipelas was phlegmonous and suppurating.

I wish to record this case, first, because my hand was bathed in ichorous pus; second, because no disinfectant was used to cleanse it; third, because I made a thorough examination of the presenting part scarcely five hours afterward; fourth, because from the slight laceration of the perineum, the patient was especially exposed to contagion.

I have no explanation to offer for this very fortunate immunity. I would merely suggest that we have not as yet, perhaps, arrived at a true knowledge of the relation between erysipelas and puerperal peritonitis.

PETER R. EAGAN,
Assistant Surgeon U. S. Army.

FORT BOWIE, ARIZONA, October 23, 1882.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending November 4, 1882.

THE RECEPTION TO PROFESSOR SAMUEL D. GROSS, M.D., LL.D., D.C.L. OXON.—Last week Drs. J. Marion Sims and his son Harry Marion Sims gave a reception for the medical profession of this and other cities to Professor Samual D. Gross, of Philadelphia. The whole affair was brilliantly successful, and the honors appear to have been equally divided between the givers and the receiver. No compliment was better merited nor more gracefully tendered than that to the distinguished Philadelphia surgeon. It is hard to imagine a more appropriate expression of respect for a well-earned reputation than was shown by the presence on that occasion of so many men from different parts, who themselves have been active and successful workers in the profession. In fact it would be easier to say who were not there than to name those who were. The large hall in the Hotel Brunswick was tastefully decorated, the supper was bountiful, and the opportunities for the freest interchange of social amenities were thoroughly enjoyed. The guest of the evening was in good health and spirits. It is the common wish that he be blessed with their continuance, and long live to enjoy the fruits of his extensive and successful labors in surgical science.

PROGRESS OF THE YELLOW FEVER.—Reports show a steady decline in the cases of yellow fever at Pensacola, Fla. Only nine or ten new cases occur daily.

THE PAYMENT FOR MEDICAL SERVICES TO THE LATE PRESIDENT GARFIELD.—The Garfield Board of Audit has received the bill of Mrs. S. A. Edson against the estate of the late President Garfield, which had been returned to her because of certain informalities. Her claim is for $10,000 for skilful attendance in her professional capacity as a physician. It will, therefore, have to be considered as coming within the limit of $35,000 allowed to the physicians under act of Congress.

THE GRAND JURY ON THE CITY INSANE ASYLUMS.—The Grand Jury has recently presented the following as the result of its investigations: At the inquest of this Grand Jury upon matters relating to the management of Ward's Island Lunatic Asylum, there has developed strong evidence of the existence of a system so dangerous to the rights of citizens that we feel it our duty to recommend that a change in the laws may be made to remedy the evil and prevent, as far as possible, the incarceration of sane persons in either public or private asylums. To this end we recommend that the alleged lunatic, in all cases, before commitment shall be examined by

three physicians, each acting separately without the presence of the others, and that the examination shall be had before a judge and in the presence of counsel for the accused; that the physicians shall be selected by the judge, in the same manner that jurors are drawn, from the names of all reputable physicians who may have been in active practice in the State, county, or city during a period of five years at least, and that a majority verdict with the concurrence of the Judge shall be necessary to a commitment. The Grand Jury also found that the sanitary arrangements were deficient, and that the opportunities for patients to communicate with their friends were too limited.

The New York Post-graduate Medical School had a very successful inauguration at Chickering Hall November 4th. Dr. Wm. A. Hammond presided and delivered the opening address. He said that the course of study for medical students in our colleges rarely lasts more than three years, and in that time it is simply impossible for a student to gain sufficient knowledge to enable him to practice his profession intelligently and safely for his patients. If the student wishes to excel, and is wealthy, he may go to Europe and there complete his studies, or, in some instances, he may enter a hospital and there gain a practical knowledge of his work; but the great majority are obliged to go out into the world without being well grounded in the principles of their profession. Medical science, too, is progressive, and it is difficult for a practitioner to keep pace with the progress of the science. It is not agreeable for him to attend the lectures to the undergraduates, and even if it were, he would not get what he wants there. It is to provide for the wants of such men, and to give them a higher clinical education than they can secure in our colleges that the Post-Graduate School has been organized. Dr. Hammond was followed by Dr. D. B. St. J. Roosa, Rev. Henry Potter, D.D., Dr. J. Marion Sims, and the Hon. John Bigelow. A large number of prominent medical men were present.

New Method of Preparing Blisters.—Mr. Limousin has devised a new form of blister, with a view of affording to the physician a greater variety of choice in degree and kind of vesication, and also with a view of preserving the ready-made blister in better condition than is usually the case. He spreads a thin layer of ordinary blistering cerate upon strong, thin, unsized paper, and covers it with the same. The vesicating layer is about one and a half millimetre in thickness, and one of its surfaces is camphorated. When using the blister, its outline is marked upon the paper covering it; it is then cut off and applied to the part by means of a piece of adhesive plaster. The covering paper may be readily removed, both from the plain and from the camphorated side, by means of a wet sponge. If the physician orders a blister covered with oil paper, it is only necessary to saturate the covering paper with oil. The same process may be also used for the preparation of other plasters.—*Rép. de Pharm.*

Curious Effect of Lightning Stroke.—Dr. Herbert C. Jones, of Cerro Gordo, Illinois, writes: "Tuesday, August 15th, at 10 A.M., I was called to see Charlie S——, aged eight years, who was suffering from slight shock induced by his proximity to a tree struck by lightning, he being not more than six feet therefrom at the time. The mother stated he had been led home by a playmate, but could not, as she expressed it, 'see across the room, nor put his right heel to the floor.'

"At the time of my visit, an hour later, his vision was somewhat improved, but both pupils were still slightly dilated and irresponsive to light. The boy, usually bright and active, was subdued in manner and indisposed to exertion. The right leg was half-flexed and foot extended, and both stiffened in these positions; the effort to extend the one and flex the other ever so gently being met with complaint of pain in knee and ankle. Upon grasping my hand with his right, he was able to make a fair degree of pressure, but complained of pain in the ball of hand upon doing so. No other muscle or part seemed affected, though there was slight nausea, but no vomiting. All possibility of injury by falling was removed by the fact of his being caught in the arms of a bystander as he staggered forward.

"The symptoms abated toward evening, and next morning he was as well as usual.

"The point of greatest interest in the case was obtained from the boy in the evening, when he became more communicative. As the shock came he had raised his foot to kick at a bee, and the muscles became fixed in that position, and so remained for several hours. What motion was taking place in the thumb at the time is, of course, uncertain.

"Though the accompanying peal of thunder was loud, the electric current must have been partly disseminated, as the bark only was stripped from one side of the tree, that nearest the boy."

The Army Medical Museum and Library.—At the last stated meeting of the Philadelphia County Medical Society, Dr. Wm. M. Welch offered the following preambles and resolution, which were unanimously adopted: *Whereas*, There is reason to fear that at the next session of Congress an effort will be made to destroy the identity of the great Medical Museum and Library at Washington, by merging them into the General Congressional Library, and placing them under the control of the latter; and, *Whereas*, Under their present management this museum and library have grown to be the most valuable collections of their kind in the world, and are consequently of incalculable value to the cause of medical science, thus rendering their preservation and progress objects of deep interest to the medical profession of this country; therefore, *Resolved*, That the Philadelphia County Medical Society earnestly, but respectfully, request the honorable senators and representatives of Congress to make no change in the present management of the Army Medical Museum and Library, but would earnestly urge upon Congress the importance of providing a commodious fire-proof building in Washington for better preservation and protection of these invaluable collections.

Dr. Julius F. Miner, of Buffalo, N. Y., has resigned from the Chair of Operative and Clinical Surgery in the Medical Department of the University of Buffalo.

Ophthalmic Division of Charity Hospital.—In the report of the Ophthalmic Division of Charity Hospital it is shown that the advantages for the successful surgical treatment of diseases of the eye are exceptionally good. The nurses, as a result of the didactic lectures given by the visiting surgeons, pay intelligent attention to details in the care of patients operated upon, thus doing away with many dangers incident to careless nursing. The number of operations and the percentage of cures compare

favorably with those of hospitals devoted to the special treatment of diseases of the eye. The surgeons of the division are Dr. E. S. Peck, Ed. T. Ely, and R. Kalish.

A Specific for Singultus in children is said to be a few grains of granulated sugar moistened with cider vinegar.

The McGill Medical Faculty, the oldest medical college in Canada, recently celebrated its semi-centennial jubilee.

The Appointment of Internes to the insane asylums of France has heretofore been made directly by the Prefet. Candidates will now have to undergo a competitive examination.

An Epidemic of Typhoid Fever in Paris.—One hundred and thirty-four deaths from typhoid fever were reported in Paris for the week ending October 5, 1882. The total number of cases is said to be over two thousand. At Lariboisière alone there were 437 cases. In two days 283 cases were received into the different hospitals. These hospitals have had to discharge or transfer a number of chronic and convalescent cases in order to accommodate the new patients.

Burning of an Asylum.—By the burning of an asylum at Halifax, N. S., last week, thirty-one inmates perished.

The New Canadian Medical School at London, Ontario, has opened with a class of fifteen.

The Toronto General Hospital is having a large and handsome addition built.

Falling by the Way.—Dr. Wm. Pepper once showed in an introductory lecture that in no other calling do so many fall by the way as in the profession of medicine.

A Society for the Protection of the Natural Form of Woman has been organized by a number of young men in Kent, England. The object of the Society is good, and we are glad to learn that there is a wide-spread eagerness to embrace it.

Obesity and its Treatment.—Ebstein, of Wiesbaden, describes a new dietetic method for the relief of obesity. He does not believe in "Bantingism," and states that it produces inanition which may be injurious. Dr. Ebstein contends that a diet of albuminous and fatty matter tends to check deposit of fat, and that it is the sugars and starches which are to be left out in an anti-fat regimen. He gives bread, however, and green vegetables, peas and beans, but no potatoes. The addition of fat to the diet-list has the advantage that it produces satiety sooner and the patient does not eat so much.

New Tests of Albumen in the Urine.—Dr. Wm. Roberts states that a very delicate test for urine is a *saturated* solution of common salt to which is added five per cent. of dilute hydrochloric acid. This gives a white precipitate with albuminous urine, which precipitate is not coagulated albumen, however, but a soluble form of this proteid. Dr. Roberts adds (*Lancet*):

"I have carried about with me for some months past a little pocket case (which is only a stiff-backed cigar case) which I have found a useful and safe clinical companion. It contains a book of litmus papers; a narrow corked phial filled with acidulated brine; a test-tube charged with Cooper's pellets of the solid Fehling's test, guarded with an india-rubber stopper; and, lastly, an empty test-tube, also provided with a cork. This compact arrangement furnishes the means of ascertaining the reaction of the urine, and of testing it in the most delicate manner for albumen and sugar. The empty test-tube also serves to carry home a specimen of the urine for further and more minute examination.

Mr. Guy Neville Stephen, in the same journal, states that the best test for albumen is a double iodide of mercury and potassium, with acetic acid. The urine is first acidulated with the acid, then the double iodide is added. This will give a precipitate when there is only five centigrammes of albumen to a litre of water. The formula for a precipitating solution which also gives quantitative results is as follows:

℞. Potassii iodid..... 3.22 grammes.
Hydrarg. bichlorid ..... 1.35 gramme.
Aquæ destillat...q. s. ad. 100.00 cub. cent.

M. One drop of this, from a pipette giving a drop of five centigrammes, precipitates 0.005 grammes of albumen.

Treatment of the Wounded in Egypt.—The antiseptics used on the wounds were iodoform, and a solution of chloride of zinc, forty grains to the ounce. Sometimes one part of this zinc solution was added to three parts of one in twenty carbolic acid solution, with excellent results.

The Fifth Anniversary of the Washington Training-School for Nurses was held at Washington, D. C., October 24th. Addresses were delivered by Dr. J. M. Toner and Judge MacArthur.

The Oil of Gaultheria now recommended for acute rheumatism is sometimes adulterated with oil of turpentine, birch, and also with alcohol.

A Case of Varioloid in the Vermont Legislature, recently, caused a stampede among the members.

State Medical Society of Virginia.—At the recent successful meeting of this Society, at the Fauquier White Sulphur Springs, Dr. Taylor received a $50 prize for an essay on "Abdominal Surgery," and Dr. Elzey received an equal amount for an Essay on "Alcohol."

The Liqueur Absinthe, of which the use is said to be increasing in France and England, has the following composition: Absolute alcohol, in a hundred parts, 50.00; oil of wormwood, 0.30; other essential oils, 2.52; sugar, 1.50; chlorophyll, traces; water, 45.65.

Small-pox in Paterson, N. J.—The health authorities of Paterson have so far been unable to suppress the small-pox, which has even increased at times despite all efforts. The Health Committee are of opinion that one chief cause of failure lies in the fact that the vaccine virus is not good.

Improvement in the Paris Morgue.—The bodies in the Paris morgue are now frozen and kept in this condition until their final disposition. The freezing apparatus consists of a modification of the Carré method, in which the cold is produced by the evaporation of previously liquefied gaseous ammonia. But instead of water, a solution of calcium chloride, which remains liquid at a temperature of 20° F., is made the direct recipient of the cold thus generated, and is carried in pipes to the top of the building, whence it falls in cascades. The same fluid is again collected and re-exposed to the freezing machine. In this way the temperature of the room is kept well below the freezing-point constantly. When bodies have become putrid or re-

quire to be kept longer than usual, they are placed in a row of cases like a set of pigeon-holes, where, by means of the same apparatus, the temperature is maintained at a much lower point. The bodies which have been kept at 20° F., and which have been for weeks of stony hardness, show very little tendency to putrefaction.

RENDERING THE LARYNX ANÆSTHETIC.—Dr. Brown-Séquard states that although the inhalation of carbonic acid gas, or of chloroform, causes at first irritation, this soon subsides and the larynx becomes almost or entirely anæsthetic. He suggests that by using these agents to reduce sensibility, instruments may be introduced into the larynx without much trouble. The carbonic acid should be given with care.

VIRGIL AS A VETERINARY POET.—The *Journal of Comparative Medicine* endeavors to show that Virgil, as a poet, properly belongs to the veterinarians. He describes in the Georgics a number of diseases that affect cattle. In one place an ox is supposed to have died from anthrax:

> "Ecce autem duro fumans sub vomere taurus
> Concidit, et mixtum spumis vomit ore cruorem
> Extremosque ciet gemitus, it tristis arator," etc.

Which Dryden translates as follows:

> "The bull, which to the yoke was bred to bow
> (Studious of tillage and the crooked plough),
> Falls down and dies; and dying, spews a flood
> Of foamy madness, mixed with clotted blood."

In the same connection Virgil describes most vividly the effects of an epidemic among horses. The clinical symptoms resemble more those of glanders.

THE CAUSES OF UTERINE DISPLACEMENT.—Dr. Graily Hewitt found that among 340 cases of misplacement in single and married women, the trouble could be traced to mechanical causes, such as straining, lifting, falls, etc., in 43 per cent. Long-continued standing, as in shop-girls, may also cause it. Mechanical causes generally need some predisposing weakness on the part of the woman in order to produce their effects.

EGYPTIAN TREATMENT OF SYPHILIS.—In the course of an article on "Medical Notes of Travel in Egypt," by Dr. Josiah Williams, in the *British Medical Journal*, occurs the following: "The native treatment of syphilis in young girls is very primitive and very barbarous. Close to the town (Souakin), in the Red Sea, is a little island, called originally Sana Gin, and from which the town takes its name. The girl is taken across to this island by six women; she is then laid naked on her back; on each arm and each leg sits a woman, another on her chest. The operator, another woman, who is provided with a sharp sea-shell, scrapes away in the vagina until she is satisfied that all diseased parts are removed, and then, utterly regardless of the shrieks of the girl, gets a handful of sand from the sea, and rubs that in. The disease is then supposed to be cured by this rather rough operation."

INOCULATION IN THE TREATMENT OF PANNUS.—The heroic measure of inoculating gonorrhœal pus for the relief of severe pannus has been tried in three cases in the Ophthalmic Division of Charity Hospital, with the following results: First patient, totally blind in both eyes for several years, was inoculated with gonorrhœal pus; discharged in April last, at his own request, as he desired to get work; vision in one eye 10-200, and 2-200 in the other. His sight has undoubtedly doubled since, though every effort to find the party has been unsuccessful. Second patient, right eye with white leukoma (large iridectomy previously made) and partial pannus; vision, 6-100; left eye, 12-100. Third patient: right eye, vision 20-100; left eye, perforated cornea and perception of a moving object at a distance of two feet. Second and third patients had perception of light in one eye, while with the other, each patient could count fingers at the distance of a foot (1-200.) Both were inoculated with a traumatic urethral discharge, which ceased after ten days' treatment. The purulent ophthalmia was very severe in all four eyes and continued for seven weeks, during which time the patients had a special nurse, night and day; and though in open ward, they were successfully secluded from the other patients by means of screens. These results are worthy of consideration, though the procedure is confessedly severe.

FORCED ALIMENTATION AND WASHING IN DYSPEPSIA.—M. Debové's method of treating phthisis by feeding the patients through a tube has been applied to cases of dyspepsia, chronic gastritis, vomiting, and dilated stomach. The stomach is first washed out, and then milk, or bouillon and eggs, or Debové's powdered meat are used. Excellent results are reported, the patients gaining in weight, and losing all their bad symptoms. Debové's powdered meat is claimed to have five times the nutritive power of ordinary raw meat.

OVARIOTOMY.—The per cent. of recoveries among 2,023 cases of ovariotomy, collected by Dr. Younkin, was 73. The lowest ratio of recoveries among modern large operators is Schroeder's, being 62. The highest is Keith's, 86. The highest ratio has been among those who used Lister's methods.

DR. MCINTYRE, and not Dr. Sibbett, should have been credited with the article on the "Per Cent. of College Bred Men in the Medical Profession" read before the American Academy of Medicine, October 27th.

PURGATIVE LINIMENT.—When medicine cannot be administered the following may be used: tincture of colocynth, ʒ j; castor oil, ʒ ij. The tincture of colocynth is to be prepared from stronger alcohol and one-tenth of its weight of colocynth deprived of seeds. A teaspoonful of the liniment is to be rubbed on the abdomen morning and night.—*Drug Circular.*

THE PREVENTION OF IRREGULAR PRACTICE.—Dr. C. R. Agnew writes: "In THE MEDICAL RECORD for November 4th, p. 524, the following sentence occurs in the report of the late proceedings of the American Academy of Medicine: 'Dr. Cornelius R. Agnew said there was some discouragement in his State with regard to laws for the prevention of irregular practice.' I said, or intended to say, the very opposite. I said, or intended by my remarks to affirm, that an excellent work was being done by the Medical Society of the County of New York in enforcing existing laws against quackery, that the defects in existing laws were being discovered, as attempts were made to enforce them, that some pretentious charlatans had been driven out of New York already, and that a spirit was aroused in the profession which would find expression in needed amendments to the laws against irregular practice; that we had every ground for encouragement."

INTERNAL ŒSOPHAGOTOMY.[1]

THE DIVISION OF MEMBRANOUS OR CICATRICIAL CONSTRICTIONS OR OBSTRUCTIONS IN THE ŒSOPHAGUS BY INTERNAL SECTION.

BY J. O. ROE, M.D.,

ROCHESTER, N. Y.,

FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION, MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK, OF THE CENTRAL NEW YORK MEDICAL ASSOCIATION, ETC.

(Continued from p. 541.)

CASE VIII. (By Tillaux).[2]—A saddler, forty-eight years of age, was admitted to Hospital St. Louis, under the care of Tillaux, October 15, 1872.

Ten years before, while in Mexico, in mistake for brandy, he took a caustic liquid, the nature of which he did not know. It caused a sensation of heat behind the sternum for a few hours, which he would have forgotten had it not been followed by dysphagia and occasional violent spasms of the œsophagus, when it was impossible for him to swallow anything.

During the following year dysphagia gradually increased, until he was obliged to abandon all solid food, and at the time of admission to the hospital it was with the greatest difficulty that he could swallow liquids in very small quantities; these he would attempt to force down by making pressure downward along the neck. He was now very weak and much emaciated. On exploration, Tillaux found a stricture at the union of the pharynx and the œsophagus, through which only the smallest olive could be passed. Catheterization and dilatation were now tried for twenty days without any increase in size of stricture, and, on November 5th, Tillaux incised the stricture with Trélat's œsophagotome, having first determined the extent of the stricture with the olive bougie. The section was made from below upward, with a lateral projection of each blade 1 ctm. There was no pain, and only a streak of blood in the saliva. Immediately after the operation the first four olives of the series could be easily passed. There was no subsequent hemorrhage, and only a slight pain in the right lateral part of the neck.

On the fifth day the fifth olive, and on the eighth day the sixth olive, the largest of the series, were passed, which was a little larger than the normal calibre of the œsophagus.

December 8th.—Stricture considered cicatrized, and the patient eats freely as before the accident in Mexico, and he is regaining his flesh and strength rapidly.

CASE IX. (By Studsgaard).[3]—Hilga R——, aged eight, was admitted to the Children's Hospital (Copenhagen), June 30, 1873. Twelve weeks previously, in mistake for water, she had drunk from a bottle a mouthful of a solution of lime and potash, used for washing. Pain in the chest and vomiting followed immediately. Swallowing became difficult, and liquids only could be taken. Treatment by dilatation with elastic catheter was attempted, but it could not be forced through the stricture, and after each trial she brought up some blood. She was getting thin, and spat and hawked up quantities of slime. She could swallow milk without difficulty, and soup and softened bread-crumbs in small quantities. After a few days she could not swallow anything.

July 9th.—Bulbous bougie No. 10 (Charrière bougie) passed through the stricture.

July 12th.—Nos. 12 and 13 passed through. A roughness or scratching was felt by the patient when the bougie passed the stricture. After this she could swallow crusts of bread in small pieces, and blood did not show itself in passing the bougie. After this her condition was variable.

August 16th.—No. 10 went through with difficulty. Stricture was getting longer and harder, and a few places above the first stricture were found narrowed.

September 2d.—Studsgaard had the good fortune to get No. 11 through again. The patient grew paler and thinner.

September 16th.—Internal œsophagotomy was performed by Studsgaard with an instrument having a concealed two-edged cutting blade,[1] much resembling Maisonneuve's instrument, having an elastic point answering to No. 11. The upper end of the stricture was 21 ctm. from the upper incisor teeth. With the head thrown back the instrument was introduced and the incision made from above downward. The knife met a strong elastic obstruction, but passed through freely, after which bougie No. 23 passed easily. She complained somewhat and brought up some blood, but was soon relieved. Two hours afterward she began to feel a severe pain in the cardia and back, which was relieved by throwing up some clear blood. Her voice got thick and she could only speak with difficulty, and three times in the afternoon there was much oppression in the chest and dyspnœa, so much so that she grew bluish red in the face, and it appeared as if she would suffocate. Raising her in bed relieved her, and there was no more vomiting.

September 17th.—Patient slept well during the night, and has pain only in the cardia on pressure and on moving. Voice about natural. Pulse, 90. Bowels moved, after an enema, without sign of blood. Bougie No. 23 passed through. No return of fever. Pain and sensitiveness disappeared altogether.

September 29th.—She could eat crusts of bread, meat, potatoes, etc., and she was not required to take a drink after each mouthful. Bougie No. 27 stuck, but on the following day it passed further down.

October 6, 1873.—The patient was discharged from the hospital, with the advise to continue the treatment of dilatation. She had increased in weight from July 2d, 37.33 lbs.; to October 6th, 48.35 lbs.

After the above report was made the stricture was reported to have gradually returned, notwithstanding continuous dilatation, allowing only Nos. 14–15 to pass, and pockets had formed above the stricture.

Internal œsophagotomy was again performed with the same instrument.

June 5, 1874.—This was followed by dilatation, and at the time this record was made, an œsophageal bougie, of a diameter "2 mm. larger than No. 28," could be passed easily.

---

[1] A portion of this paper was read before the Medical Society of the State of New York at Albany, February 8, 1882.

[3] Studsgaard, C.: Œsphagotomy interna ved Cicatriciel Strictur. Hospitals-Titende, p. 173. Kjöbenhavn, October 29, 1873.

[1] For illustration vide Hospitals-Titende, loc. cit., p. 174.

Cases X. and XI. were reported by Schiltz [1] to the Society of Physicians at Cologne, December 12, 1876, as cases on which he had performed internal œsophagotomy several years before. An instrument was employed, devised by himself, after the manner of a urethrotome. A description of the instrument will not be published until after the passage of the German patent law.

Case X. (By Schiltz).—That of a woman who had suffered for months from a difficulty in swallowing from a carcinomatous stricture of the œsophagus. Treatment by dilatation being ineffectual, internal œsophagotomy was performed. Pain and hemorrhage was insignificant. The patient was enabled to swallow meat and bread, and a large sound could be passed into the stomach. Gradually, however, the stricture contracted again, so that after several weeks the incision had to be repeated, which was followed by the same successful results. Altogether the incision was repeated five times without pain or hemorrhage, but always with transient success. The patient finally died from tuberculosis which had existed for a long time, life having been sustained by means of the sound to the very last. No autopsy was made.

Case XI. (By Schiltz).—This patient had an œsophageal stricture, thought to be the result of a cicatrized ulcer, which had been produced by strong brandy. In this case, too, the dilatation was unsuccessful and œsophagotomy was resorted to. After the operation, which had caused no small amount of pain, a large sound could be introduced one inch deeper, but not into the stomach, but a smaller sound passed through and revealed a second deeper stricture. Inasmuch as after the operation the patient had hemorrhage, lasting for five hours, which could not be checked by chloride of iron or by sounds retained *in situ*, incision of the second stricture was refused. Death occurred eight days later from increasing failure or exhaustion of the vital powers.

At the post-mortem the incision was found cicatrized, and near it a narrow stricture occupying the cardia, through which a thin lead pencil could be passed with but little difficulty. Schiltz regrets not having recognized the two strictures at first, so as to have incised them both at one sitting. In his opinion this case would then have been cured by the operation.

Case XII. (By Czerny).—A girl, eight years of age, was admitted to the Surgical Clinic, Heidelberg, February 20, 1877, with stricture of the œsophagus, caused by the accidental swallowing of lye ten months previous. The only history obtainable was, that since that time difficulty in swallowing had gradually increased, until only liquids could be swallowed slowly and in small quantities.

When admitted the little patient was pale and emaciated. Upon introducing the œsophageal sound a narrowing of the œsophagus was encountered 18 ctm. from the incisor teeth, about opposite the manubrium sterni, into which an elastic catheter, 4 mm. in diameter, was introduced without difficulty. Pushing the instrument further on, it became tightly engaged, so that a reliable opinion as to the extent of the stricture could not be obtained. Other organs healthy. The stricture was now dilated daily with conical œsophageal bougies, and, March 6th, a sound, 6 mm., could be passed, and liquids, farinaceous food, and soft bread could be swallowed.

March 25th.—Catheter, 7 mm., passed. Finely cut meat could now be swallowed, and the nutrition of the patient much improved.

April 8th.—Child dismissed at request of the parents.

May 16th.—Child readmitted. Return of the dysphagia. A bougie, 5 mm. in diameter, could only be passed with difficulty. Several strictures, "shelves of membrane," were now found—the lowest, the smallest. Tin sounds of Billroth were now used, but they could not be retained for any length of time, owing to pressure against the larynx; and more or less pain in the throat was produced. Continuing the progressive dilatation, the limit of dilatation was not only reached, but the stricture soon began to grow smaller.

May 29th.—It was no longer possible to introduce the thinnest tin sound, and only an elastic bougie, $4\frac{8}{10}$ mm. in diameter, could be passed, even under anæsthesia.

June 9th.—Attempts to dilate stricture with Jameson's dilator failed. All attempts at dilatation having failed, Professor Czerny performed internal œsophagotomy with an œsophagotome, patterned after Ivanchich's urethrotome, only much longer. Patient under an anæsthetic. The stricture was divided from below upward, once to the right and once to the posterior surface, the blade projecting 2 mm. Only a trace of blood seen in the mucus. Immediately after bougies 8 and 10 mm. in diameter passed easily. After recovery from the narcosis there was only slight pain, but several times violent vomiting. In the evening the neck became swollen from the clavicle to the region of the larynx. For the next few days the emphysema increased, until the whole neck from the lower jaw to the clavicle was decidedly tympanitic, and painful on pressure; and swallowing was performed with difficulty. Temperature, $38\frac{6}{10}$° C. to 39° C.

From June 17th emphysema subsided, and by 19th was gone. Only fluids and two raw eggs taken daily.

June 21st.—Diphtheritic deposit upon tonsils and swelling of cervical glands. Chlorate of potash locally and internally. Constant pain in throat, though deposit did not extend. Marked dyspnœa. Without special symptoms, patient gradually failed, and died June 24th, 4 A.M.

Autopsy by Professor Arnold.—Considerable swelling of lymphatic glands of neck. Diphtheritic deposit and filtration of soft palate and tonsils. An abscess was found between the œsophagus and spinal column, extending from the third cervical to the third dorsal vertebræ. Opposite the manubrium sterni it communicated with the pleural cavity on each side. At the fifth and sixth cervical vertebræ there was a wound in the posterior wall of the œsophagus 2 ctm. in length, having smooth-cut edges somewhat infiltrated.

The peri-œsophageal tissue the whole length of the œsophagus was swollen and infiltrated. In the lower third of the œsophagus the mucous membrane was deficient and replaced by cicatricial masses, and at several points large folds of cicatricial tissue. Here, also, there was an extensive communication between the lumen of the œsophagus and the peri-œsophageal abscess. Both pleural cavities contained ichorous pus, the pleural membranes were opaque, and both lungs highly compressed. Death,

[1] Schiltz: Correspondenzblatt der ärztlichen Vereine in Rheinland, Westphalen und Lorthringen, 1877: April, W. 19 S. 19, also vide Braun's article, Œsophagotomia Interna, "Czerny's Beiträge zur Operativen Chirurgie," 1878, p. 70 et seq., which contains an excellent review of all the cases to that date, and from which these two cases are taken, owing to the failure of the writer to obtain a copy of Schiltz's original article.

in this case, says Braun, must be attributed to section through the whole thickness of the walls of the œsophagus, which was followed by an abscess in the posterior mediastinum, which opened into both pleural cavities shortly before death. Perhaps the "fatal exit" was hastened by a diphtheria, which supervened a few days before death.

Case XIII., by Mackenzie, has been given.

REMARKS.—I have cited these cases of internal œsophagotomy more or less in detail, in many of them following the language of the author.

By so doing we are able to study them more closely, and to arrive at a more accurate opinion concerning the operation, its advisability, the best method of performing it, its after-management, and the complications which may arise and which are to be guarded against.

Out of the fifteen cases in which the operation has been performed, there were nine recoveries and six deaths; and but two of the deaths were a direct result of the operation.

In the first two cases by Maisonneuve there was no connection between the operation in the œsophagus and the peritonitis, as was shown by the autopsy.

To explain these singular coincidences, Maisonneuve asks, "if there is not between the peritoneum and the œsophagus one of those mysterious connections which exist between wounds of the head and abscesses in the liver, or between those terrible attacks of pernicious fevers and injuries of the urethra, which have so long puzzled the most scientific anatomists."[1]

As no such sympathy between the peritoneum and the œsophagus appeared in the other thirteen cases, the fact that these two patients were both in the same hospital, and were both attacked by peritonitis on the same day, though operated on four days apart, and dying but one day apart, indicates quite clearly that the peritonitis was occasioned by a common ulterior cause.

In the two cases of Schiltz which terminated unfavorably the one in which the stricture was due to cancer could not be expected to recover, and only temporary improvement could result.

A similar case of cancerous stricture in the upper part of the œsophagus came under the care of the writer a short time ago. Though he was requested to perform an operation, and the case was no more unfavorable than the one of Schiltz, he refused, as there could be no permanent benefit, and discredit would be brought on the operation.

The operation in the second case of Schiltz was successful, so far as it went; but as it was incomplete from failure to divide the lowest and tightest stricture, the result must be considered negative, the same as if no operation had been attempted. Had all the constrictions been accurately determined and carefully divided, the result would doubtless have been quite different.

In the two cases (Czerny's and Mackenzie's) where death ensued as a direct result of the operation, the cause was, in both instances, cutting too deeply and penetrating through the walls of the œsophagus.

These two cases should therefore warn future operators to exercise great care to guard against the occurrence of this almost inevitably fatal accident.

Method of performing the operation.—The operation in itself differs but slightly from internal urethrotomy; and the instrument used is essentially a urethrotome, modified and adapted to the œsophagus.

The instruments used by the operators since Studsgaard have had but one cutting blade.

The advantage of an instrument with but one cutting blade is at once apparent. With it, the side on which the stricture is deepest, as is sometimes the case, can be incised without wounding the opposite side, which may be thin and easily cut through. Also, the side against which external pressure may be exerted, can be avoided, as, by the crossing of the left bronchus, by the aortic arch, or by enlarged lymphatic glands, the resistance of which would increase the danger of penetration through the wall.

We see that in the operations by the more recent operators all the incisions have been made from below upward, which is considered by far the safer method.

The danger attending the incision of a stricture from above downward is not so great in the upper as in the lower portion of the œsophagus, for the reason that the portion of the œsophagus above the crossing of the left bronchus is more rigid, being bound down more firmly than the portion below. The lower portion being more yielding to allow for the great mobility of the diaphragm, and being more markedly curved as it passes forward to enter the cardiac portion of the stomach, would be liable to cause the instrument to impinge with greater force against the lower side and penetrate the œsophageal wall.

It is observed, however, that the only two deaths caused by the operation followed division of the stricture from below upward. This was due, especially in Dr. Mackenzie's case, to the unfavorable condition of the stricture rather than to the method employed.

The limited number of operations and the great variations in different cases which have to be studied independently, prevent the establishing of a specific rule for performing the operation.

Notwithstanding this fact, it may not be amiss to detail briefly the general plan which the writer deems it safest to follow, and which is deduced from the reports of the previous operations and his own experience.

The œsophagus should first be thoroughly explored to determine its exact topographic-anatomical position, in relation to the location and extent of the stricture; the condition of its walls, if atrophied or thinned; the calibre of the stricture compared with that of the œsophagus above, and, if possible, below; and if the stricture be circular or located mainly or wholly on one side.

The exploration of the œsophagus is ordinarily best made with small olive-shaped balls, tapering alike at both ends, made of ivory or hard rubber, in different sizes, and mounted on a whalebone stem.

The writer has also a set of metallic bulbs mounted on a gum-elastic stem. These he finds of advantage in some cases, on account of their weight, as they will drop down the œsophagus by their own gravity, and, having a very flexible stem, will sometimes indicate the condition and location of a stricture more accurately than a light ball mounted on a whalebone stem, which is necessarily more or less rigid.

For determining the side on which a stricture is located or is the deepest, he employs an olive, which he has made with the bulb entirely on one side, as shown in Fig. 3, page 538. At the upper end of the handle is an indicator to show the side toward which the bulb is directed when introduced into the œsoph-

[1] Maisonneuve: loc. cit., p. 413.

agus. By passing the instrument gently down and up, each time turning it partly around, the side on which it meets with the greatest resistance will be indicated as the side on which the stricture is deepest.

After the condition of the stricture is accurately determined, the depth to the upper and also to the lower side of the stricture is measured and marked on the stem of the œsophagotome, taking the upper incisor teeth as the point to measure from.

The œsophagotome is now introduced (the tongue being drawn gently out and held in a napkin), until the upper mark on the stem indicates that the blade has passed through the stricture. The blade is now thrown out and the instrument drawn out until the second mark shows that the blade has cut through the stricture, when it is thrown back and the instrument withdrawn.

If the stricture has been found to be deeper on one side, the blade is turned to that side. Should there be more than one stricture, it is advisable to determine the situation of each, and to divide them separately. If this cannot be done at one time each can be successively dealt with as the passage is cleared above.

In all cases an opening through the stricture must be found before an operation can be attempted, for in plunging a cutting instrument downward without a guide, the danger of making a false passage is apparent.

As in urethrotomy, the treatment of the stricture is by no means ended when the operation has been performed.

For a day or two after the operation the patient should be permitted to take only the blandest substances, in order to avoid irritating the wound. It may sometimes be better not to give anything by the mouth for two or three days, but to sustain the patient by nutritive enemata.

The following day after the operation, dilatation should begin. Without exercising force, the bougies should be gradually increased in size until the fullest extent of dilatation is attained. Should the opening be then insufficient to allow complete alimentation, the operation should be repeated.

In performing the operation it is far better and safer to make several shallow incisions at intervals, and follow each by dilatation, than to make one or two deep incisions at one time.

Afterward, notwithstanding the fact that nearly all of the cases operated on have been reported as remaining permanently cured, the precaution of occasionally having the bougie introduced should be urged, for, as in urethral strictures, there may remain some contractility of the tissue at the former site of the stricture which may cause it to return.

Indications for the operation.—In the treatment of œsophageal stricture the time-honored sound still maintains its recognized place, for it is only after a patient and thorough use of the sound has failed, and other means of alimentation have also failed, that resort to the operation of internal œsophagotomy is justifiable.

The assertion by Hüter [1] that all strictures through which a sound can be made to pass can be cured by dilatation is entirely disproved by these cases, for in each one it was only after the sound had completely failed that the operation was resorted to.

The operation of internal œsophagotomy is clearly indicated in all forms of stricture of the œsophagus caused by membranous or cicatricial formations. Membranous formations usually arise spontaneously, as was seemingly the case in the first patient operated on by the writer. They may also be of congenital origin.

Three cases of membranous contraction in the upper part of the œsophagus, supposed to be congenital, are reported by Zenker and von Ziemssen.[1]

In all three the stenosis was located at the entrance of the œsophagus. In two cases it was a simple ring about the tube; in the third the canal was narrowed by membranous bands for a distance of eight millimetres.

Illustrative specimens, both of spontaneous and congenital membranous formations are preserved in the museum of the College of Surgeons, London.[2]

One (No. 1,079) shows a stricture of the œsophagus from a fold of mucous membrane. Just below the cricoid cartilage the œsophagus gradually contracts to half its diameter and then dilates. The mucous membrane, at the contracted part, forms transverse, sharp-edged, and projecting folds, which pass around the chief part of the circumference of the tube.

Cicatricial formations are most commonly the result of swallowing some acrid substance, as sulphuric acid, nitric acid, lye, or caustic potash, though any substance sufficiently acrid to produce erosion or destruction of the mucous membrane will give rise to cicatricial formations.

Respecting the changes in the œsophagus which result from the swallowing of an acrid substance, Rokitansky remarks that when "mucous membrane has been destroyed by the energetic action of the poison, it is replaced by serous and sero-fibrous tissue, which gives rise to peculiar valvular strictures of the œsophagus, somewhat analogous to those consequent on dysentery." [3]

Strictures will sometimes contract to a certain point and then remain stationary for many years without showing signs of further contraction and not requiring any operative interference. An interesting case of this character is reported by Easton.[4]

A man, aged twenty-five years, swallowed by mistake a corrosive liquid, which produced a stricture in the lower part of the œsophagus. He was unable to swallow any solid food, and being fond of milk and cake, he made them his exclusive diet, living upon them fifty-five years, and being able to perform laborious farm work.

Instances are also reported in which cicatricial strictures have yielded spontaneously when death from starvation seemed imminent.

Braun refers to two cases. One reported by Ashurst,[5] where a stricture caused by swallowing lye, resulted in a spontaneous cure. One by Hutchinson,[6] caused by swallowing caustic potash, in which gastrotomy had been proposed but not performed, also yielded spontaneously.

When, however, the stricture contracts notwithstanding the most careful and thorough use of the sound the operation of internal section should be resorted to while the opening is sufficiently large to admit the œsophagotome.

[6] Hutchinson, Jonathan: Case of Stricture of the Œsophagus after Swallowing Caustic Potash. Gastrotomy Proposed but not Performed. London Hospital Reports, vol. iv., p. 56.

Even on a limited search through medical journals and hospital reports we shall find numerous instances recorded where patients have died from starvation with œsophageal stricture (or from external œsophagotomy, or gastrotomy, performed in the attempt to avert this result), when it was found on post-mortem examination to have been caused by narrow bands of cicatricial or elastic tissue, or membranous folds, in which, if the operation of dividing them by internal section had been made, the obstruction could have been readily and permanently removed.

Contra-indications. — The operation of internal œsophagotomy is contra-indicated in all cases where the walls of the stricture are atrophied or contracted so as to greatly reduce the external circumference of the œsophagus, or where the narrowing of the tube is produced by diseased conditions located in the walls or by pressure from without.

It is especially contra-indicated in cancerous contractions. It is equally true, here as elsewhere, that when a cancerous tumor cannot be completely extirpated, the use of the knife only goads it to a more rapid growth.

Dangers attending the operation.—As accidents are liable to occur in every operation, either during or after the performance, an understanding of them will the more readily enable us to prevent them.

The complications which have been thus far observed to attend or follow this operation are cutting through the wall of the œsophagus, hemorrhage, pain, pneumonia, dyspnœa, emphysema, and œsophagitis.

The greatest danger attending the operation is that of cutting too deeply and penetrating through the wall of the œsophagus, and the escape of blood and other substances into the surrounding parts, and the consequent formation of peri-œsophageal, mediastinal, or pleural abscess, which is inevitably fatal.

Hemorrhage.—In nearly all cases the hemorrhage was so inconsiderable as only to tinge the saliva. In the first patient operated on by the writer there was slight hemorrhage, which continued for two or three hours, but subsided spontaneously and did not recur.

Hemorrhage may, however, prove a serious complication, as it did in the cases of Trélat and Schiltz. This was undoubtedly due to the unnecessary depth of the incision, and the wounding of an arterial branch leading into the stricture that had become enlarged in consequence of the diseased action going on in the morbid tissues of the stricture, rather than simply to incising the œsophageal wall, as in both instances in which this accident occurred there was almost entire absence of hemorrhage.

In the one by Trélat, he had made two incisions which gave him an opening of from ten to eleven millimetres. He now sharpened the blades to the point, and opened them two centimetres on making the incision. A glassful of blood was immediately lost, and followed next day by bloody stools.

On the twelfth day after, secondary hemorrhage occurred from straining at stool, and again on the thirteenth day, losing in the aggregate, it was estimated, four hundred grammes.

Braun[1] considers that the last operation was quite unnecessary as the nutrition of the patient could have been very well accomplished through an œsophagus whose lumen was from ten to eleven millimetres, which was present before the third incision was made.

Bearing on this point Trélat[2] remarks that it is the surface of the stricture rather than the diameter that is to be compared. When a stricture is enlarged from eight to twelve millimetres, the diameters are in a ratio of eight to twelve, while that between the surfaces is as four to nine.

In the second case by Schiltz, quite profuse hemorrhage occurred, which lasted five hours and could not be controlled by chloride of iron or by sounds retained *in situ*.

Pain.—Excepting the second case of Schiltz the operation in every instance was painless—so much so that an anæsthetic was entirely unnecessary, though one was administered by Czerny. In the case of Schiltz it was evidently due, either to the unnecessary depth of the incision or to an extremely sensitive or neuralgic condition of the œsophagus.

Pneumonia is a complication which may arise as a direct result of a wound inflicted on a part so closely contiguous to the lungs as the œsophagus. In the case in which it occurred—Mackenzie's—it was produced evidently by the pleuritis resulting from the incision through the œsophageal walls.

Œsophagitis.—More or less œsophagitis may also be occasioned by the incision, as was observed in Trélat's case, though it quite readily subsided on the withdrawal of all irritants.

Dyspnœa is a more rare complication, as it has occurred in but one case, that of Studsgaard. It was here evidently due to distention of the œsophagus by blood, as it was immediately relieved by vomiting, and the unloading of the œsophagus. The dyspnœa from distention of the œsophagus being produced either by direct pressure against the trachea or by pressure on the pneumogastric nerve, causing by reflex irritation spasm of the larynx, as so frequently occurs when foreign bodies have become lodged in the œsophagus.

Emphysema is also an infrequent complication, as it was only observed in Czerny's case.

This was certainly caused by air entering the cellular tissue through the opening in the œsophagus made by the incision and the violent vomiting after the operation. It could not have been due to injury to the lungs, as the lung-tissue cannot be easily reached by a vertical incision directly through the posterior wall of the œsophagus.

Emphysema is a phenomenon which also sometimes occurs, from the lodgment of foreign bodies in the œsophagus and from violent vomiting. An interesting case has been recently reported in which emphysema of the face, neck, and chest, followed the lodgment of a piece of pork in the œsophagus.[1]

A case similar is also cited by Poulet.[2] For emphysema to occur in such cases Poulet states that the mucous membrane must be perforated to place the cellular tissue in communication with the air, most frequently by means of a communication with the trachea.

From an analytical review of these cases the following deductions can be drawn:

First.—That the operation of internal œsophagotomy for the division and removal of the membranous or cicatricial constrictions or obstructions in the œsophagus is established beyond question as a justifiable operation; and in all cases where it is clearly indicated it is the only warrantable operation for relief against impending starvation.

[2] Poulet, A.: Foreign Bodies in Surgery, vol. i., p. 79. Wood's Library, 1880.

Second.—That it is a safer operation in its immediate results, and is attended by fewer complications than external œsophagotomy or gastrotomy.

Third.—Notwithstanding that it is a safer operation than external œsophagotomy or gastrotomy, when done with equal care and skill, it is one requiring great care and ofttimes the utmost surgical and manipulative dexterity, for the careless and reckless performance of it, even in the most favorable cases, would at once lead to the most serious consequences.

Fourth.—That it is an operation applicable to strictures in every region of the œsophagus, whereas external œsophagotomy is only applicable to those located in the region above the sternum.

Fifth.—That, as in external œsophagotomy and gastrotomy, it is an operation to be undertaken only when dilatation of the stricture has failed.

Sixth.—That success in this operation means a permanent relief to the patient and cure of the stricture. The restoration of the œsophagus to a normal condition rendering alimentation normal and leading at once to comfort and freedom from annoyance, whereas success in œsophagotomy or gastrotomy necessarily means a life of continued torment, the patient being in constant danger of the most serious complications and unfavorable terminations.

Seventh.—That the operation does not dispense with the use of the sound, but renders its use rapidly effective.

Eighth.—That it is inadmissible in strictures through which an opening cannot be found.

Ninth.—That it is contra-indicated in every instance in which the obstruction is cancerous or of a malignant nature, or caused by conditions external to the lumen of the œsophagus; where the walls are greatly atrophied, thinned or indurated; and where internal urethrotomy would be impracticable under like conditions of the urethra.

The Mud-Baths of Europe represent a stage of therapeutics which America has not yet reached. A correspondent of the *Cincinnati Lancet and Clinic* gives an interesting description of them: "Here in Austria they excavate a marsh where decaying vegetable mould and water is in abundance, cart it to the bath-houses, grind it in a mill and pass it into a large tank, where it is mixed with water and heated by steam. From the tank it is drawn off into portable bath-tubs, where it is again mixed, more water added, and the temperature brought to the desired grade. Then it is wheeled into the bath-room and the unfortunate bather plunges into a black, bad-smelling mixture, where he remains from twenty minutes to half an hour, when he steps into a second tub, full of pure water, to cleanse himself. The moor is too precious to be wasted, so after being used it is deposited in a great heap, where it is said to remain ten years before it will be fit for use a second time. These heaps remind one in more ways than one of those which the dairy farmer accumulates behind his cow stable. The moor-bath is popularly believed to be very beneficial in all cases —a veritable cure-all. The physicians questioned on the subject were unwilling to commit themselves as to its indications and effects, except in the case of hypochondriacs, with one exception, and he said where a poultice for the whole body was necessary he knew of no more convenient method of applying it."

MEDICAL LATIN.

By JOHN A. ARMSTRONG, Esq.,
BROOKLYN, N. Y.

An eminent Scotch physician and lecturer, addressing his class one hundred years ago, said: "I hope I have no need to recommend to you a *thorough* acquaintance with the Latin tongue. A physician's reading must be confined within very narrow bounds who is unacquainted with what *has been* the universal language of the learned in Europe for so many ages. . . . The interests of learning will very soon suffer by its disuse."

Doubtless, as it seems to us now, a very extravagant estimate of the importance of the Latin language, but one which was fairly justified by the condition of scientific learning generally at that time. Every educated man in Europe was presumed to be capable of writing Latin, which thus became the common medium of intercommunication. French was merely a colloquial language—the language of the courtier. Latin was the language of science and philosophy. The other languages of Europe were little studied. Comparative philology was as yet unknown. It had not come, as it has since, to be an acknowledged fact that it requires less time to master all the languages of Europe than it does to acquire "a *thorough* acquaintance with the Latin tongue."

That period has passed, with many of its learned prejudices, and Latin no longer jealously monopolizes the attention of youth to the exclusion of the living languages. Latin has ceased to be "the universal language of the learned;" but instead of suffering to any great extent, "the interests of learning" seem rather to have been benefited, inasmuch as the light of philological investigation has cleared up much that was hitherto unexplained in Latin and Greek. An American physician acquainted with French or German has now no need of Latin in order to exchange views with his brethren on the continent of Europe. Nor is it even necessary for an American physician to understand French or German in order to keep *au courant* of the current literature of Europe. Every work now-a-days which possesses merit enough to sell well finds translators everywhere.

To medicine and pharmacy, however, Latin holds the old relation. It is still the universally recognized medium of professional intercourse between physician and pharmacist, and will long continue to be such, despite the attacks which have been made on it in this relation.

M. Victor Hugo has savagely assailed the technical Latin of medicine and of the professions generally, attributing to it the same questionable purposes as those subserved by Argot.

A portion of the press, here and in England, has endeavored from time to time, to bring into disfavor the practice of writing prescriptions in Latin, arguing that it belongs to a past age, and that serious mistakes would be less frequent if it were the practice to write prescriptions in English. All very well, provided physician, patient, and pharmacist all understand English. But let us suppose, nor is it a thing altogether impossible here in America, that a United States physician or an English physician has occasion to prescribe for a patient in a community where two-thirds of the pharmacists are Spaniards and the remaining third German and French. What is he to do, supposing he can neither read nor write Spanish, German, or

French, and no one near him understands a word of English? He has recourse to the universal medium; he writes his prescription in Latin, and, whether it goes to a Spanish, German, or French apothecary, the desired remedy is forthcoming. Is any other argument necessary to show that if Latin did not happen to be the language already established as the universal language of physician and pharmacist, the necessity for some such medium would compel them to adopt it or some other? But Latin having been so long and so illustriously idenfied with the literature of medicine, and having contributed so largely to its terminology, it is not easy to see how it could be advantageously superseded by any other language.

The only objection which can be urged with any appearance of fairness against the practice of writing prescriptions in Latin is that they are sometimes written by persons who are not competent to write them. There can be no objection to sound Latin, legibly written. A prescription in doubtful Latin, written illegibly, is too dangerous to be meddled with.

Every physician is presumed to know Latin well enough to be able to write a prescription correctly. There is hardly a drug store in New York in which cannot be found abundant proof that the contrary is the fact. Indeed, to those who have opportunities for observation, it is only too deplorably evident that the degree of proficiency in Latin which is exacted of matriculates in medicine is not very high. The practice of abbreviation in prescriptions renders the study of syntax unnecessary. It would be well if prescriptions, under all circumstances, were written out in full without any but the mere technical abbreviations representing quantities.

To acquire a competent knowledge of the Latin of medicine and pharmacy does not imply in these practical times that the physician must be a thor ough Latinist; and yet it is quite possible for him not only to acquire all of the language which will be necessary to him in his profession, but with it a more correct knowledge of the construction of the language generally, than that possessed by some of the reputedly learned physicians of the last two centuries. This result will be attained by a new and discriminative method of instruction. The old method, for those who intend to become medical men merely, and not great scholars, is a waste of time and attention, to which the more important study is better entitled.

In the beginning of the present century medicine still numbered among her votaries, eminent scholars, like Boerhaave, Van Swieten, and Cullen, who wrote Latin with elegance and facility; but the exactions in this department of knowledge, being extravagant in consequence of such examples, pretensions to scholarship were much more common than the evidences of its possession. Of this fact we find proofs in the contemporary literature of the profession itself; such, for instance, as the ludicrous etymological blunders in "Fyfe's Anatomy," "Hooper's Vade Mecum," and other works, regarded in their day as infallible authorities.

Having had occasion to compare several works on medicine and pharmacy within the past year, I have been frequently amazed at the bad Latin to be met with in the best of them.

On the adoption of our present pharmaceutical nomenclature, the London and Edinburgh Colleges of Physicians differed in assigning the gender to such nouns as *carbonas*, *murias*, *sulphas*, etc.; the London college (rightly, according to analogy), making them feminine, and the Edinburgh college, for no apparent reason, making them masculine; which accounts for many apparent errors formerly to be found in the pharmacopœias and dispensatories—the result of quoting different authorities.

Allowance being made for such discrepancies, one of the most carefully edited works on the pharmacy of its day, was a little volume, entitled "A Conspectus of the Pharmacopœias of the London, Edinburgh, and Dublin Colleges of Physicians; being a Practical Compendium of Materia Medica and Pharmacy. By Anthony Todd Thomson. London, 1824."

In this work, not only is the gender of the noun given, but the quantity of a syllable, where otherwise liable to be mistaken, is marked by the long or short sign; the importance of which feature in the case of such words as *ricinus*, *lavandula*, etc., is sufficiently obvious. In this work, *carbonas* is intentionally feminine when the "London Pharmacopœia" is quoted; masculine when the "Edinburgh Pharmacopœia" is quoted, but never neuter.

For the discrepancies which abound in works on pharmacy, published in later times, there is neither reason nor excuse.

One of the volumes which engaged my attention was a neat little 12mo, entitled "Selecta e Prescriptis; or, Selections from Physicians' Prescriptions, containing Lists of the Terms, Phrases, Contractions, and Abbreviations used in Prescriptions, etc., with Examples of Prescriptions, grammatically explained and construed, etc., etc. Seventh edition. Much improved. London, 1837."

At page 34, in an enumeration of the parts of the body we find "*cubitus*, the fore-arm," and a foot-note informing us that *cubitus* "signifies, also, a lying down;" the author not being aware, apparently, that *cubitus*, the fore-arm, and *cubitus*, a lying down, are two different nouns and of different declensions.

At page 75, in the line—

℞. Ferri carbonatis, ʒ jss.

the abbreviation "ss.," is thus "grammatically construed." "*Cum*, preposition governing the ablative case; *semisse*, a substantive, ablative case sing., from *semissis*, *-is*, *f.*, third decl., governed by *cum*"! The author not being aware, apparently, that *semis*, the noun here used is neuter, indeclinable, and means half of anything; while *semissis*, which is masculine, means half a pound!

On page 68, is given the Latin rule, "One substantive agrees with another signifying the same thing, in case; as, ℞. *potassæ tartratis unciam.*" Where, as any school-boy would perceive at a glance, *potassæ* holds to *tartratis* precisely the same relation that *tartratis* holds to *unciam;* none of the substantives being in apposition at all.

On the very next page is the proper rule for this construction: "One substantive governs another, signifying a different thing, in the genitive." After an example, the author rightly observes in an interjectional note, "The substantive governed may govern another signifying a different thing; as, *drachma sodæ carbonatis.*"

"A Hand-book of Hospital Practice; or, An Introduction to the Practical Study of Medicine at the Bedside." By Robert Lyons, K.C.C., M.B.T.C.D., L.R.C.S.I., M.R.I.A., etc., London, 1859," contains, among other things, "Directions for Writing Prescriptions," and a "Glossary." In the former, is given what the author is pleased to call "a classic prescription

secundum artem;" in which we find one of the ingredients written "*aquæ menthis*" (menthæ?) "*piperitæ.*" To the "Glossary" is prefixed an "N. B.," informing us that "nouns ending in *a* are feminine, and declined like *musa*, except when a different gender and declension are given." And on the same page we find *asthma* and *atheroma*, with neither gender nor declension indicated, though farther on we find "*enema, -tis*, n." And we find *crepitus, -i*, m., instead of *crepitus, -ús*, m.

Every one has seen "A Dispensatory and Therapeutic Remembrancer, comprising the Entire Lists of Materia Medica, Preparations and Compounds, etc., as authorized by the London, Dublin, and Edinburgh Royal College [Colleges?] of Physicians, in the latest editions of their several Pharmacopœias, etc. By John Mayne, M.D., F.R.C.S., Edin." (Reprint of Lea & Blanchard, 1848.)

In this work we find the following extraordinary instances of mutability of gender: *Calcis carbonas præparatum*, page 34; *potassæ carbonas purus*, page 39; *sodæ murias purum*, page 46; *zinci carbonas præparatus*, page 78.

In "Gray's Supplement to the Pharmacopœia," a bulky and costly English work, which has run through numerous editions, we find: *Calcis phosphas præcipitatum*, page 629; *ferri carbonas saccharatum*, page 703; *carbonas ferri præcipitatus*, page 707; *potassæ carbonas purum*, page 836; *potassæ nitras fusa* and *potassæ nitras depuratum*, both on page 840; *sodæ carbonas exsiccata*, page 867.

It is in the highest degree creditable to the ability and care of the gentlemen hitherto engaged in the compilation of the "United States Pharmacopœia," that their work is disfigured by no such blunders. Such words as *carbonas sulphas*, etc., in the "United States Pharmacopœia," are rightly made to follow the analogy of their class of nouns of the third declension, and are qualified by adjectives in the feminine gender. We find, however, in a recent report of the American Pharmaceutical Association's Committee on the Revision of the "United States Pharmacopœia," page 119, the expression *rhus glabra* recommended to take the place of *rhus glabrum*, but no reason assigned for the proposed change. Why, *rhus glabra? Rhus glabra* is very proper sometimes; but the propriety of writing *rhus glabra* or *rhus glabrum* must depend on the part of the tree which it is meant to designate. If the bark or leaves are meant, by all means let us have *rhus glabra;* if the berry or seeds, *rhus glabrum*. Now, our officinal *rhus* is the berry or seed; and the noun is of the second declension. But where the name of a fruit-tree is of the second declension feminine and ends in *us*, the name of the fruit is neuter; as *malus*, an apple-tree; *malum*, an apple; *pirus*, a pear-tree; *pirum*, a pear. *Rhus*, the fruit or berry is exceptional in not taking the neuter termination; but Pliny and Celsus both make *rhus* neuter when they use it to express the *berry* or seed of the *Syrian sumach. Stet rhus glabrum.*

THE ODOR OF DEATH.—Dr. E. A. de Cailhol, of St. Louis, asserts (*Southern Clinic*) that he has the faculty of telling when death is to occur by a peculiar odor which he smells or sensation which he feels. He can detect this odor, he says, within twelve to forty-eight hours before death. Dr. C. evidently believes in this grim idiosyncrasy, but cites few instances to prove it.

A COMPARISON OF THE BODILY TEMPERATURE IN DIFFERENT SITUATIONS.

BY HENRY LING TAYLOR, M.D.,

HOUSE PHYSICIAN, ROOSEVELT HOSPITAL.

IT is generally taken for granted that the temperature of the human body is about a degree Fahrenheit higher in the rectum than in the axilla. That a rectal temperature is usually higher than an axillary may be readily admitted (and I shall adduce a series of observations which show this), though the difference varies between quite large limits; the average being, as we are in the habit of assuming, in the neighborhood of 1° F.

That this rule is subject to some remarkable exceptions was observed by the House Staff of Roosevelt Hospital in 1880, while taking simultaneous rectal and axillary temperatures on at least two cases of typhoid fever. These observations were frequently repeated with tested instruments and were verified by the entire medical house staff, so as to leave no margin for any error sufficient to explain away the results obtained.

The first case, a girl, aged sixteen, was admitted to the hospital October 14, 1880, with typhoid fever, having been sick three weeks.

I subjoin all the temperatures noted in the records as taken simultaneously in the axilla or rectum (or first in one position and immediately afterward in the other with the same thermometer).

Date.	Hour.	Axilla. Degrees.	Rectum. Degrees.	Difference. Degrees.
Oct. 19, 1880..	2.45 P.M.	103.0	101.4	—1.6[1]
Oct. 19, 1880..	4.45 P.M.	101.8	100.0	—1.8
Oct. 19, 1880..	7.45 P.M.	103.4	103 0	—.4
Oct. 19, 1880..	9.45 P.M.	102.6	102.8	.2
Oct. 19, 1880..	11.45 P.M.	102.2	102.8	.6
Oct. 20, 1880..	11.30 P.M.	102.2	103.0	.8
Oct. 21, 1880..	10.45 P.M.	104.4	105.0	.6[1]
Oct. 22, 1880..	9.30 A.M.	100.8	101.2	.4
Oct. 23, 1880..	9.30 A.M.	102.6	102.2	—4

Two affusions were given while the temperatures were being taken; one just before, October 18th at 8.30 P.M., and one on October 21st at 11.10 P.M.

The second case was a man, aged twenty-four, admitted November 12, 1880, with typhoid fever, having been sick in bed a week.

Date.	Hour.	Axilla. Degrees.	Rectum. Degrees.	Difference. Degrees.
Nov. 14, 1880..	7.15 P.M.	105.4	106.0	.6
Nov. 14, 1880..	11.00 P.M.	102.6	102.2	—.4
Nov. 15, 1880..	2.15 A.M.	101.8	102.4	.6
Nov. 15, 1880..	5.15 A.M.	101.4	101.8	.4
Nov. 15, 1880..	10.00 A.M.	101.8	101.6	—.2
Nov. 15, 1880..	1.00 P.M.	104.6	105.2	.6
Nov. 15, 1880..	4.44 P.M.	105.0	105.4	.4

During this time affusions were given as follows: November 14th, 4.10 P.M.; November 14th, 7.15 P.M.; November 15th, 1.30 P.M.; November 15th, 4.24 P.M.

[1] — Denotes that the difference is in favor of the axillary temperature.

The last temperature in the table was taken during the affusion.

On the other hand, in collapse, or at the moment of death, the difference in favor of the axillary temperature is increased. In a case of collapse from rupture of the intestine the temperature, thirteen hours before death, was: Axilla, 101.5°; rectum, 103.8°; difference, 2.3°.

In a case of typhoid fever where the prostration was profound, the extremities cold and the pulse a flicker, the following temperatures were observed three days before death:

Date.	Hour.	Axilla. Degrees.	Rectum. Degrees.	Difference. Degrees.
Nov. 1, 1882..	9 A.M.	103.2	105.4	2.2
Nov. 1, 1882..	12 M.	103.4	106.1	2.7
Nov. 1, 1882..	7 P.M.	104	106.4	2.4

Showing the unreliability of axillary temperatures in the later stages of this disease.

Two minutes after death, in a case of typhoid fever, the temperature was: Axilla, 103.8°; rectum, 107°; difference, 3.2°.

In order to determine the average difference between axillary and rectal temperature, Dr. J. B. McMahon, then House Physician, instituted a series of simultaneous observations, taken regularly morning and evening by Dr. Wm. T. Van Vredenburgh, then Junior Assistant Physician, in a case of typhoid fever, a girl sixteen years of age. The results were as follows:

Date.	Morning or Evening.	Axilla. Degrees.	Rectum. Degrees.	Difference. Degrees.
Dec. 23, 1881..	A.M....	103.0	103.4	.4
	P.M....	102.0	103.8	1.8
Dec. 24, 1881..	A.M....	101.2	102.4	1.2
	P.M....	103.8	105.0	1.2
Dec. 25, 1881..	A.M....	101.3	103.6	2.3
	P.M....	102.8	104.7	1.9
Dec. 26, 1881..	A.M....	102.6	103.8	1.2
Dec. 29, 1881..	P.M....	100.0	101.2	1.2
Dec. 30, 1881..	A.M	101.8	102.8	1.0
	P.M....	102.3	103.2	.9
Dec. 31, 1881..	A.M....	96.6	97.8	1.2
	P.M....	100.8	101.6	.8
Jan. 1, 1882...	A.M....	97.2	98.2	1.0

In two other cases of typhoid and one of remittent fever, these were the results:

Date.	Disease.	Axilla. Degrees.	Rectum. Degrees.	Difference. Degrees.
Sept. 10, 1881	No. 1, typhoid..	102.7	103.9	1.2
Aug. 20, 1881	No. 2, typhoid..	103.0	103.7	.7
Sept. 1, 1881	No. 3, remittent	105.4	106.4	1.0

The average difference of these sixteen observations is nearly 1.2°.

A series of observations on simultaneous axillary and vaginal temperatures was also instituted on the patient who furnished the largest number of data for the preceding table.

Date.	A.M. or P.M.	Axillary. Degrees.	Vaginal. Degrees.	Difference. Degrees.
Jan. 1, 1882..	P.M.....	100.1	101.0	.9
Jan. 2, 1882..	A.M.....	97.0	97.8	.8
	P.M.....	98.2	99.0	.8
Jan. 3, 1882..	A.M.....	97.8	98.7	.9
	P.M.....	98.4	99.4	1.0
Jan. 4, 1882..	A.M.....	98.3	99.5	1.2
	P.M.....	97.4	98.5	1.2
Jan. 5, 1882..	A.M.....	98.2	98.9	.7
	P.M.....	98.2	99.0	.8
Jan. 6, 1882..	A.M.....	97.0	98.3	1.3
	P.M.....	97.9	98.3	.4
Jan. 7, 1882..	A.M.....	97.6	98.5	.9
	P.M.....	97.4	98.5	1.1
	A.M.....	96.0	98.6	2.6
Jan. 8, 1882..	P.M.....	104.2	104.7	.5
	9 P.M...	102.2	103.5	1.3
Jan. 9, 1882..	A.M.....	96.9	98.3	1.4
	P.M.....	96.8	98.2	1.4
Jan. 10, 1882..	A.M.....	99.8	100.8	1.0

The average difference in these nineteen observations is nearly 1.1°.

Five weeks later, two observations showed in the same patient the axillary temperature higher than the vaginal: February 17th, P.M., axillary, 97°; vaginal, 95.8°; difference, —1.2. February 18th, A.M., axillary, 97.6°; vaginal, 95°; difference, —2.6°.

The vagina was somewhat patulous from emaciation of patient.

In seven comparisons of simultaneous mouth and axillary temperatures taken by the Junior Assistant Physician, Dr. Duncan Emmet, in five different cases, the following were the results.

Date.	Case No.	A.M. or P.M.	Axilla. Degrees.	Mouth. Degrees.	Difference. Degrees.
Oct. 24, 1882..	1	A.M.....	96.7	97.5	.8
Oct. 25, 1882..	1	A.M.....	97.1	97.3	.2
Oct. 24, 1882..	2	A.M.....	96.7	97.5	.8
Oct. 25, 1882..	3	A.M.....	98.5	98.7	.2
Oct. 25, 1882..	4	P.M.....	101.9	102.5	.6
Oct. 25, 1882..	5	P.M.....	102.3	102.6	.3
Oct. 26, 1882..	5	A.M.....	102.1	103.8	1.7

The average difference of these seven observations is over .6° in favor of the mouth.

The above tables comprise *all* the observations I could find recorded in the hospital books of temperatures taken simultaneously in different parts of the body.

It is perhaps hardly justifiable to draw conclusions from such a limited number of observations, but I may perhaps be allowed to provisionally sum up the results of these observations as follows:

First.—The difference between axillary and rectal and axillary and vaginal temperatures is not constant, but averages about 1° F. in favor of the rectum and vagina.

Second.—In certain exceptional cases the temperature may be considerably higher in the axilla than in the rectum or vagina.

Third.—The difference does not seem to vary directly with the height of the temperature.

Fourth.—The difference in favor of the mouth, in buccal and axillary temperatures, averages about one-half that in favor of the rectum and vagina, when axillary temperatures are compared with the latter.

Reports of Hospitals.

BELLEVUE HOSPITAL, NEW YORK.

CLINIC OF PROFESSOR L. A. SAYRE.

DIASTASIS OF THE HEAD OF THE LEFT FEMUR IN A CHILD EIGHT YEARS OF AGE MISTAKEN FOR MORBUS COXARIUS.

THIS case was that of a little girl eight years of age, sent on account of supposed hip-disease.

The father stated that she had always been lame, her left leg had always been shorter than the right. On examining her with great care, no disease whatever of the hip-joint was found. The legs were parallel, and the shortened limb could be drawn to an even length. The leg could be flexed in every possible direction, but when the two were placed together the left leg was one and a half inches shorter than the other, and it lay perfectly parallel with the opposite limb; the foot was parallel also. If this had been the result of dislocation upon the dorsum of the ilium, the foot would be turned in; if it had gone on to the third stage of hip-disease, it would result in shortening of the head from absorption and enlargement of the acetabulum from carious degeneration, the foot would also be turned in and at the same time anchylosed more or less completely, and we would have that distortion or inversion and crossing of the limb peculiar to the third stage of hip-disease.

Standing the little child so as to expose her back, she had the appearance of lateral curvature, because the left leg was shorter and she was compelled to twist the pelvis to place the left foot on the ground. That lateral curvature depended, of course, entirely upon the shortened leg. The trochanter major on the left side was "clear up" near to the crest of the ilium, as was shown by Nélaton's test. The latter was given as follows: We pass a string from the tuberosity of the ischium around the thigh posteriorly to the anterior superior spinous process of the ilium, and if the femur is normal, the head in its acetabulum, that line ought to pass directly over the top of the trochanter major. That is called "Nélaton's test."

The trochanter was one and a half inch above that line. When the neck of the femur was broken the trochanter also rode above that line.

The case was diagnosticated not as one of diseased hip-joint, but of diastasis. Nature had made an artificial joint, but not having any buttress, allowed the femur to glide up upon the ilium, and had made the child lame and greatly deformed.

Dr. Sayre had made an instrument for bringing that limb down and retaining it there so that Nature might create a new joint in as favorable a position as possible.

In this connection allusion was made to a child brought to him when six years of age, in which he found there was no disease of the hip, but there had been a fracture of the neck of the femur. The leg was flexed nearly at right angles and quite firmly anchylosed. He broke up the adhesions, divided the tendons, and brought the limb to a natural position; then, putting on a long splint, the leg was kept in that position until it formed an eburnated condition of the bone, and the head of the femur became rounded to fit this place, and made a perfectly good movable joint. The child ran around for some three years or more with simply a shortened limb, dying eight years after from double pneumonia, and I obtained the ilium showing the acetabulum nearly obliterated. Previous to death, for two or three years the child could walk without any artificial aid whatever, with the exception of a high-heeled shoe to equalize the length of the limbs.

In describing the treatment, Dr. Sayre continued: Now, this is what I propose to do with this child. I intend to pull the limb out. Now, if I can keep it in that place and allow her to make free motion, it will thus give Nature a better opportunity for forming a new joint than if left to be pressed up on the dorsum of the ilium.

The instrument is simply a pelvis belt, with two perineal straps. On the outside of the distorted limb a shaft, as you see, runs down which connects with the belt by a movable joint, and has at the same time a hinge which will either abduct or adduct, there is also a joint at the knee to allow the child to sit down; at the lower part of the shaft is another shaft running into the other, capable of adjustment, this terminates in a small axle running under the shoe, which axle fits into a little box. There is also a band which goes loosely around the knee to assist in retaining the instrument in position. In putting this instrument on, you have the pelvis belt go around just under the crest of the ilium, and have the perineal bands buckled on either side, putting some soft rags between the bands and the perineum to absorb the perspiration; these should be changed every day, otherwise the velvet becomes hard and irritating; it is also desirable to wash the perineum for a time every night with a little alcohol and alum.

Now the box for the axle being screwed fast to the shoe under the instep, the axle being slipped in and fixed, the pelvis belt fastened, and the perineal bands buckled, the instrument is screwed out and adjusted by the application of a key. The limb is now extended until the trochanter major has passed nearly an inch below the lower border of the pelvis belt, which it remained against before the extension was applied.

Now, as the child stands up, you will observe that the limbs are of equal length and the lateral curvature has disappeared.

The child then walked around with the greatest ease.

This is the first experiment on this child; had the case been diagnosticated earlier there would have been a much better opportunity to get a good result than there will now be.

CONSERVATIVE SURGERY IN CHRONIC DISEASE OF ANKLE-JOINT.

The case was a boy who had come to the clinic a year ago with chronic disease of the knee-joint.

The foot was a shapeless mass and intensely painful, with numerous sinuses leading to dead bone, and had been condemned to amputation by three of the surgeons of the hospital. Dr. Sayre was not aware at the time of their conclusion, and determined upon the removal of all diseased bone. The House Surgeon thereupon removed the os calcis, astragalus, cuboid, scaphoid, and cuneiform bones subperiosteally with the periosteum elevator, the os calcis being removed almost in its normal shape; the remaining bones were taken out in small fragments.

The wound was then thoroughly filled with Peru-

vian balsam, so that all parts were covered from the effects of the air; Listerism carried out to perfection, the creosote in the balsam being the antiseptic. It was then filled with oakum, which kept the heel in shape, a flannel blanket was drawn tightly over the whole foot, and the leg firmly encased in a plaster-of-Paris bandage, the foot and leg being held firmly in the normal position. After the bandage was set a fenestra was cut through on either side of the foot and a large wad of oakum placed in either fenestra, a roller bandage was then firmly applied to the whole limb, the plaster casing protecting the limb from pressure, but allowing pressure over the fenestras, while the internal stuffing being made of picked oakum, percolation could take place and no danger of pyæmia or septicæmia was to be feared.

The oakum was removed every day, the amount reapplied being daily diminished as the cavity became filled with osseous matter, until the amount of oakum applied became merely a thread (movement being given daily to the foot). The sinus was completely closed and an almost perfect foot secured, with the exception that the heel did not project to the normal position, but the motions of the foot upon the leg were almost equivalent to a normal joint, and the child walked with scarcely a perceptible limp. The only defect was in the inversion of his toes from want of power in the peroneal muscles to evert the foot. The application of a little elastic band from his shoe opposite to the little toe to the outside of the leg, by giving slight elastic force would guide the foot in the proper direction and enable him to to walk almost normally.

Progress of Medical Science.

The Pathogenesis of Gastric Ulcer.—In the course of some experiments on the production of nephritis by the injection of cantharidin under the skin, Aufrecht (*Allgemeine Med. Central Zeitung*, 1882) has made the remarkable discovery that ulceration of the stomach may result from these injections. After the subcutaneous injection of cantharidin, suspended in oil to lessen the local irritation, he found in guinea-pigs a large number of circumscribed changes in the mucous membrane of the stomach. These were at first regarded as merely hemorrhages, but on closer examination were found to be spots of loss of substance, the boundary of which projected above the level of the adjacent mucous membrane. These changes were especially conspicuous in the stomach of a rabbit which died ten days after the injection of two and a half milligrammes of cantharidin. About fifteen small ulcers were found in the stomach, many of them with raised edges, and all filled with blood clot. There were also six circular spots of a dull gray color, sharply limited, without any extravasation. A microscopical examination showed in the latter the following changes: The epithelium of the glands was paler and less granular than normal; between the glands was a clear amorphous material; the capillaries were distended with blood, whereas elsewhere they were empty. A similar change was found in the vicinity of the extravasation, and the glandular epithelium here presented irregularity. The extravasations were of uniform brownish red blood, in which no intact blood-corpuscles could be seen. There was no sharp limitation to the blood effused, such as might have been expected had the hemorrhage resulted from the rupture of one vessel. From these facts he concludes that the extravasation is the second stage in the process, consecutive to inflammation, which appears to be the first alteration. Aufrecht believes that these facts indicate that in man a similar sequence may obtain, and that ulcers of the stomach probably commence as inflammation, and not, as is commonly assumed, by hemorrhage.

Spasmodic Stricture of the Œsophagus.—At a meeting of the New York Medical and Surgical Society, Dr. Francis Delafield narrated a case as follows: The patient was an unmarried woman twenty-three years of age. He saw her first on February 16, 1882, when she stated that she had always enjoyed good health until eighteen months before. At that time she began to suffer from attacks of severe pain, which was referred to the region of the lower end of the œsophagus. These attacks occurred about once a week, lasted ten or fifteen minutes, and had no relation to the taking of food. They sometimes occurred in the night, sometimes in the day. There were no other symptoms whatever. After three months she experienced difficulty in swallowing solids, and subsequently in swallowing liquids. At length she could take no solid food, and liquids could be swallowed only at times. On some days she could swallow nothing whatever. She starved to a certain extent, but had no other symptoms. Menstruation continued regular, and there were no neurotic symptoms. Dr. Delafield was able to pass a large œsophageal tube into the stomach, and he therefore supposed the case was one of spasmodic stricture of the œsophagus, and at first attempted to treat it by passing the bougie every day, under which she seemed to improve for a time only. On some days she could swallow fluids, but oftener she could not, and as she gained nothing in weight, she was taught how to introduce half a pint of milk and a half pint of cream, mixed, into the stomach through the stomach-tube, to be repeated once a day. Besides, she was to try to eat regularly. She had done this since the 9th of March, and during all this time had been able to eat solid food at any time in the day, but it was her custom to eat an ordinary meal for breakfast and dinner, and to take the milk and cream in the manner indicated in the evening. From her normal weight of 125 pounds she had fallen to 99 pounds, but after adopting this plan she had gained 14 pounds. It was probable, however, that, like some cases of spasmodic stricture which had been reported, this one would continue for a long time.—*The New York Medical Journal and Obstetrical Review*, October, 1882.

Puerperal, Joint, and Bone Diseases.—Dr. Fasola draws the following conclusions from a study of ten cases of joint and bone disease in the puerperal state, observed by himself and others. 1. These diseases may appear in an otherwise normal puerperal state. 2. The joint affections are sometimes acute, sometimes chronic in their course, and may be suppurative or fungous in character. Diseases of the bone may be confined to the epiphysis or attack the entire bone, and may likewise be either suppurative or fungous. 3. Puerperal arthritis and osteomyelitis differ from the similar diseases in the non-puerperal state in their mode of onset, their course, and their results. 4. These diseases are always to be regarded as septic processes even when

they run a subacute course without fever. Prophylaxis consists in the employment of antiseptic measures during childbirth. The treatment of these diseases should be conducted according to the ordinary principles of medicine and surgery.—*Centralblatt für Gynäkologie*, September 23, 1882.

SPONTANEOUS DISCHARGE OF AN HEPATIC ABSCESS INTO THE BRONCHI.—Dr. Menacho relates the following case: A woman, sixty years of age, though living in a marshy district, had never had malarial fever. There was no enlargement of the spleen. Without any marked hepatitis there was developed an abscess of the liver, characterized by a tumor easily distinguished on palpation. For several days she suffered from difficult respiration, which only subsided after the expectoration of a considerable quantity of pus. This discharge of pus through the bronchi continued for about six weeks and was accompanied by a subsidence of the tumor, the liver dulness returning to its normal limits.—*Journal de Médecine et Chirurgie*, October, 1882.

A TRACHEAL SPECULUM.—Dr. E. Braatz describes in the *Centralblatt für Chirurgie*, September 23, 1882, an instrument to be used in place of the ordinary tube after tracheotomy. It consists of two narrow but strong blades, fastened, one on each side, to a ring, which may be attached to a shield in the ordinary manner. The blades are given the usual curve of a tracheotomy tube. The author was led to devise this instrument from the difficulty experienced in removing a large piece of false membrane through a canula. He claims for it that it offers less obstruction to the passage of false membrane, and permits of a thorough inspection of the trachea and under surface of the larynx. Through it, also, local applications may be made to any portion of the trachea.

PERIODICAL SORE THROAT RECURRING AT EACH MENSTRUAL EPOCH.—Dr. Genet (*Journal de Médicine et Chirurgie*, October, 1882) describes a sore throat which makes its appearance with great regularity a few days before each menstrual period, and subsides upon the appearance of the catamenial flow. It is characterized by a slight sensation of dryness in the throat, with thirst, and a little tickling cough. There is neither fever, headache, foul breath, nor any actual pain in the throat. Examination shows a slight redness of the fauces, and a little swelling of the tonsils. The affection lasts two or three days and disappears immediately upon the establishment of the menstrual flow. At the menopause, when the courses become irregular, the sore throat ceases to appear every month, but is observed only before the catamenia, at whatever time the flow may occur.

DILATATION AS A CAUSE OF CARDIAC HÆMIC MURMURS.—Dr. George W. Balfour has been led to adopt the theory of dilatation of the heart, as a cause of all cardiac chlorotic murmurs through the following considerations:

1. *This theory is alone capable of explaining in a rational manner all the discrepancies in the prevalent theories of these murmurs.* The aortic orifice has been most frequently mentioned as the seat of the hæmic murmur. But, although it is a basic murmur, it cannot be located at the aortic valve, since at its first appearance it is not propagated along the aorta or into the carotids. Neither can it be at the pulmonary orifice, for though its position of maximum intensity is in the neighborhood of the pulmonary artery, yet there are no causes for a murmur here that are not equally operative at the aortic opening. It has been referred by some writers to the mitral or to the tricuspid valve, but the universally recognized basic position of the primary hæmic murmur excludes this theory. Thus the position of this sound has been referred in turn to each of the four cardiac orifices. The only explanation of such a discrepancy is that the hæmic murmur is one which may be audible in all the positions described.

2. *It is thoroughly consistent with the results obtained by experiment.* When Marshall Hall was investigating the effects of loss of blood upon the system he observed that in the reaction subsequent to such loss the heart's action was "accompanied by a peculiar noise resembling that of the saw or of the file." He recognized also the identity of this sound with the chlorotic murmur. Beau determined the fact that the murmurs following loss of blood resulted, not from the primary anæmia, but from the secondary spanæmia, a condition to which he gave the name of "serous polyæmia." He also found that this condition of the blood was invariably associated with a dilated and hypertrophied heart.

3. *This theory is perfectly consonant with clinical experience.* It is known that in chlorosis a similar condition of the heart exists to that found in the "serous polyæmia" produced by repeated bloodlettings—dilatation and hypertrophy. The chlorotic murmurs are not due to anæmia, but to spanæmia, a condition in which the blood is not diminished in amount, though its nutritive and oxygenating properties are greatly lessened. The primary murmur in such cases is the venous num depending upon abnormal friction between the spanæmic blood and the venous walls. The next phenomenon observed is an accentuation of the pulmonary second sound due to increased intrapulmonary blood-pressure, the only possible cause for this being obstruction to the onward flow of blood. This latter, in a disease such as chlorœsis, can only be due to a loss of tone and contractile force in the cardiac muscle. Less able to do its work, yet having no less work to do, the heart slowly dilates and at the same time slowly hypertrophies. As the heart dilates, the mitral and tricuspid valves become incompetent and give rise to murmurs. The regurgitation in the tricuspid causes pulsations in the jugular veins, and the abnormally large ventricular blood-waves give rise to systolic murmurs in the pulmonary and aortic areas. These murmurs are propagated along the carotids, and may be heard on the slightest compression in every artery in the body. Thus we have murmurs in every area of the heart in advanced chlorosis. The primary cardiac hæmic murmur is basic, is not propagated in any special direction, but radiates around the pulmonary area. On careful examination its position of maximum intensity is found to be in the second interspace, from one to two inches to the left of the sternum. In this position the author states that he has always detected pulsation —at least during expiration. Occasionally this pulsation is so marked as to form a tumor, and has even been mistaken for an aneurism. Now, dulness and pulsation in this region are signs of dilatation of the left auricle; hence the author concludes that this murmur is propagated outward from the dilated appendix of the left auricle. This view receives further confirmation from a comparison of the primary chlorotic murmur with the similar murmur sometimes heard in mitral stenosis, which has

been shown by Naunyn to be due to mitral regurgitation. The tense auricular wall is thrown into sonorous vibrations by the impinging blood-streams, the sound being conveyed to the chest-wall by the auricular appendix which lies in contact with it at the base of the heart. Since these two murmurs are similar in character and position, it is fair to assume that they arise under similar conditions.—*British Medical Journal*, August 26, 1882.

Elastic Tension and Articular Motion as Therapeutic Agents in the Treatment of Pott's Disease.—Dr. M. Josiah Roberts criticises the want of uniformity in the principles of the treatment of Pott's disease as advocated by Sayre. In the lower dorsal and lumbar regions the attempt is made to secure rigid extension and absolute rest of the diseased parts, while in the cervical region the means employed afford elastic extension and a limited degree of motion. From his study of the subject the author concludes that the rational treatment of cervical caries (and incidentally of disease of other portions of the spinal column) is by elastic extension, permitting of limited voluntary articular motion. He claims that by this method the carious vertebræ are relieved of undue pressure, reflex spasm is overcome, and the jar incident to walking or riding is reduced to a minimum. As a consequence of the limited motion, without irritation, allowed to the diseased spine, the flow of blood through the capillaries is facilitated, and the nutrition and repair of the diseased tissues are promoted.—*New York Medical Journal and Obstetrical Review*, October, 1882.

Boracic Acid in the Treatment of Furuncle.—Dr. Gourgnes claims speedy and excellent results in the treatment of boils by boracic acid. He employs an ointment of 4 grammes boracic acid in 20 grammes vaseline with ½ gramme benzoic acid. The boracic acid should be finely powdered and not dissolved in alcohol or glycerine. This ointment continuously applied relieves the pain promptly and causes the disappearance of the furuncle in three or four days. *Journal de Médecine de Paris*, September 22, 1882.

Peritonitis caused by Vaginal Injections.—Dr. Mascarel reports a case of peritonits following the employment of the vaginal douche at a thermo-mineral bath. The tube employed was of large size, with a single opening at its extremity, and the fluid was injected with considerable force. Subsequent examination showed that the uterus was prolapsed and the os widely patent. The author insists upon the danger of medicated douches in women who have borne children, and urges in any case the employment of a tube with a bulbous extremity, perforated with a number of small holes.—*Journal de Médecine de Paris*, September 22, 1882.

Possibility of the Easy and Painless Introduction of a Tube into the Larynx.—Dr. Brown-Séquard in a communication addressed to the Académie des Sciences, relates some experiments undertaken by him, with the view of facilitating the introduction of a tube or other instrument through the rima glottidis. The pharynx was opened by an incision extending from the angle of the jaw to the base of the tongue, exposing the epiglottis and larynx. A very rapid current of carbonic acid gas was then projected over these parts, and at the expiration of from fifteen seconds to two or three minutes it was found possible to introduce a tube, or even the finger, into the larynx without giving rise to pain or any irritation. This local anæsthesia (accompanied by incomplete general anæsthesia) disappeared in from two to eight minutes after the withholding of the gas. No local or general bad effects followed the experiments. At first an extreme irritation of the larynx is produced by the carbonic acid, which soon, however, passes away and is succeeded by complete local anæsthesia. The vapor of chloroform produces like effects. The experiments were made upon dogs and rabbits. The author promises soon to determine the feasibility of the application in the human subject.—*La France Médicale*, October 3, 1882.

Contraction of the Vessels in a Limb remaining after Amputation.—Dr. Paul Segond, in a study of the changes occurring in the vessels of a limb from which a portion has been removed by amputation, arrives at the following conclusions: After an amputation, the arteries and veins of the affected limb undergo a notable diminution in size. This is observed even where the member removed is but a small part of the entire limb, as in hand or foot amputations. The reduction of the blood supply takes place, not only in the stump, but in the whole extremity. The diminution in the calibre of the vessels follows immediately upon the amputation and is not consecutive to the atrophy of the soft parts. It may indeed play an important role in the pathogenesis of this atrophy.—*Revue de Chirurgie*, August and September, 1882.

Deafness following Mumps.—Dr. Johannes Seitz reports a case of deafness following an attack of parotiditis, but five other cases having been hitherto recorded. The patient, a student nineteen years of age, was seized with inflammation of both parotid glands, of considerable intensity, but unaccompanied with any cerebral symptoms. On the sixth day the patient seemed well. Two days later he returned, complaining of deafness on the right side with tinnitus aurium and dizziness. The watch could be heard only when in contact with the head. The drum of the right ear was thinned, opaque, and slightly sunken, yet the light pyramid appeared normal. On the left side there were evidences of old middle-ear catarrh, but no signs of recent inflammation. There was no complaint of the left ear except for a day or two, when a sound like the roaring of the wind was present. This soon subsided and no further trouble was experienced on this side. The dizziness and tinnitus continued for two or three weeks and then gradually ceased, but the loss of hearing on the right side remained permanent.—*Correspondenz-Blatt für Schweizer Aerzte*, October 1, 1882.

Tabes Dorsalis in Early Childhood.—Dr. G. Leubuscher, in the *Berliner Klin. Wochenschrift*, September 25, 1882, reports the following case of locomotor ataxy, occurring in a child only three and a half years old. The patient was brought to the Jena Policlinic by his parents, who stated that for six weeks past the child had been unable to walk. He had always been a healthy boy, though he stuttered. There was no history of nervous diseases or of syphilis in the family. The boy complained of no pain, there was no strabismus and no disturbance in the functions of the bladder or rectum. Intelligence was unimpaired. The legs could be raised from the table, flexed and extended. Tendon reflex, and foot clonus absent, skin reflexes normal. The patient was unable to stand or walk alone, and when assisted by the hand, exhibited a typical ataxic gait. There was also commencing ataxia of the upper extremities. Slight improvement seemed to follow galvanization with a mild ascending current.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, November 18, 1882.

HERBERT SPENCER ON AMERICA.

In a recent London address, Mr. Matthew Arnold said that if he were asked to name the chief defects in the three leading nations of Europe, he would say that the French lacked morality, the Germans civic courage, and the English lucidity, *i.e.*, a capacity for judging things intelligently and without prejudice. Mr. Herbert Spencer, in his farewell speech last week in this city, supplemented these international criticisms and asserted that the fault of Americans was their passion for work, their persistent unrelaxing business activity.

He said: "Everywhere I have been struck with the number of faces which told in strong lines of the burdens that had to be borne. I have been struck, too, with the large proportion of gray-haired men; and inquiries have brought out the fact that with you the hair commonly begins to turn some ten years earlier than with us. Moreover, in every circle I have met men who have themselves suffered from nervous collapse due to stress of business, or named friends who had either killed themselves by overwork, or had been permanently incapacitated, or had wasted long periods in endeavors to recover health. I do but echo the opinion of all observant persons I have spoken to, that immense injury is being done by this high-pressure life—the physique is being undermined."

This exclusive devotion to work ends in a way every one knows. The individual finds that toil has become a necessity; not that he entirely enjoys his continual labor, but he is uneasy or unhappy without it. By and by, when relaxation and recreation are made necessary by undermined health, no enjoyment is gotten from them. The capacity for being amused may be starved out as well as destroyed by satiety.

Still further, the evil does not end in this generation. The health is injured.

"Damaged constitutions reappear in children, and entail on them far more of ill than great fortunes yield them of good. When life has been duly rationalized by science, it will be seen that among a man's duties care of the body is imperative, not only out of regard for personal welfare, but also out of regard for descendants. His constitution will be considered as an entailed estate, which he ought to pass on uninjured, if not improved, to those who follow; and it will be held that millions bequeathed by him will not compensate for feeble health, and decreased ability to enjoy life."

Mr. Spencer has much to say about the "complete" or ideal life. It is one in which neither knowledge, nor work, nor moral aspiration, nor indulgence is the leading *motive* of existence. But all these things are secondary, are to help us in the great aim of life—right living.

To the medical man Mr. Spencer's remarks have a special interest and pertinence. He has formulated what we all have known and perhaps spoken, but they come with especial force from one who is so profound a thinker and philosopher.

The doctor is an example of the persistent worker, and of one who, with rare exceptions, becomes finally the victim of his work. At the age of fifty most physicians are in a harness out of which they feel restless and useless. Life is no longer made for them, but they for a certain kind of life.

To the medical profession, then, our English philosopher preaches weightily the gospel of living, of getting more sweetness out of existence, and less of the sourness that comes with persistent toil in narrow routines of thought and activity.

Our practical readers will at once say that it is easy for well-fed philosophers to preach of sweetness and light, of relaxation and amusement. We must keep our patients, pay our bills, support our families. It is true that Mr. Spencer's "complete life" is quite unattainable for most of us just now. Our country is young, there is too much to do, we have fierce competitors to meet. Nevertheless, it will be wise to bear in mind that there is a higher philosophy of living. And it will be found that often one can get nearer to it than he had ever thought.

AUXILIARY HOSPITAL SATURDAY AND SUNDAY ASSOCIATIONS.

As the time approaches for the annual hospital Saturday and Sunday collections, we are glad to notice any movement calculated to further still more the charitable care of the sick poor. Notwithstanding the liberality which has characterized donations to the yearly hospital fund, it has been quite apparent to those interested in the movement that something more than a mere trust in impulsive alms-giving must be done to secure the grand end in view. Accordingly, managers of the hospital associations have, wisely we think, determined to form auxiliary associations in the different departments of trade

from which subscriptions can be systematically received. In return for such contributions it is intended that members of the auxiliary societies shall, on a provident system plan, be entitled to admission and treatment in any of the hospitals comprised in the parent association, at the rate of the care of one patient a day for every dollar contributed. In the hospitals for the treatment of children, at the same rate for every seventy-five cents thus accumulated, and in the hospitals for the treatment of diseases of the throat, eye, and ear, at the rate of the care of one patient per day for every one dollar and twenty-five cents thus subscribed.

It is provided, however, that each hospital shall be required to keep patients from auxiliary associations for such number of days only as it shall be compensated for, at the rates above allowed for patients, by the whole amount it shall receive from the annual collection; that no auxiliary association shall be entitled to keep patients, in any hospital, for a greater number of days than the hospital shall be compensated for, at the rates above specified, by such part of the whole amount received by it, in the annual distribution, as shall be in the proportion of the amount contributed by the Auxiliary Association, in the annual collection, to the whole amount collected, other than amounts specially designated; and that all rights and obligations under this resolution shall be limited to the year commencing on the 1st day of January next after the annual collection.

The plan of organization is a good one, and there is no doubt it will give satisfaction to all concerned. A more effective and simpler one could hardly be conceived. We are pleased to learn that it is beginning to be adopted by some leading trade concerns with a view to the care of the sick poor among their employés. Such medical men as may be interested in similar organizations elsewhere may address Rev. G. S. Baker, Superintendent of St. Luke's Hospital, New York, for any desired information regarding details. It is fair to say in this connection that Mr. Baker's untiring efforts in the direction of systematizing and making practical the movement in question cannot be too highly appreciated.

CHANGES OF ELECTRICAL RESISTANCE IN FUNCTIONAL NERVOUS DISEASES.

THE physical or chemical changes that take place in functional disturbances of the nerves and nerve-centres have generally been considered quite without the pale of any known method of analysis. That some peculiar physical changes do take place, however, is of course admitted, and the fact has recently been demonstrated in a very interesting manner.

Dr. A. Estorac, interne of the Montpellier Hospital, tested the resistance of the tissues to electrical currents in healthy persons, and then in patients suffering from hemianæsthesia and hemihyperæsthesia. It is well known that when galvanic currents are directed through any part of the body, there is usually a higher resistance at first, which resistance gradually diminishes with the continuance of the stream. In different persons, and in different parts of the same person, there are slight variations in the amount of resistance. In the same parts, or in symmetrical parts of the same individual, however, the resistance is practically always of equal amount.

M. Estorac found that in hysterical hemianæsthetic patients, there was a greater resistance upon the diseased than upon the healthy side. This resistance, in some cases, disappeared after prolonged applications; in other cases it continued. On the other hand, there was a less resistance upon the hyperæsthetic side than upon the normal one. This was true even when the hyperæsthesia had taken the place of a previous anæsthesia.

It is always laid down in electro-therapeutical manuals that the conductability of the body is due to that of the saline solutions contained in it. M. Estorac's experiments would lead to the inference that there are, in addition, some other factors in the matter which control, at least, the finer changes in conductibility. Whether these are simply slight changes in vascular supply, or are something yet more intangible, cannot yet be determined.

The experiments referred to are in harmony with some previous observations by Vigouroux. They may lead to further practical applications of electricity in electro-diagnosis. Thus, in alleged hypnotic conditions, local anæsthesia or hyperæsthesia can be readily produced. It is possible that the test of current resistance may be used here.

COLLEGE-BRED MEN IN MEDICAL SCHOOLS.

IN an editorial upon the "American Medical Student," published last winter, we gave some approximate estimates of the per cent. of college-bred men among this class. These figures were based upon returns obtained by the Commissioner of Education. It was asserted recently by our correspondent, Dr. Tyson, that they did not accurately represent the per cent. of students who had received degrees in letters or science in the Pennsylvania Medical colleges, because the Jefferson Medical College had failed to give any returns. Assuming that it has as large a number of baccalaurei as the University of Pennsylvania the proportion for the State would be raised to about sixteen per cent.

As regards the per cent. for the State of New York, our correspondent was in error in his attempt at correction. The last report of the Commissioner of Education shows that there were in the regular medical schools of this State in 1880, 2,037 students. Of these, 237 were reported to have received degrees in letters or science. This gives a ratio of about eleven

per cent., or of about seventeen per cent. among the 1,309 students of the colleges which reported. Three colleges did not report, and it is very safe to assume in such cases that their per cents. are low.

With regard to other States, the recent statistics give a per cent. for Illinois which does not vary much from that stated by us, and, in general, the facts and conclusions which we first gave were quite correct, as our correspondent would have found by more extended investigation.

The Boston *Medical and Surgical Journal* has recently published some interesting statistics showing the gradual changes in the proportion of college-bred men in the professional schools of Harvard University during the last five years. Thus the per cent. of baccalaurei in the medical school for the year 1881–2 was 50.65, while five years ago it was only 42.94 per cent.

The figures show also that the ratio is steadily increasing in the medical school at a greater rate than in the law-school, while in the divinity school the per cent. is actually decreasing, being about 40 now against 61 five years ago.

A PROSPECTIVE ATTACK ON THE BACILLUS OF TUBERCULOSIS.

THE editors of the *Chicago Medical Journal and Examiner* announce that they will shortly publish an article by Dr. H. D. Schmidt, of New Orleans, which article will contain very strong evidence, if not actual proof, that the *bacillus tuberculosis* is not an organized body, but a fat crystal. Dr. Schmidt began a series of studies upon the subject of tubercle a year ago. When Koch's discovery was announced he tried to find the new organisms, following strictly Koch's directions. Like others, he was unsuccessful, although he states that in some specimens of sputa certain bodies became visible, having a faint bluish color and presenting something of the shape and size of the bacillus. Still, it was impossible to say that these were organized bodies. He then used the caustic potash method adopted by Baumgarten, the sections being soaked in a thirty per cent. solution. In this way the presence was established in tuberculous tissue and sputa of minute rods which in every respect corresponded to the description given of Koch's bacilli.

In close connection, however, with these minute bodies, there were almost always droplets of fat. The idea was suggested that the bacilli might be only crystals, such, for example, as had already been seen in the degenerating fat-cells of leprous tissue. This idea was strengthened by finding that potash sections of various tissues in which there was fatty degeneration developed fine crystals in a short time, even after they had been mounted. We are told that Dr. Schmidt, pursuing his theory further, now claims that every form of Koch's bacillus can be artificially produced. He does not succeed in staining them, however, although they are highly refractive and have a faint bluish color, which may have deceived some observers.

By Ehrlich's and by Gibbes's method the supposed organisms were demonstrated, but not in a stained condition. In tuberculous tissue the rods were by no means found to correspond with each other in the matter of form and size. They were generally recognizable in those elements of the tubercular mass which had undergone degeneration.

Dr. Schmidt has a high reputation for microscopic skill, and his views will be examined with much interest. By a coincidence, one of the best microscopists in this city has, we are told, expressed opinions similar to those of Dr. Schmidt.

It is, of course, difficult to suppose that a discovery which has been confirmed quite widely and by a considerable number of skilled observers, should prove to be a mistake after all.

Furthermore, the fall of the *bacillus* of tuberculosis would involve that of a number of other infectious organisms. There will be very strenuous opposition, therefore, to the fat-crystal theory.

PROFESSOR BILLROTH'S AMPUTATIONS.

DR. ANTON WÖLFLER, Docent for Surgery and one of Billroth's assistants, has written a small work giving an account of the larger amputations in Billroth's clinic during the years 1877–1880.

There were, during these three years, 91 of the larger operations performed. In the previous nine years there had been 146 amputations. The increase was to some extent due to an increased ratio in the number of operations for bone and joint diseases. Of these 91 amputations 70 were healed, 3 were not healed, and 18 died, being a mortality of 19.7 per cent. This is a low rate, especially if contrasted with that of Billroth's former nine years' work when the per cent. of deaths was 45—a rate rarely exceeded, except in Zurich and Paris. The average mortality-rate in English cottage-hospitals, as stated by Mr. Burdett, is a little over 17 per cent. The average in German hospitals during the last few years has been only 15.6 per cent., according to Wölfler. Professor Billroth's ratio is thus above the average, but he undoubtedly had a severer class of cases. The remarkable improvement during late years in the results of large amputations is, of course, attributed to the introduction of antiseptics. If surgery is inclined to be boastful of what it accomplishes now, a useful antidote to its pride is furnished in reflections upon the number of lives lost through ignorance in years gone by. For seventeen years Germany's greatest surgeon lost nearly one-half his amputations; now it appears that he need only have lost one-sixth. The effect of antisepsis is especially shown in Billroth's record of amputations where

there were no complications, meaning especially thereby, no septic infection. This record is as follows: Zurich, 1860–67, mortality 35.1 per cent.; Vienna, 1868–76, 29.5 per cent.; Vienna, 1877–80 (careful antisepsis), 5.7 per cent.

Dr. Wölfler draws some conclusions regarding the relative dangers of traumatic and pathological amputations. That amputations for injuries are more fatal as a whole is admitted, but with some modifications. "A traumatic amputation," he says, "in and of itself is not more dangerous than an amputation for disease. It is the septic infection which causes the bad results. The mortality ratio is much lower in the first week for traumatic than for pathological amputations. After the first week, however, this relation is gradually reversed.

The effect of antisepsis in complicated or infected cases is strikingly shown. In the years 1877–80, 9 of these amputations proved fatal; in 1871–76, among 14 complicated cases the deaths were 12; in 1860–76, among 69 cases the deaths were 55!

In the last three years such complications as osteomyelitis, erysipelas, phlegmons, and phlebitis, were never present—a fact which means that such accidents are now almost inexcusable in modern surgery. Four times among twelve cases where reunion did not take place, reamputation was necessary.

On the other hand, there were quite frequently found small, circumscribed, superficial areas of gangrene. These have been met with and noticed by other surgeons using antiseptics and tight dressings. Wölfler ascribes them to the use of Esmarch's bandage, to carbolic acid, and the compression of the wound dressings.

Health of Criminal Women.—Dr. E. M. Mosher, in an article upon this subject (*Boston Medical and Surgical Journal*), comes to the following conclusions:

First.—Intemperance and unchastity are the two vices which fill our penal institutions with women.

Second.—The influence of these vices is detrimental to health of body, increasing its susceptibility to disease, and lessening its recuperative power.

Third.—The diseases which follow as a direct result of these vices are syphilis, alcoholism, dyspepsia, rheumatism, and general anæmia.

Fourth.—Morbid conditions of body react upon the moral nature, increasing and perpetuating the tendency to criminality; hence the importance of careful medical supervision as a reformatory measure.

Fifth.—More ample provisions should be made in all large cities for the isolation and thorough treatment of venereal patients of *both sexes*, either by the addition of special wards to the general hospitals or by the establishment of hospitals for this class.

Sixth.—The women who commit high crimes, that is, larceny, burglary, arson, manslaughter, etc., possess a more sensitive nervous organization than those who commit only offenses against chastity and public order.

Reviews and Notices of Books.

A Practical Laboratory Course in Medical Chemistry. By John C. Draper, M.D., LL.D., Professor of Chemistry in the Medical Department of the University of New York, etc. New York: William Wood & Co. 1882.

In this little work of only sixty pages Dr. Draper has managed to write a very serviceable, because eminently practical, guide-book to the student who is pursuing a laboratory course in medical chemistry. The working practitioner also will find it useful to refresh his memory by a perusal of its pages. Both student and physician scarcely require more than the knowledge it conveys for a satisfactory and reliable performance of those every-day tests which they must needs perform in the pursuit of studies on the one hand and the exercise of a calling on the other.

On Asthma: Its Pathology and Treatment. By Henry H. Salter, M.D., F.R.S. First American from the last English Edition. New York: William Wood & Co. 1882.

Salter's treatise on Asthma forms the September number of Wood's Library. In all that relates to the clinical history of this affection, and also as regards its etiology, consequences, and prognosis, no better work has been published in the English language than Salter's. The various existing theories, regarding the phenomena of the disease, are also analyzed and dealt with by the author from the standpoints of fact and experience. The chapters on treatment are most comprehensive. The several depressants, stimulants, sedatives, and antispasmodics, their mode of action and relative value, are fully discussed and supported by the citation of numerous cases. Diet and hygiene and the influence of locality also receive their due weight and consideration, with illustrative histories. In addition, there are special appendices, A and B, given respectively to clinical and to tabulated cases.

Hygienic and Sanitative Measures for Chronic Catarrhal Inflammation of the Nose, Throat, and Ears. By Thomas F. Rumbold, M.D., Professor of the Diseases of the Nose, Throat, and Ears in the College for Medical Practitioners of St. Louis, etc. Second Edition. Medical Journal Publishing Co. 1882.

The present edition of this practical little treatise will be read with interest and profit by the practising physician. It contains some new matter, although scarcely any new therapeutic suggestions. The author again forcibly points out the advantage, or, as he calls it, the necessity of proper hygienic and sanitative measures, in treating the troublesome catarrhal conditions of the parts mentioned in the title. If Rumbold's faith in such measures seems somewhat excessive, the fact nevertheless remains that these adjuvants to rational treatment are too often neglected by the general practitioner. A perusal of the author's views cannot fail, therefore, to lead to a more successful management of chronic catarrh by that large class of physicians who, without being specialists, are yet frequently called upon to treat this obstinate affection.

A Treatise on Therapeutics, Comprising Materia Medica and Toxicology, with Especial Reference to the Application of the Physiological Action of Drugs to Clinical Medicine. By H. C. Wood, Jr., M.D., Professor of Materia Medica and Therapeutics in the University of Pennsylvania, etc. Fourth Edition. Philadelphia: J. B. Lippincott & Co. 1882.

For those who wish to study rational therapeutics based on scientific principles, without disregard of the great practical aids supplied by careful empiricism, Wood's treatise will be a welcome, nay, an indispensable volume. It is a book which stands alone in its special sphere. It is not encumbered with the confusing optimism of Bartholow's popular manual, while on the other hand it does not breathe the chilling nihilism of some German works on therapeutics. The student who wishes to copy and utilize ready-made prescriptions for book-cases of disease will search in vain in the work before us. But he who wishes to learn what painstaking observation has taught us in regard to the action of various drugs in health and disease, will be amply gratified. A mastery of this knowledge will make the self-reliant practitioner who extemporizes his prescriptions to meet the wants of individual cases, and who has no need of burdening his memories with the formulas recommended by "authorities" in the various departments of the healing art. The present fourth edition has taken due cognizance of the advances made since the publication of the third issue. The chapter on electricity is too meagre in details to prove satisfactory. In future editions it should be materially amplified, or else entirely omitted. Wood's "Therapeutics" is earnestly recommended to the student and the aspirant for success in practice.

The Treatment of Diseases by the Hypodermic Method. By Roberts Bartholow, M.A., M.D., LL.D. Fourth Edition. Philadelphia: J. B. Lippincott & Co. 1882.

The present edition of Bartholow's manual of Hypodermic Medication has been revised and enlarged in such a way as to do most complete justice to the progress made in this department of therapeutics since the issue of the preceding edition. Nevertheless, the work is neither complete nor perfect. There are some omissions and several blemishes in the make up of the volume which, it is to be hoped, will be supplied and rectified in future editions. Among the former the hypodermic employment of pilocarpine in various throat affections, notably in diphtheria, might certainly have been noticed. Resorcin has been found useful in the hands of several European observers, and deserves mention in a modern hand-book purporting to be as complete as the treatise of Bartholow. Nitrite of amyl has been used hypodermically with signal benefit in impending syncope, as well in chloroform narcosis as from other causes. The principal blemish which we wish to point out is the undue prominence given to polemical reasonings concerning antagonism of various drugs. Certainly, Dr. Bartholow, of all persons in the profession, is perhaps the best qualified to discourse on this interesting topic. Nevertheless, in a work of the kind before us, it is hardly necessary to present these problems with such fulness, not to say self-complacency. In spite of these minor faults, which the reviewer feels called upon to point out, the book is by all means the best and most handy of its kind, and will be profitably consulted both by students and practitioners.

A System of Surgery, Pathological, Diagnostic, Therapeutic, and Operative. By Samuel D. Gross, M.D., LL.D., D.C.L. (Oxon.), LL.D. (Cantab.). Sixth Edition. 2 vols. 8vo, pp. 2,368. Philadelphia: Henry C. Lea's Son & Co. 1882.

The sixth edition of this work comes to us bearing evidence of very thorough revision. It is rarely the lot of an author to have a treatise so long before the profession—nearly a quarter of a century—and be privileged at the end of that period to go over his task afresh and maintain the high standard of previous efforts. But more fortunate still is it for his readers that such a thing is possible, and that the ripe experience of the writer is so satisfactorily brought down to the present date. The work, as a whole, needs no commendation. Many years ago it earned for itself the enviable reputation of the leading American work on surgery, and it is still capable of maintaining that standard. The reason for this need only to be mentioned to be appreciated. The author has always been calm and judicious in his statements, has based his conclusions on much study and personal experience, has been able to grasp his subject in its entirety, and, above all, has conscientiously adhered to truth and fact, weighing the evidence pro or con accordingly. And all this is done consistently with an independence of opinion regarding points of practice. In fact, he has stamped his individuality on every page, and has not left the student in doubt as to any given course to pursue. But these are only general considerations which may serve as preface to what may be said of the work in this last edition. A considerable amount of new material has been introduced, and altogether the distinguished author has reason to be satisfied that he has placed the work fully abreast of the existing state of our knowledge. In so doing he has availed himself of the assistance of his talented son, Professor S. W. Gross, who has much enriched the subject of morbid growths by personal contributions thereto. Recognizing the benefits of specialism in the study of surgery in its broadest sense, the author has wisely given the supervision of some parts of the work to experts in different branches. Hence we learn that Dr. J. Solis Cohen has revised the chapter on respiratory organs, Dr. George C. Harlan that on the eye, and Dr. Charles H. Burnett that on the ear. The chapter on refraction and accommodation by Dr. W. Thomson is retained from the fifth edition. Dr. E. C. Seguin furnishes an interesting and instructive section on cranio-cerebral topography. Dr. Battay supplies the material for the discussion of oöphorectomy, and Dr. L. H. Sayre discourses on the treatment of spinal diseases. The work is copiously illustrated as usual, and altogether contains sixteen hundred engravings.

The Principles and Practice of Surgery. By John Ashhurst, Jr., M.D., Professor Clinical Surgery in University of Pennsylvania, etc. Third Edition. 8vo, pp. 1,064. Philadelphia: H. C. Lea's Son & Co. 1882.

Within a short period of time Ashhurst's Surgery has advanced to a third edition. This is generally a very fair indication that the author has written a good book. In this particular instance the verdict is rightly rendered. The author, long known as a thorough student of surgery, and one of the most accomplished scholars in the country, aims to give in this work "a condensed but comprehensive description of the modes of practice now generally employed in the treatment of surgical affections,

with a plain exposition of the principles upon which these modes of practice are based." In this he has so well succeeded that it will be a surprise to the reader to know how much practical knowledge extending over such a wide range of research is so well compressed in a volume of this size. This feature of the work must be its best claim for continued popularity with students and practitioners. In fact, in this respect it is without any equal in any language. In the present edition many novelties in surgical practice are introduced, many modifications of previous statements made, and several new illustrations added.

MEDICAL ELECTRICITY. By ROBERTS BARTHOLOW, A.M., M.D., LL.D. Philadelphia: Henry C. Lea's Son & Co. 1882.

THE second edition of this work following so soon upon the first, would in itself appear to be a sufficient announcement; nevertheless, the text has been so considerably revised and condensed, and so much enlarged by the addition of new matter, that we cannot fail to recognize a vast improvement upon the former work. The methods of determining and expressing current strength, tension, resistances, etc., are more fully presented, and the action and uses of the magnet, and the polar method, are also entered into more extensively. It would be impossible, however, for us to mention the work in detail, embracing as it does such an extent of united interest that to touch upon any particular portion minutely, necessarily involves the notice of others equally important.

The first part of the work is devoted to electrophysics, including magnetism, static and dynamical electricity, and their various phenomena and laws, demonstrated by numerous experiments. The various forms of galvanic combinations also receive attention, with special chapters on electro-magnetism and magneto-electricity, and on the various batteries for medical use, their form, management, and manipulation.

Part II. takes up electro-physiology, treating of animal electricity and the action, severally, of the galvanic and of the induced currents on motor, sensory, and mixed nerves; of the effects of both galvanic and faradic currents, direct and indirect, on the sympathetic and vaso-motor systems, on muscle, on the cerebro-spinal axis, and on the pneumogastric nerve and heart. A closing chapter is also given to the action of electricity on the special senses.

Part III. is devoted to electro diagnosis, presenting various methods and exhibiting the nature of reactions to electrical stimulation when the disease is located in the muscles themselves, in the motor nerves supplying the muscles, in the spinal cord, or within the cranium. The diagnostic value of reactions to electrical stimulation of the nerves of the special senses also receives marked attention.

Part IV. is confined to electro-therapeutics. Beginning with the history and the physiological effects of magnetic applications, its therapeutic results are entered into, followed by chapters on static electricity, its appliances and therapy, and on general electro-therapeutics, exhibiting the applications of electricity in cerebral affections, in spasm and cramp, in the various paralyses, in the treatment of pain, in anæsthesia, in the vaso-motor and trophic neuroses, and in certain constitutional and local diseases.

In Part V. electrolysis and the use of electricity in surgery is treated of, together with medical electric lighting and heating, the cautery and laryngoscope. Finally, Part VI. is devoted to thermo-electricity and its medical uses.

The author has prepared his work for students and practitioners; for those who have never acquainted themselves with the subject, or having done so, find that after a time their knowledge needs refreshing. We think he has accomplished his object. The book is neither too scientific, nor too voluminous, but is thoroughly practical, simple, complete, and comprehensible. It is, moreover, replete with numerous illustrations of instruments, appliances, etc., is printed on fine paper, and handsomely bound in cloth.

HOW TO BE WEATHER-WISE: A New View of Our Weather System. With Illustrations. By ISAAC P. NOYES. 12mo, pp. 51. New York: Fowler & Wells.

THIS is a brief and plainly written explanation of the causes of changes in the weather, based upon the system of the United States Signal Service.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 11, 1882.

E. C. SEGUIN, M.D., PRESIDENT, IN THE CHAIR.

DR. HEINEMAN, in behalf of a candidate, presented a specimen of *suppurative hepatitis*.

SCARLET FEVER AND DIPHTHERIA.

DR. J. LEWIS SMITH presented the larynx and trachea from a child that died in the New York Foundling Asylum, at the age of three and a half years. The following is the history, written by the resident physician, Dr. Swift:

The child was well nourished and healthy till September 29th, when he had symptoms of what seemed to be catarrhal croup. The faucial surface was red, but he did not seem seriously ill. On the 30th he was cheerful, but his tongue was coated. On the night of the 30th he breathed well and slept well.

October 1st. — The rash of scarlet fever appeared over the neck, back, chest, arms, and thighs. In the course of the day it extended to the feet; rash profuse, tongue covered with a white fur, fauces of a deep red color, but without pseudo-membrane; axillary temperature, 103°; pulse, 140; slight stridor in breathing and some cough. 4 P.M.: Temperature, 103¼°. The patient is bright and is interested in what is going on around him.

October 2d.—Restless nearly all night, and slept only a few hours. Skin hot and dry; breath foul; lungs clear; has vomited four times to-day; no diarrhœa; throat still very red, but without pseudo-membrane.

October 3d.—Had some sleep during the night; temperature, 103¾°; pulse, 120; is very talkative; fauces much swollen; vomits occasionally; eruption well out over the entire body. 4 P.M.: Temperature, 104¼°; pulse, 128; tongue moist and clean; some discharge from the nares; urine free from albumen, but its quantity somewhat diminished.

October 4th.—Is very sick; profuse discharge

from the nostrils; throat of a deep red color, and a white pseudo-membrane over both tonsils and uvula; glands at angle of jaw much swollen; temperature, 104°; pulse, 140; some stridor in breathing; passes rather more urine than yesterday. 9.30 P.M.: Temperature, 105°; tongue clean.

October 5th.—Croupy again during the night; tonsils and uvula greatly swollen, so that the fauces are almost occluded; profuse discharge from nostrils, thin and acrid; breathes with difficulty, but so far seems to receive enough oxygen; breath not offensive; temperature, 103¾°.

About 1.30 P.M., after being raised to take some milk, sudden asphyxia occurred. His face was black, his eyes protruded, and he voided fæces and urine. Tracheotomy was immediately performed by Dr. Swift, which gave temporary relief. A large amount of pseudo-membrane was expelled through the opening in the trachea.

October 6th, 12.30 A.M.—Breathes again with great difficulty, and face becoming livid, but the canula is not obstructed; attempts to clean out the obstruction in the trachea below the canula fail to give relief; convulsions occurred, followed by death at 3.30 A.M.

At the autopsy Dr. W. P. Northrup, curator, found the following conditions:

Body.—Well nourished, branny desquamation on the trunk; post-mortem lividity back and sides; tracheotomy wound of neck; membrane to be seen in nose.

Brain.—Normal.

Larynx.—Trachea and pharynx coated with pseudo-membrane. Some of the membrane has been removed from trachea below the wound, leaving the denuded surface bright red and smooth. Tonsils covered by deep slough of fetid odor. Membrane can be traced distinctly up into pharynx and naso-pharynx. Membrane also traced down into two to three divisions of bronchi. Below that point the mucous membrane is very red and covered with viscid mucus, with some pus.

Lungs.—Right: Congested; no consolidation. Left: Old adhesions over middle-third of posterior surface. These adhesions cover a definitely circumscribed area of consolidation about the size of a small hen's egg. When cut this shows a honey-combed, discolored, gangrenous condition. This area extends from the root backward and outward to the surface, where the strong adhesions were encountered. At the lip of the lung, and at the apex, are two to three small triangular areas, the size of a bean, deeply congested, or possibly filled with blood from insufflation after tracheotomy (if that is possible). Otherwise the lung seems normal, excepting a moderate congestion.

Liver.—Somewhat enlarged; congested; one and a half pound.

Spleen.—Normal size; rather pale, and three ounces friable.

Kidneys.—Cortical markings rather indistinct; capsule not adherent; six ounces.

Stomach.—Slight catarrh.

Intestines.—Small: Scattered areas of congestion circumscribed and bright red. Large: Solitary follicles swollen, and some apparently ulcerated. Contents, mucus and some watery, yellowish fluid.

Heart.—Normal.

"*Remarks.*—The history of this interesting case, in brief, is this: The child had symptoms of catarrhal croup, from which he was apparently improving when scarlet fever commenced. This continued three or four days, when severe and fatal diphtheria supervened. I need not state to New York physicians, who are in general practice, that the coexistence of these two infectious maladies is very common. It is rare that a child having diphtheria primarily, takes scarlet fever during the progress of the diphtheritic inflammations; but scarlet fever becomes so often complicated by diphtheria after it has continued a few days in localities like New York, where diphtheria is endemic, that the former may be considered one of the causes of the latter. After having observed many epidemics of these two diseases, I am of the opinion that sometimes when both maladies are prevailing together, as large a proportion as one-fourth of the cases of scarlet fever become complicated by diphtheria, greatly augmenting the danger of the case, and perhaps rendering it fatal. When a complication of these two maladies occurs, it is usually about the third or fourth day of scarlet fever when the symptoms become suddenly aggravated. The temperature is higher, the pulse more rapid, and the heat of surface greater. On inspecting the fauces, the pseudo-membrane is already seen forming over the tonsils, and it may appear over a large extent of surface, faucial, nasal, laryngeal, and bronchial, as in the present case.

"The house-physician, who saw and treated this patient through the entire sickness, was inclined to consider it an exceptional case in which diphtheria alone preceded the scarlet fever; but as the croupy symptoms with which the attack began were abating, and no pseudo-membrane appeared till after five days from the commencement, and three or four after the setting in of scarlet fever, the explanation which I have given seems to be more probable; that is, of a catarrhal croup, scarlet fever, and diphtheria.

"According to my observations, it is rare that diphtheria attacks that portion of the air-passages below the epiglottis when it complicates scarlet fever. It is, as a rule, limited to the faucial and nasal surfaces; though in one instance it extended along the lachrymal duct to the left eye, causing much tumefaction and redness of the skin over the nose and eyes, destroying the eye and producing a thick pseudo-membranous exudation on the under surface of each eyelid. It is well-known that when diphtheria occurs, it attacks by preference those surfaces which are already the seat of inflammation. This is my explanation of the fact that in the case now before the society the specific inflammation was so extensive over the air-passages.

"We have now in the city a distinguished specialist in throat diseases, Dr. Mackenzie, and we have this week an opportunity of hearing his remarks on diphtheria. Specialists are apt to look at diseases in the light of the specialty to which they devote their attention. Contrary to the opinion of many specialists in throat diseases, I have no doubt that diphtheria is primarily a constitutional disease; among other reasons, from the fact that in certain malignant cases the kidneys are affected as early as the second day, showing blood-contamination; from the fact that some cases have an incubation of six or seven days, and local treatment, however early, and perseveringly used, does not prevent blood-poisoning in severe cases.

"It is evident that diphtheritic laryngitis, of which our patient died, can only be successfully treated by solvent inhalations, or, if they fail, by tracheotomy. From experiments made in the New York Foundling Asylum, it was shown that a two per cent. mixture

of liquor potassæ in water is a more efficient solvent than any other agent which is commonly used, and with this dilution it does not cause smarting or irritation of the healthy buccal or faucial surface. It is acrid and irritating in its nature, and I am afraid that in this proportion it may irritate those surfaces which are already inflamed in diphtheria. I therefore give the following prescription, to be used almost constantly by the steam atomizer: Liq. potassæ, ʒ i.; aquæ calcis, ℥ vij. The liquor potassæ being still farther diluted by the steam from the boiler, reaches the faucial and laryngeal surfaces in the proportion of one part to eighty-four. Of course, diphtheria, when it complicates scarlet fever, requires even more active stimulation than when it is idiopathic. I am in the habit of giving one teaspoonful of brandy or whiskey every half hour to a child of three years having these two infectious maladies. On some other occasion I hope to give statistics of the antiseptic treatment of scarlet fever and diphtheria by Listerine, which I am now using locally and internally, in conjunction, it is true, with the old remedies."

Dr. Briddon asked concerning the frequency with which a punctate scarlatinous form of eruption occurred in diphtheria. He was of the opinion that such an eruption appeared not infrequently.

Dr. Smith said that an efflorescence frequently accompanied diphtheria, but he thought it was so distinct in its appearance as not to lead to error in diagnosis by the eruption. In the case reported the scarlet-fever efflorescence preceded the diphtheria by two days. In most instances in his practice, where diphtheria had complicated scarlet fever, the complication developed at about the third or fourth day.

Dr. Briddon said that he had been accustomed to regard cases such as Dr. Smith had reported as diphtheria attended by a cutaneous efflorescence, which he thought could not be distinguished from the efflorescence of scarlet fever.

Dr. J. C. Peters referred to the fact that, thirty or forty years ago, in nearly all severe cases of scarlet fever there was the same diphtheritic appearance in the pharynx and sometimes in the larynx as seen in Dr. Smith's specimen. All the old books described scarlatina anginosa as a disease with diphtheritic exudation upon the uvula, pharynx, and, occasionally, within the larynx.

Dr. Van Santvoord suggested that the continued high temperature in Dr. Smith's case was in favor of scarlet fever, and would aid in making a differential diagnosis between the two diseases.

Dr. Smith said that he appreciated the difficulty in making an exact diagnosis, especially in scarlatina anginosa, to which Dr. Peters had alluded. That is, a malignant form of scarlet fever occurred in which, after the disease had lasted a few days, the surface of the mucous membrane of the fauces became jagged and foul, and then the appearance was very much like that presented in diphtheria. Still there were cases in which the diagnosis was easy, and in which it could be stated positively that diphtheria complicated scarlet fever, especially where there had been faucial inflammation, moderate in character, followed by grave symptoms attended by the appearance of membrane upon the tonsils.

Dr. Ripley regarded Dr. Smith's statement as an important one, namely, that during the prevalence of diphtheria in the city, cases of scarlet fever were very liable to be complicated with diphtheria. He had also observed the same fact with reference to measles. He saw no reason for doubting the diagnosis of scarlet fever complicated with diphtheria in the case reported.

With regard to diphtheritic croup as a complication, he was somewhat surprised in hearing that Dr. Smith had not seen it more frequently. Dr. Ripley had performed tracheotomy for diphtheritic croup complicating scarlet fever at least three times during the last year. During the last few years, also, he had frequently seen croup as a complication of diphtheria; that is, the false membrane had often invaded the larynx.

Dr. Smith thought that, in a large majority of cases, where diphtheria complicated whooping-cough and measles, diphtheritic croup developed. But in his experience, diphtheritic croup complicating scarlet fever had been rare.

Dr. Van Gieson had met with three cases. In one the eruption had begun to subside, the temperature was falling, but at the end of the fifth day the child became slightly hoarse, and upon that fact he based an unfavorable prognosis. The patient died twenty-four hours afterward with all the symptoms of suffocative croup. He regarded the development of hoarseness on the third, fourth, or fifth day in the course of scarlet fever as a very ominous symptom.

Dr. Tauszky regarded the inflammatory condition preceding the appearance of the croup as an important factor, and a condition which was present invariably. This being true, it ought to be utilized in the prophylactic treatment of all cases during an epidemic of diphtheria. Every catarrhal inflammation of the fauces should be treated, and possibly in that way diphtheria might in some cases be prevented.

THE PRESENCE OF PUS-CORPUSCLES IN THE BLOOD-VESSELS IN PYÆMIA.

Dr. C. Heitzmann exhibited a microscopical specimen from a forming pyæmic abscess of the liver. Pyæmia in former times was termed "pernicious intermittent fever," was believed by Cruveilhier to be intimately connected with purulent phlebitis, while Piorry proposed the name *pyœmia* upon the suggestion that pus was present in the blood, and that view was corroborated by Schuh, although no one had positively proved the presence of pus-corpuscles in the vascular system. Virchow contradicted this possibility, and Klebs more recently attributed the whole prccess to the presence of infectious germs, penetrating a wound from without, forgetting that pyæmia had been observed when a closed abscess was present in the depth of the tissues without communication with the outer world. The patient (about fifty years of age) whose liver furnished the specimen, was operated upon for cancer of the throat, did well until the tenth day after operation, when suddenly rigor set in, and three days afterward death occurred. Infarctions and abscesses were found in the lungs, the liver, and the kidneys, nowhere large or numerous. Sections through the tissues of the liver at a point where an infarction the size of a hazel-nut had occurred, which to the naked eye looked dark purple red at its periphery, and yellow in its centre, exhibited the following features:

The portal veins were engorged with coarsely granular, irregularly globular corpuscles, red blood-corpuscles, and a finely granular detritus. The coarsely granular bodies were very numerous and showed the characteristics of pus-corpuscles, viz.: the granules of living matter which they contained were of greatly varying sizes. In colorless blood-corpuscles, even

of persons of a good constitution, the granules are more or less uniform in size, and their increase in such an irregular manner could be due only to inflammation. Hence, the diagnosis of pus-corpuscles in the portal veins was made. These corpuscles could not have originated *in loco*, for the surrounding connective tissues displayed very slight, if any, inflammatory changes. A branch of the hepatic artery also contained a limited number of corpuscles of this kind, and pale granular plates, probably detached endothelia of the blood-vessel. Large, coarsely granular pus-corpuscles were present in all the capillaries within the lobules at the place of the infarction. The specimen seems to prove that pyæmia was really caused by the embolic accumulation of pus-corpuscles, which circulate in large numbers in the whole vascular system. The older views concerning the cause of pyæmia unquestionably deserved attention, although it was difficult to explain why pus-corpuscles, collected in a certain vascular district, should excite purulent inflammation in the neighboring tissues.

Dr. Wendt asked Dr. Heitzman if what he called pus-corpuscles were, as he had represented them, some six or seven times larger than the red blood-globules.

Dr. Heitzman answered in the affirmative.

Dr. Wendt said that that fact of itself spoke against the assumption that they were pus-corpuscles, for all observers had found that most pus-corpuscles were of about the same size as the white blood-corpuscles. To him it was a rather novel theory that pus-corpuscles were five or six times larger than red blood-corpuscles, and he thought it required further substantiation than had been offered.

Dr. Heitzman said that he did not wish to claim that these corpuscles were exactly six times larger than red blood-corpuscles, but that they were very much larger than colorless blood-corpuscles. Indeed, it was easy to determine that there were many pus-corpuscles which decidedly surpassed in size the colorless blood-corpuscles.

Dr. Ferguson presented specimens illustrating

THE ANOMALOUS ORIGIN OF THE VESSELS GIVEN OFF FROM THE ARCH OF THE AORTA.

In the examination of one hundred specimens the following varieties had been found: In two instances the left common carotid and the innominate were given off by a common origin. The brachiocephalic, in both instances, was the usual length, and the left carotid was given off close to the aortic arch. In three specimens the left vertebral artery arose directly from the arch of the aorta, between the left subclavian and the left common carotid. In one specimen the innominate was only one-fourth inch in length; the right subclavian and right common carotid arising almost separately.

In addition to these, there were two specimens from the dissecting-room, sent to him by Dr. A. H. P. Senf, in which the innominate and left common carotid had a common origin.

Dr. Ferguson also presented specimens of

ACUTE ENTERITIS FOLLOWING BURNS.

They were removed from the body of a girl nine years of age. On April 16, 1882, she was extensively burned over the body and lower extremities by the explosion of a kerosene lamp. Previous to her injury she was quite healthy. The burns on the anterior surfaces of the lower extremities were of the first, second, and third degrees. Those covering the abdomen were of the first and second degrees. The neck was also similarly burned. She lived seven days after the accident. During that time her temperature, pulse, and respiration were elevated; pulse was rapid and feeble, ranging from 120 to 150 per minute; respiration, 28 to 48; temperature, 99.4° F. to 102° F. The patient did not rally from the shock, and was delirious most of the time. There was no diarrhœa.

The autopsy was made ten hours after death. The lower lobe of the right lung was in the condition of red hepatization; the lungs, in other respects, were congested and œdematous. The intestines were congested throughout. The mucous membrane of the lower half of the ileum was intensely congested and swollen, Peyer's patches and the solitary follicles standing above the mucous membrane. The first preparation was the last six inches of the ileum, showing two or three of Peyer's patches much swollen; also many solitary follicles.

The second specimen from the same body was a portion of the ascending colon, showing the prominence of the solitary follicles.

The President referred to Brown-Séquard's theory, namely, that ulceration of the intestine is reflex from the spinal cord, and that it could be produced at will in animals. He inquired if it was a fact that ulceration of the intestine rarely occurred after extensive burns?

Dr. J. C. Peters said that ulcer of the duodenum was at one time supposed to be a very frequent result in extensive burns, and that several cases were reported and had been published in the Transactions of the Society.

UTERUS AND APPENDAGES OF A WOMAN WHO DIED WHILE MENSTRUATING—NO MARKED HYPERTROPHY OR DESTRUCTION OF MUCOUS MEMBRANE.

Dr. E. C. Wendt presented a specimen of the uterus and appendages removed from the body of a woman who had died of pulmonary œdema, in the course of chronic diffuse nephritis. It was obtained a few hours after the death of the patient, who was menstruating when she died. The woman was a multipara, about twenty-eight years of age.

On examining the pelvic cavity, the uterus was found attached posteriorly by superimposed layers of partly organized perimetritic membranes. Both ovaries appeared globular, and had a purplish hue. On the left side the fimbriated extremity of the oviduct was intensely red, and seemed to hug the enlarged ovary. A recent hemorrhagic effusion was found in the latter organ. The right ovary contained a clot of the size of a hickory-nut, its color being a dirty brownish red. In addition, a small sebaceous cyst was also discovered adjoining the clot. This cyst contained the usual yellowish, gritty substance, mixed with numerous hairs. In the interior of the cyst cavity, a reddish body, seemingly well organized, was found attached to the cyst wall by an extremely slender pedicle. What, if any, pathological significance could be properly attached to this little polypoid body did not appear clearly established. The Fallopian tube of that side was devoid of a fimbriated extremity, nor could any abdominal opening be found. This had evidently become obliterated, in consequence of local inflammatory deposits.

The occlusion of this orifice was not devoid of some practical interest; for ovulation on the side in question could not be followed by the entrance of

the ovum into the right Fallopian tube. Such a condition might, therefore, be readily conceived to predispose to extra-uterine pregnancy.

The point of chief interest, however, was the interior of the womb, and the condition of its mucous membrane.

On opening the organ, the uterine cavity was found to contain about twenty drops of fluid blood, which was devoid of all odor. After this had been very gently removed, the mucous membrane appeared, with a faintly rose-colored surface, without a single fold, and apparently not at all, or only very slightly thickened. Further examination elicited the fact that a small number of quite superficial hemorrhages had taken place into its substance. But beyond this no change was discoverable. Of course from a single observation of this kind no general inference could or should be drawn. Nevertheless it did show that the changes now commonly held to take place during menstruation were not of unexceptional occurrence. But the case seemed more particularly interesting and important, as affording corroborative evidence of recent assertions made by Dr. Möricke, formerly Schröder's first assistant, at the gynecological clinic of Berlin. In this connection he would briefly allude to some of the more important recent contributions to the histological processes involved in menstruation. It would be remembered that in 1873 Kundrat and Engelmann had stated, as the result of an extensive series of investigations, that not only a large proportion of its lining epithelia suffered destruction, but that a portion of the mucosa itself was regularly shed at each menstrual period. These authors also found the interglandular tissue much richer in round corpuscles than normal. Moreover, according to them, fatty degeneration both of epithelia and blood-vessels invariably occurred in conjunction with the flow. This fatty metamorphosis was not only independent of the hemorrhage, but the catamenial flow was directly attributable to it. Later, Williams (*Obstet. Journal Great Britain*, February and March, 1875; *ibid.*, December, 1877) even went so far as to claim that the entire mucosa was constantly destroyed, and that complete regeneration regularly occurred in the intermenstrual period. This restitution he supposed took its origin from the muscular walls of the uterus. More recent researches by Leopold (*Archiv f. Gynäk.*, vol. xi.) and Wyder (*ibid.*, vol. xiii.) have led to still more conflicting views concerning the tissue-changes which characterize the uterine mucosa during the menstrual epoch.

The latest, and to Dr. Wendt's mind the most trustworthy and convincing publication, was found in vol. vii. of the *Zeitschrift für Geburtshülfe und Gynäkologie*. Dr. Möricke, who was the author of the exhaustive essay already referred to, minutely described the structure of the mucous membrane of the uterus at different periods of life, and more particularly immediately before, during, and after menstruation. He had conclusively demonstrated that fatty degeneration did *not* take place in connection with the catamenial flow.

His method of procedure was certainly a novel, if not a somewhat barbarous one. With a sharp curette he removed portions of the mucosa from the uteri of living women, at different times, before, during, and after the period. These fresh, one might say living specimens, were then immediately submitted to microscopical examination. As the result of a rather large series of observations of this kind, the author positively asserted that the mucous membrane of the uterus was neither entirely nor yet in part destroyed during menstruation. It even invariably retained its ciliated epithelial lining. There was no increase of corpuscles in the interglandular tissue, and fatty degeneration even moderate in extent was never observed. There was, however, vascular dilatation and some extravasation of blood in the superficial layers of the mucosa. The homogeneous basis substance was always increased. Finally the changes described again and again by other authors must be regarded as the expression of post-mortem changes which are proven to take place very rapidly in the uterine mucous membrane.

Dr. Heitzman said that in his laboratory had been examined shreds of the so-called decidua catamenialis, and what he had seen was certainly not fatty degeneration, not the cloudiness of modern observers, neither so-called granular degeneration. If it was known what the process consisted in, it was an augmentation of the living matter within the epithelia and in the cells in the tissue beneath the epithelia. What formerly was supposed to be fatty degeneration, and at present called cloudiness, was nothing but an increase of living matter, the points of intersection of the reticulum being enlarged. The whole process was a low grade of inflammation.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 2, 1882.

Fordyce Barker, M.D., LL.D., President, in the Chair.

MANAGEMENT OF LABOR WITH REFERENCE TO THE PREVENTION OF SUBSEQUENT UTERINE DISEASE.

Dr. W. E. Forest presented a paper on the above subject, which was read by Dr. Katzenbach, and in which he directed attention, first, to the practical aspect of the subject, and second, to certain anatomical and physiological facts. The most generally accepted causes of uterine disease subsequent to labor were, first, laceration of the cervix and pelvic tissues; and, second, sub-involution both of the uterus and of the vagina, either with or without laceration. Laceration of the cervix as a cause was the first in time as well as in importance, and the author of the paper then proceeded to study the manner in which lacerations were produced and the means by which they were to be obviated. In connection with this part of the subject reference was made to the writings of Dr. Emmet and Dr. Sinclair, in which it had been made to appear that the most prominent among the causes of laceration of the cervix was a rapid first stage of labor. Dr. Forest, however, believed that a rapid first stage of labor was an infrequent cause of laceration of the cervix. He believed that normal dilatation of the cervix was not a mechanical but a physiological process; that it was rather a relaxation than a dilatation, and that the preparation for this process commenced weeks before labor was established. This part of the subject the author of the paper illustrated with diagrams made from frozen sections of the uterus and pelvic organs. The conclusions which he reached were, first, rapid labors are natural except when there are disturbances of nerve-force; second, that there might be no more pressure in rapid than in tedious labor; third, in rapid labor the resiliency of the cervix is not exhausted by long-continued pressure.

Another cause of laceration of the cervix was tedious first stage of labor. According to the same authorities, to whom he again referred, this was a very prolific cause of laceration of the cervix. The remedy, therefore, was apparent, that is, to prevent a tedious first stage of labor. The object to be accomplished was, to restore the harmony of action which should exist between the body of the uterus and the cervix, and this could be accomplished by anything which quieted perverted nerve-force. The remedies ordinarily used were morphine and chloral, which regulated nerve-function, and by so doing allowed dilatation to take place. In addition, gentle digital dilatation might be resorted to for the purpose of restoring the normal relations existing between the external os and the lower uterine zone.

With reference to the use of forceps as a cause of lacerations of the cervix, it was impossible to say how often it was produced by the instrument, but the conclusion which the author reached was that laceration of the cervix was seldom caused by the use of instruments when they were carefully and properly employed.

Laceration having occurred, notwithstanding all the precautions used, how was it to be treated? The ordinary way of treating a lacerated wound was by keeping the surface clean, by the use of stitches, or plasters, or compresses which brought the lips of the wound into apposition. In this instance, however, stitching was hardly to be thought of; neither could plasters or compresses be applied. The author then briefly alluded to the use of elastic bands applied to the cervix on the third or fourth day after confinement, in the meantime strict cleanliness having been secured by vaginal injections with antiseptic solutions. On the third or fourth day, other things being equal, the parts might be exposed, the lacerated surfaces brought into apposition, and the elastic band slipped over the torn cervix. In a certain number of cases this method of treatment had apparently been beneficial. The number, however, was too small to allow of any deductions, but at the same time it seemed to be a method worthy of trial. The special effort of the accoucheur, however, should be directed toward prevention of laceration.

With reference to subinvolution, the author of the paper believed it was not so much a cause of uterine disease as a disease itself. Reference was then made to the conditions which might interfere with normal involution, and among them laceration of the cervix was most prominent. Again reference was made to Dr. Emmet's writings and to Sinclair's tables.

Laceration of the perineum had also been said to be a cause of subinvolution of the uterus. In Dr. Sinclair's tables, however, it became apparent that such a laceration favored involution rather than otherwise. Perhaps this apparent paradox could be explained on the ground of additional precautions being taken with reference to cleanliness when it was known that laceration existed. The number of cases, however, which appeared in Dr. Sinclair's tables were hardly sufficient to establish any principle. The conclusion reached was that normal involution would probably be interfered with if laceration of the perineum extended into or through the sphincter.

Septicæmia had also been regarded as a cause which interfered with normal involution. Dr. Forest thought, however, that there was hardly any excuse for the development of septicæmia in these days of antiseptics. Brief reference was then made to the views which have been published concerning the time when the patient should get out of bed, and allusion was made to the views of Dr. Goodell concerning the advisability of the woman assuming the upright position a few days after confinement.

Dr. Beckwith being requested to open the discussion, said there were many points of interest in the paper which he would like to discuss, but he did not feel able to do so without previous preparation. He fully agreed with the author as to the importance of making a careful examination of the uterus and its appendages, and of the vagina, within six weeks after delivery.

Dr. Castle could not fully accept all the author's views with regard to the rationale of laceration of the cervix. He was of opinion that a disparity between the size of the brim of the pelvis and of the head of the child was sometimes the real cause of laceration of the cervix, when the supposed cause was rigidity of the os. He thought Dr. Forest's views with regard to an œdematous condition of the cervix were open to criticism. Dr. Castle believed that the softening which took place in the cervix up to the first stage of labor was largely due to a condition of œdema, and was desirable in order that dilatation might properly take place. Dilatation was also assisted by the hydrostatic pressure exerted upon the cervix by the bag of waters, and when this ruptured too early there was greater liability to laceration.

Dr. C. C. Lee fully agreed with the author of the paper that in the majority of cases in which laceration of the cervix was sufficiently extensive to be appreciated by the accoucheur it was due to tardy labor, which had produced an œdematous or macerated condition of the cervical tissues. Laceration, however, to the degree referred to by the author, had rarely taken place in the cases of rapid labor which had come under his care. In cases of arterial hemorrhage which was very difficult to account for occurring after labor, he had often made an examination with Sims' speculum, and found the origin of the hemorrhage to be in a laceration of the cervix. With regard to closure of the laceration immediately after its occurrence, a procedure of which Dr. Pallen was a strong advocate, he had done it in two cases. In the first case, that of a primipara, the laceration extended to the utero-vaginal junction. He closed the wound with silk sutures, exercising the greatest care, but within three days all the sutures had cut through the tissues and the operation was a complete failure. In the second case the patient was a multipara, and the silver-wire suture was used, but the result was the same as that in the first case. Dr. Lee spoke of tedious labor, particularly in the second stage, as the great cause of vesico-vaginal fistula. The methods for hastening delayed labor with a view to avoiding this and other serious results, which were recommended by the author of the paper, were such as Dr. Lee had also adopted and had found of great benefit.

Dr. W. T. Lusk said that it was considered among women a great recommendation for an accoucheur if it were said of him that he never lost a case. He thought that in the future the question which would be asked as a proof of the accoucheur's merits would be, What has been the condition of his patients some time after confinement? He said that in those cases of rapid labor in which the patient's nervous

system was in such a condition as to lead her to bear down strongly almost from the beginning, bad lacerations were liable to occur. In such cases the disorder of the patient's nervous system should be controlled by such means as were at our command (anæsthetics, etc.) in order to avoid these bad results. He seldom employed digital dilatation of the cervix, which acted simply in a mechanical manner. He used Barnes' dilator, which simply rendered the cervix tense and excited normal uterine pains, and when these occur the cervix, which was previously rigid, became soft and the dilator was expelled. If required, it could be reinserted. Whenever it became necessary to use the forceps, traction force should be exerted only during the intervals between the pains, at which time the parts were relaxed. If it were exerted during a pain, when the parts were rigid, laceration would almost surely occur.

Dr. S. T. Hubbard thought that in the matter of the statistics quoted by Dr. Forest, if an examination had been made twenty days, instead of sixteen days after confinement, fewer lacerations would have been found; some of those mentioned would probably have healed in the meantime. Many years ago he found recommended in Byrne's "Midwifery" the administration of fifteen or twenty drops of laudanum every hour or so in certain cases of tedious labor, and having adopted the suggestion it had often proved of great benefit. He had found with Dr. Forest that most of the cases of tedious labor occurred among the strong and robust, as among the laboring Irish women, while the less sturdy, and even those far advanced in phthisis, gave birth to children with comparative ease.

The Academy then adjourned.

A New Method of Staining Nerve-fibres.—Professor Weigert, of Leipsic, has found a new and more effective way of staining the nerve-fibres of the central nervous system. The method consists in staining the preparations in acid fuchsin (fuchsin, S. 130 of the Berlin Aniline Manufacture), washing in a weak alcoholic potash solution, and then mounting in the ordinary way in Canada balsam. This method has great advantages above all other methods; it selects the nerve-fibres only, of which it stains portions of the medulla, while it leaves the axis cylinder free, and it picks out the smallest fibres, such as no other reagent, not even gold chloride, does. The aniline colors, now so much used by German pathologists, are obtained by them, says a correspondent of the *Lancet*, from Dr. Gübler, 17 Dufour Strasse, Leipsic. Many of them can be obtained in this city, however.

A Severe Operation.—At the Surgical Section of the Association of German Naturalists and Physicians, Professor König showed a patient in whom he removed the greater portion of the sternum, which was the seat of a rapidly growing osteo-sarcomatous growth. The whole of the sternum, except the uppermost part and the xiphoid process, was removed, and during the operation air entered both pleural cavities, and also the pericardium, which was found adherent to the sternum, and was opened during the operation. The patient made a good recovery, and the wound is now almost entirely healed, except at one point, where a portion of an adjacent rib is necrotic and keeps up some little suppuration.

Correspondence.

BLACK ANTS AS ANTISCORBUTIC FOOD.

To the Editor of The Medical Record.

Sir: I have just been reading in The Record for September 23d Lieut. Schwatka's article on scurvy, and wish to call attention to an article of diet, which, if procurable in sufficient quantities, might be a valuable addition to the Arctic voyager's diet-list, namely, the large black ants found in the wood of the pine trees. Scurvy very frequently attacks the lumber men of Maine, and they adopt this food as a remedy when suffering from the disease. Indeed, some of them become so fond of it as to eat these ants whenever they can be found. As these insects retain their vitality while frozen imbedded in the wood-dust which they themselves make, might it not be possible, if they could be collected in sufficient quantity, to carry them frozen and packed in sawdust till needed for use? Of course, the question arises, how long will they retain their vitality in this condition? Are there not many classes of hibernating insects which might answer the same purpose?

This is simply a suggestion which occurred to me while reading Lieut. Schwatka's very valuable paper. It may be of no value, but as I do not expect to have an opportunity of studying the disease, scurvy, I venture to state a fact in apparent confirmation of his theory with a view at least of directing attention to a new point in the discussion of the subject.

Yours respectfully,

E. F. Brush, M.D.

Mount Vernon, N. Y.

PLUMBERS AND ZYMOTIC DISEASES.

To the Editor of The Medical Record.

Dear Sir: In Dr. John F. Ridlon's interesting comments on my communication to The Record of October 14th, concerning "The Exemption of Plumbers from Zymotic Diseases," he overlooks the fact that my paper did not refer to plumbers and their families, but to the plumber as an individual. It is hardly necessary to observe that plumbers are not accompanied by their families while making repairs, and therefore the plumber as an individual is exposed to very different morbid influences from those to which his family is subject. It is very interesting to know that the plumbers' children, "though sleeping in the same room with their parents, suffer from zymotic diseases quite as often as other children." since, as statistics show us, unless phthisis and pneumonia are zymotic diseases, the plumber stands unscathed and germ-proof in the midst of mephitic exhalations.

Respectfully yours,

F. A. Burrall, M.D.

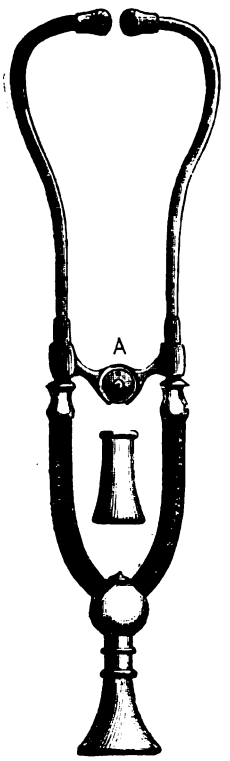
48 West Seventeenth Street.

Tincture of Burdock in Psoriasis Inveterata.—Dr. Reiter writes to Squibb's *Ephemeris*, giving an account of a cure in his own case of chronic hereditary psoriasis by the use of tincture of burdock (Rappa major) seed. The maximum dose used was ʒ iv. t. i. d., to be kept up for four months if necessary. The doctor had suffered from the disease for many years.

New Instruments.

IMPROVED CAMMAN'S STETHOSCOPE.

By T. A. McBRIDE, M.D.,
VISITING PHYSICIAN, PRESBYTERIAN HOSPITAL, NEW YORK.



The Camman binaural stethoscope has been much improved by an ingenious device of Mr. Ford, of the surgical instrument department of Messrs. Caswell, Hazard & Co. One great objection to this instrument has been the manner in which the aural extremities have been kept in place in the meatus auditorii. The india-rubber band which was formerly used would exert too little or too great pressure, and noise was often produced by its vibrating in the expired air, and, moreover, it had often to be replaced. As a substitute for this, a spiral spring concealed in a tube was employed, but this, if not kept carefully oiled and clean, produced more or less noise. Mr. Ford has apparently surmounted these difficulties, and now presents a perfect instrument. The spring from which the requisite amount of pressure is obtained is concealed in the hinge, which connects the aural extremities. The strength of this spring may be graduated to the individual case. No noises are now heard, and, as I say, the instrument is now apparently perfect in every way.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from November 4, 1882, to November 11, 1882.

Spencer, W. C., Surgeon. In addition to his duties at Fort Snelling, Minn., to perform the duties of Attending Surgeon at Department Headquarters. S. O. 176, Department of Dakota, October 24, 1882.

Ainsworth, F. C., Assistant Surgeon. Granted leave of absence for one month with permission to apply for extension of one month. S. O. 120, Department of Texas, November 1, 1882.

Ainsworth, F. C., Assistant Surgeon. The leave of absence granted November 1, 1882, is extended one month. S. O. 121, Military Division of the Missouri, November 9, 1882.

Barnett, Richards, Assistant Surgeon. Granted leave of absence for one month with permission to apply for extension of five months. S. O. 202, Department of the East, November 1, 1882.

Brewster, Wm. B., Assistant Surgeon. On being relieved by Acting Assistant Surgeon Potter, will proceed to Fort Bridger, Wyoming, reporting to the Commanding Officer thereof for duty. S. O. 116, Department of the Platte, November 4, 1882.

Gray, W. W., Assistant Surgeon. Granted one month's leave of absence on Surgeon's certificate of disability, with permission to apply for an extension of five months. S. O. 103, Department of the South, October 31, 1882.

O'Reilly, Robert M., Captain and Assistant Surgeon. Detailed member of Board of Officers to assemble at Washington, D. C., to examine into and report upon qualifications of candidates for Superintendents of National Cemeteries. S. O. 254, A. G. O., October 31, 1882.

McElderry, Henry, Assistant Surgeon. Upon arrival of Assistant Surgeon Brewster at Fort Bridger, Wyoming, to be relieved and ordered to Fort Robinson, Neb., to report to the Commanding Officer thereof for duty. S. O. 116, Department of the Platte, November 4, 1882.

Appel, Aaron H., First Lieutenant and Assistant Surgeon. Leave of absence extended two months. S. O. 255, A. G. O., November 1, 1882.

Brechemin, Louis, First Lieutenant and Assistant Surgeon. Leave of absence for five months granted. S. O. 259, par. 2, A. G. O., November 6, 1882.

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending November 11, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

Dr. Paul F. Mundé has been appointed gynecologist to Mount Sinai Hospital, to fill the vacancy caused by the resignation of Dr. Noeggerath.

A Law Forbidding the Sale or Use of Toy-pistols has been passed by the Vermont Legislature.

An Anti-Tobacco Law.—A bill has been presented to the Michigan Legislature forbidding the use of tobacco by boys. The *Free Press* now urges the passage of an "Anti-pie Law," to prevent the "enormous and growing evil" of eating too much pie.

The Warren Triennial Prize. — The Warren Prize Committee offer a premium of four hundred dollars for the best dissertation, worthy of a prize, upon the following subject: "Chronic Bright's Disease (parenchymatous and interstitial nephritis). The Nature and Mutual Relations of the Derangements in the Circulatory and Secretory Organs."

Dissertations should be forwarded to the Resident Physician, Massachusetts General Hospital, Boston, on or before February 1, 1883.

The First Successful Ovariotomy in Bellevue Hospital was performed by Dr. W. Gill Wylie recently. The operation was done in the new pavilion.

A Wholesale Chemist in London manufactures one ton of homœopathic globules annually.

"Compound Oxygen."—Professor Prescott, of the University of Michigan, has been analyzing several brands of this widely advertised substance. One bottle, labelled "Compound Oxygen—Keep Dark," was found to be a colorless aqueous solution of nitrate of ammonium and nitrate of lead, the two salts being in nearly equal proportions, and together forming about three per cent. of the solution. A companion bottle, labelled "Oxygen Aquæ for Digestion," was found to be water of a commendable degree of purity, quite free from sophistications. Probably this is the original compound oxygen. Another compound oxygen contained nitrate of ammonium alone; a fourth specimen, from Boston, was a colored, fragrant liquid, consisting of alcohol, chloroform, and balsam of tolu.

Norwegian Cod-Liver Oil.—Consul Gade, of Bergen, Norway, writes to the Department of State that against last year's yield of 11,500,000 fish, the net result of this year is estimated at only 5,300,000 fish and 9,300 barrels of liver, producing, in all, 4,100 barrels of oil, of which a little more than 2,000 barrels will be exported as steam-refined, first quality.

Friedrich Woehler, the Nestor of chemistry, died at Göttingen, on September 23d, after a brief illness (of four days), aged eighty-three. He was born on July 31, 1800, at Eschersheim.

Quinine.—At present there is not much prospect of a lower price, since the influence of speculation has outstripped that of normal demand and supply.

The consumption of quinine is constantly on the increase Of the 4,000,000 ounces consumed in 1881, about 1,600,000 ounces fall to the share of the United States, and only one-third of this quantity is imported from Europe, the other two-thirds being manufactured here. The American manufacturers have been constantly endeavoring to have the import duty re-imposed upon foreign quinine, and to have the crude material placed on the free list: their efforts have been successful only with regard to the latter point. From and after January, 1883, East Indian bark will be admitted duty free, the same as South American barks.

Condurango.—Mataperro-condurango (from Ecuador) has suddenly again come into favor, and the supplies are about exhausted. The new German Pharmacopœia has recognized this bark. Venezuelan condurango, really the stems of guaco (*stipites guaco*), has constantly been in limited demand, and appears to have as much therapeutic effect as the former.

"Vesico-Vaginal Fistula Cured by Position" is the title of a case published by Dr. J. T. Winn in the Virginia *Medical Monthly*. The fistula occurred in a woman recently confined. She was told to assume the genu-pectoral position at intervals, thus allowing the urine to accumulate in the fundus of the bladder. No catheter was used. A moderately strong solution of sodium bicarbonate was used as an injection immediately after each urination. In twenty days the cure was complete.

Sewage Gas Poisoning.—The Philadelphia *Medical Times* contains the report by Dr. J. T. Eckridge of an interesting case of the poisoning of a strong healthy man who went into a privy-well, about fifteen feet deep, for the purpose of cleaning it. Before going in a light had been lowered, but it was not extinguished, and it is important that the fact should be made known that this is no sufficient test of the presence of deadly gases in such places. The poisonous gas in this case was probably either sulphureted hydrogen or sulphide of ammonia, or a mixture of the two. Insensibility was rapidly produced, and his condition for several hours was such that death seemed almost inevitable. He was saved by twelve successive injections of aqua ammonia into the superficial veins of the forearm, a heroic method of treatment, used only as a last resort after all the usual methods had failed.

A Novel Use for Pepsin.—Dr. Hollmann (*Nederland Weekblatt*, 18, p. 272) has used an aqueous solution of sixteen grains of pepsin as an injection into the bladder of a patient who had hæmaturia, and in whom a catheter failed to empty the bladder. A few hours later, a dark, viscid, fetid fluid readily escaped through the catheter.

Viburnum Prunifolium.—Dr. O. E. Herrick, in commenting upon the occasional toxic effects of viburnum prunifolium (dryness of mouth, dimness of vision, dizziness, etc.), says: "Next to ergot I place more dependence upon viburnum in the treatment of diseases of females than any other agent for internal administration. Its action is not limited to the prevention of miscarriage by any means, but it is alike applicable in cases of uterine engorgement, ovarian irritation, and numerous other conditions of the female sexual organs."—*Obstetric Gazette.*

A Large Lunatic Asylum has recently been erected at Bayreuth. We are told that it has nothing to do with Herr Wagner or his music.

A National Vaccine Institution.—Dr. W. E. Bessey is making strenuous efforts to establish a national vaccine institution in Canada. A small appropriation has already been obtained for this purpose.

The National Drug Association held its annual meeting at Peoria, Ill., on November 8th and 9th. It will meet next year in this city.

A Stupid Town.—Certain citizens of Red Bank, N. J., have begun an action for conspiracy and libel against John H. Cook, editor of the Red Bank *Register*, for publishing certain statements regarding the prevalence of typhoid fever. The principal matter in dispute seems to be the number of cases said to be typhoid fever, which, it is alleged, were overstated by Mr. Cook, it being held by the citizens of the town that there was only one case, and that an imported one, and that the other cases were "typho-malaria." When the strength of the case depends on a fever being "typho-malarial" instead of typhoid, it would be far wiser to clean out the privies than go to law.

The "Raspberry" Vaccination Scar, and its Guarantee of Protection from Small-Pox.—Dr. Richard C. Newton, Assistant Surgeon, U. S. Army, Fort Cummings, New Mexico, writes: "I have read with interest during the past summer a good deal of matter relative to vaccination and vaccine virus, which The Record and other journals have set before their readers. And although the gentlemen who are interested in vaccine farms are thoroughly convinced that their particular brand of virus is all sufficient, others have grave doubts as to what form of vaccine it is best to use. Without in any manner

considering myself competent to enter into this discussion, I wish to relate, very briefly, a case of my own, because, as it seems to me, it throws some light upon the matter, and may be of help to both practitioners and patients.

"I have always used fresh bovine virus and have generally been satisfied with the results. I even supposed that the 'raspberry' scar indicated that a modified protection against small-pox had been obtained.

"I noticed that a writer in THE RECORD denounced this peculiar scar as of no avail because it follows a worthless bovine (?) vaccination.

"Last August I saw J. R——, aged twenty-eight; American; healthy; good family history; by occupation a railway employee, although he was then in a mining camp. At first he had the lumbar pains, fever, cough, and great depression; these soon developed into a well-marked case of discrete small-pox. The man was isolated, and the best care possible, under adverse circumstances, was taken of him. He did not recollect having been vaccinated in childhood. He had nursed a case of small-pox; after which, he had been vaccinated, this was about five weeks before I saw him. He said that a doctor whose name he did not know had vaccinated a large number of railroad men, himself among them, and as nearly as I could judge from the patient's account, the physician had used a cone of bovine virus. The man said that the vaccination had "taken" well, and he supposed himself amply protected. This conversation occurred about ten days after I first saw the case. I rather doubted the word of my patient, who thereupon pulled up his sleeve and showed me a distinct 'raspberry' scar on his arm, and this was surrounded by the umbilicated pustules of small-pox. No other vaccination marks could be discovered on either arm, although of course, some might have been present and not discernible.

"The man died in the third week of the disease, after the case had passed out of my hands. I heard, however, that he ran out in a violent shower of rain. With better surroundings I should have expected a favorable result; although I no longer believe in the modified protective influence of a vaccination leaving, a 'raspberry' scar."

SUFFOCATION BY ILLUMINATING GAS.—From July 1st there have been fourteen deaths from the escape of illuminating gas in bed-rooms. The last two cases occurred during the past week. Most of them have resulted from blowing out the gas.

DR. EDWARD C. SEGUIN.—Several of the medical societies of this city have very appropriately passed resolutions expressing sympathy with Dr. Seguin in his recent affliction. He sailed for Europe on Wednesday last, with the intention of remaining abroad for a considerable period.

INOCULATION IN THE TREATMENT OF PANNUS.—Dr. Edward S. Peck writes: "In THE MEDICAL RECORD for November 11th, p. 560, the above caption is followed by this sentence: 'The heroic measure of inoculating gonorrhœal pus for the relief of severe pannus has been tried in three cases in the Ophthalmic Division of Charity Hospital,' etc. I desire to anticipate an erroneous impression which might attach to this statement, and to state that only *one* patient was inoculated with gonorrhœal pus, the second and third patients having been treated with a simple traumatic urethritis, as your extract states several lines below. The first case was detailed in your journal July 2, 1881. In this case gonorrhœal pus was resorted to after the failure of, 1, laudable pus from a post-aural incision; 2, pus from an adult purulent ophthalmia; 3, pus from a case of ophthalmia in the newly born. The results were so marked that I was induced to inoculate, with their consent, two other patients with a simple urethritis from a private patient, in co-operation with a distinguished writer on genito-urinary diseases, of this city, in whose care he was at that time. It is to be noted that all four eyes were materially improved in vision, though one had a perforated cornea. Gonorrhœal pus should never be used until other and presumably less virulent types have been tried."

AN EPIDEMIC OF TYPHOID FEVER AT PROVIDENCE, R. I.—Typhoid fever is said to be prevailing extensively at Providence, R. I. The fever began to manifest itself early in the fall, and seemed to spring up immediately after the continuous and heavy rains which visited that section of the country then. The disease is not confined to the city. In East Providence nearly fifty cases were reported last week, while some have gone so far as to credit Providence with two thousand cases of various kinds of fever. The latter figures are, no doubt, rather too large.

A NEW MEDICAL COLLEGE AT SAN FRANCISCO.—A new building has been erected by Dr. L. C. Lane, at a cost of about $85,000, on a lot worth $15,000, and conveyed by him as an unreserved donation to the Cooper Medical College, which is a reincorporation of the Pacific Medical College, the Faculty of which remains unchanged. The college is named after Dr. Elias S. Cooper, now deceased.

OVARIOTOMY IN AN INFANT.—Dr. Hingston, of Montreal, recently removed an ovarian tumor from a child two years of age. The patient was doing well at last account.

DR LYONS, M. P. for Dublin, has been appointed a Deputy-Lieutenant.

A MEMORIAL FUND TO THE LATE PROFESSOR BALFOUR is to be subscribed at Cambridge. The fund is to be used for the promotion of biological research.

THE END OF THE YELLOW FEVER.—On November 13th, only one new case of yellow fever was reported at Pensacola. The total number of cases at Pensacola is reported to be 2,330, with 191 deaths, a remarkably low death-rate after all.

THE FRESH AIR FUND.—By far the largest and most successful season in the history of the Fresh Air Fund has just been brought to a satisfactory close, and the results are reported in the *Tribune*. A fortnight's vacation was given to 5,599 poor people from the city; 3,944 were received as guests by the people in the country, and for 1,655 board was paid. The total cost was $21,556.01, being an average of $2.85 per child. The work of the Fresh Air Fund began in 1877, with only seventy beneficiaries.

ILLNESS OF SIR THOMAS WATSON.—Sir Thomas Watson is seriously ill and not expected to recover. He is now ninety-one years old. A stroke of paralysis has prostrated him, but left him in possession of his mental faculties. When stricken down, he calmly remarked to an attendant: "This is the beginning of the end."

Original Lectures.

LECTURE ON EMPHYSEMA.

By BEVERLEY ROBINSON, M.D.,

PROFESSOR OF CLINICAL MEDICINE AT THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

GENTLEMEN: The older writers applied the term "emphysema" to an infiltration of air into the cellular-tissue of the lung which lies between the separate lobules. When pathological researches were more accurately made, and auscultation had received its immense impetus from the remarkable work of Laennec and his immediate followers, it was clearly shown that interlobular emphysema was a comparatively rare affection, and that the form usually met with was, strictly speaking, vesicular.* In this latter variety the pulmonary alveoli, and sometimes the terminal divisions of the bronchial tubes are notably enlarged.

This variety is doubly important by reason of its manifest and numerous symptoms, and also by the sequelæ, or resultant changes of tissues and viscera, which are so apt to follow its continuous presence. These changes in the structure of different organs sufficiently explain, in the majority of instances, the symptoms and physical signs which are present. After what precedes we recognize the *vesicular* as the important form of emphysema. In this form there are sub-varieties which receive their special designations from the manner in which the pulmonary tissue is affected. Sometimes only portions of it are implicated, and, indeed, the morbid change is so restricted that one side of a lobule is markedly dilated, while the other half is in its normal condition. This *partial lobular emphysema* does not exist by itself as a rule, but accompanies the *real lobular emphysema*, or the form in which the entire lobule is equally dilated. A frequent site for this form is the free margins of the lungs, and here we often remark at the autopsy numerous dilated air-sacs, which, as Waters remarks, have a similar appearance to that of the bullæ of pemphigus.

Lobular emphysema is a frequent accompaniment of the different forms of pulmonary phthisis, and is also frequently met with in pneumonia. The dilated lobules stand out prominently from the surface of the surrounding lung, and occasionally appear as appendages of some volume. The intervening walls between separate lobules are everywhere apparent, and only in extreme and very rare cases are at all broken down. Anatomically, the air-cells should be all of similar size, but with dried sections they often seem unequal. In many examples this condition would be properly explained by the imperfection of the pulmonary preparations.

The third form of vesicular emphysema is the lobar. It is also the most important. Not unfrequently it attacks both lungs, and may, when extensive, become the immediate cause of death. The aspect of the lung when the chest-walls are removed is quite characteristic. The surface is usually smooth, the marks of the interlobular septa have disappeared; the entire lung bulges forward as if the chest cavity were too small to retain it; the anterior surface of the heart is almost entirely covered by the dilated lungs; upon their exterior surface the marks made by pressure of the ribs are at times very pronounced. If we place our fingers upon it so as to note its consistence, it has a resistance resembling that of dough. Its color is very much that of the lungs of some herbivorous animals. Occasionally the surface of the lung is not smooth, on account of scattered collapsed portions, or appendages of different size and volume, which are much more commonly met with in this variety than in lobular emphysema. At first the air-sacs are merely dilated. Then the septa between the sacs lose in height, become considerably thinner, and finally perforate. The holes in the beginning are small, round or oval. They may also be present in the alveolar walls. These finally give way more and more, until two or more cavities are united in one.

It is at this stage that the inter-lobular walls are frequently lost as a visible appearance upon the surface, and the appendages, due to excessive dilatation, appear along the margins of the lungs. In rare instances interlobular emphysema is then present, and starts in reality to spread from the vicinity of the root of the lung. With extreme dilatation the interior surface of the air-sacs becomes perfectly smooth, owing to the complete obliteration of the dividing septa. The distention of the air-sacs is, of course, accompanied by thinning of their walls, and also by expansion and separation of the elastic fibres which form an integral part of their structure.

In the appendages from the margins we find dilated air-sacs of different sizes. The larger ones are near the distal extremities. The epithelium lining the healthy or dilated air-sacs is similar. In the dilated portions of lung the capillaries are widely separated, and for that reason the lung has here a pale, anæmiated appearance. Now and then a slight hemorrhage occurs from rupture of some one of these small vessels. The fragments left of the dividing walls are moderately vascular, but not sufficiently so to increase in any marked degree the respiratory function of the lung. The perforations of the alveolar walls in lobar emphysema, even when the dilatation is not more pronounced, are more frequent than in lobular emphysema. For this reason it would seem as if the degeneration of lung-tissue were certainly more advanced. The large bronchial tubes are dilated, and the mucous membrane lining them is thickened; the contrary holds true of the small tubes, which are notably narrowed and bloodless. The appearance of the large tubes is darker than in healthy lung. There are no ulcerations in either the large or small bronchial divisions. The circular muscular fibres of the bronchi are certainly more developed than in healthy lungs.

In *interlobular emphysema* the air passes into the cellular tissue between the lobules. Rarely it is an independent affection. Frequently it accompanies vesicular emphysema, especially of the *lobar* form, and when it is unusually extensive.

The air in *interlobular emphysema* may extend throughout the pulmonary structure, may manifest itself under the pleura in rare instances, and may even work its way into the mediastinum and cellular tissue of the neck. The most accentuated forms have shown themselves in children after severe attacks of whooping-cough (Guillot).

The pathology of vesicular emphysema shows dilatation of the alveoli, perforation of the walls of the air-sacs, then atrophy, and finally complete disintegration at certain points. Vesicular emphysema is more marked at the apex and along the margins of

the lungs than in the interior. The pathology must be thoroughly understood in order that wise therapeutics be followed. In a measure the effects of curative agents tend to confirm or invalidate the data furnished by researches into the morbid alterations of the disease. Whenever vesicular emphysema follows a long-continued or violent cough, mechanical violence appears to be the proper explanation of its production. If on the contrary, the disease has marched insidiously without being preceded by cough, it is evident that the changes which occur are of constitutional origin, and the local alterations within the lungs clearly show in what manner the dyscrasia has become localized. The lungs which are emphysematous are pale and anæmic. This is due, doubtless, to the separation and absorption of the capillaries, and inasmuch as less blood is distributed the lungs suffer in their nutrition and atrophy. In the emphysema peculiar to old age the lungs are subject to the same senile changes which appear active elsewhere in the body. In lobar emphysema the pathology is not perfectly satisfactory. It often comes on insidiously, is not preceded by cough, and the patient only complains of sensations of smothering. Some writers have affirmed that in these cases there was fatty degeneration of the walls surrounding the air-sacs. Waters has rarely found this alteration. The lesion has been considered to partake of fibrosis of lung-tissue, caused by long-continued bronchial congestion. Atheromatous changes have been found in the pulmonary, as well as in the aortic artery, but these, of course, are not characteristic in emphysema. The elastic fibres may not have their outline distinctly marked, and may not curl up as well as usual, but otherwise may offer a healthy aspect; still they may be altered in some way that with our present means of research we are unable to detect. The same remark is true of capillaries which show no evident signs of morbid change. The fact that there is an hereditary tendency to the transmission of emphysema, that it is analogous to gout in this and other particulars, makes one believe that there underlies in most of these cases a special blood dyscrasia, and that mechanical obstacle will not explain them in a satisfactory manner. Malnutrition in the lung is first occasioned, and this leads to dilatation and degeneration of tissue. In cases of emphysema which follow upon bronchitis it is quite possible that severe cough may occasion the dilatation and even the rupture of the air-sacs, but in the numerous instances in which emphysema is the initial condition a morbid change of tissue must have preceded its development. It has been stated that there is hypertrophy of the pulmonary tissue in emphysema, and this affirmation is based on the fact that in the heart and stomach when they become dilated in organic disease they also become thickened. In taking this view it is not considered that in expiration air is not driven from the chest by forcible action, but rather by the normal elasticity of the lungs. There is fair ground for the belief that emphysema is best treated when the therapeutic measures employed are chosen with respect of the chronic constitutional change which exists. The general nature of the affection in its advanced form (lobar) is shown by its insidious progress, its hereditary character, the implication of both lungs in their entire extent, and the effects of remedial measures which are likewise useful in degenerative changes of other organs (heart, kidneys).

Some cases of emphysema arise spontaneously, others follow directly the obstinate cough of bronchitis or certain senile changes. It was usually supposed that localized emphysema was always due to cough, until Louis demonstrated that oppression and difficulty of breathing might come on slowly but surely and without any cough preceding these symptoms. Moreover, bronchitis is not prone to affect those portions of the lungs in which emphysema is particularly developed. The former seats itself in the posterior portion of the lungs or near their base, while the latter affects the anterior margins or the apices. The precise mechanism of the formation of vesicular emphysema is not admitted by all to be similar. Two theories are opposed. The first sustains that forced inspiration dilates and finally breaks through the air-cells; the second holds that forced expiration is the efficient cause of the morbid changes. Laennec conceived, indeed, that it was the retained air which dilated the pulmonary vesicles, and this view he held to because the inspired current was thought by him the more forcible, and therefore the one which could pass through tubes obstructed with viscid mucus, while the expired air was often forced back into the air-sacs and retained there. Unfortunately, it has been shown conclusively that the forced expiratory current is the stronger of the two. Moreover, as the bronchial tubes are cylindrical in form, and as they divide and subdivide, becoming smaller in calibre, a plug of mucus has more difficulty in moving forward than backward. Each time a plug of mucus is drawn into a small bronchus by an inspiratory act, it is again expelled a certain distance by the effort of expiration until finally all the air is driven from a given air-sac, passes alongside the mucus plug and goes out of the lung. An effort of inspiration then occurs, drives the plug back to remain where it becomes fixed, and local atelectasis, and *not emphysema*, is the pathological result.

In further support of this view it should be mentioned that Traube introduced plugs into the circulation which caused collapse of lung-tissue wherever they were transported and left. Never, however, were the collapsed portions of the lungs found near the regions affected with emphysema. Inasmuch as localized emphysema is at times found adjoining collapsed pulmonary tissue, it is presumed by some that a greater quantity of air is drawn into the emphysematous sections, so that they may fill up the cavity left by the portions which have receded from the chest-walls. To admit such a theory would be to assume that under like circumstances the inspired current of air took special directions by direct guidance. This is not true. The inspired air, if it enter in equal quantity into the lungs when there are collapsed portions, may dilate all the open air-sacs equally but cannot expand certain alveoli more than others. Moreover, if collapsed lung-tissue was cause of localized emphysema, it should be found always alongside of it, which has not usually been noted. If we consider the fact that the inspired air, even if forced, rarely causes dilatation or rupture of pulmonary air-sacs in health, it is far less probable that it will occasion this result in disease where it has diminished power. There are certain facts which lend support to the expiratory theory of emphysema. In ordinary expiration air is forced out from every portion of the lungs by pressure of all the chest-walls. In forced expiration after cough the supra-clavicular spaces become bulged and hyper-resonant. This is due doubtless to their minor resistance. Moreover, the margins of the base and the anterior

borders of the lungs are apt to become emphysematous because they are outside of the direct axis of pressure, and besides, contain less air than other portions of the lungs. In forced expiration the diaphragm and thoracic parietes especially contract with force to press the air upward and forward from the bases to the pulmonary apices and anterior borders. It is stated also that the anterior margins become emphysematous because the cartilaginous extremities of the ribs yield somewhat to the forced expiratory current. Certainly in a case of absence of the sternum it was shown that in forcible expiration the anterior borders of the lungs always became prominent through the opening present.

It would appear as if emphysema especially followed those affections, such as pertussis and bronchitis, which are accompanied with violent cough. Pleurisy and pneumonia do not occasion it frequently, because the cough of these diseases is not very intense. These explanations do not apply to lobar emphysema, especially to the cases which develop insidiously and without being preceded by cough. In these examples the tissue of the lungs is morbidly affected and ordinary inspirations are sufficient to cause their expansion. They continue to expand until the resistance of the thoracic walls prevents its continuance. Having lost their elasticity through dilatation, they have not the power to return to their normal volume, and hence remain much distended. We conclude from what precedes that in many essential particulars the pathology, causes, and mechanism of ordinary lobular emphysema and of lobar emphysema differ very much. Among the symptoms which are characteristic of emphysema we should specially emphasize a constant sense of oppression, or difficult breathing. By degrees this increases, until the slightest exertion makes it almost painful to witness. The air is drawn into the chest with a noisy reverberation and is expired slowly, with difficulty and even more pronounced sonorous vibrations than are caused by inspiration. An attack of bronchitis, a large or imperfectly digested meal, emotional excitement, will increase the dyspnœa to a considerable degree. Such patients are usually more tranquil, less suffering in summer than during the cold or damp days of winter. This is not always true, however, and the patient who is here to-day states very positively that he does not experience any relief in warm weather. Too frequently these patients have poor nights; they cannot sleep on account of their difficult breathing. Often they are propped up with several pillows, and even then toward morning they are awakened from a troubled repose by a real asthmatic attack, in which their breathing becomes stertorous, their face, lips, and extremities cyanosed. Their temperature is often lowered one or two degrees, and their hands and feet have an icy feeling. They are particularly troubled with cough and expectoration if an intercurrent attack of bronchitis is present. The cough is often paroxysmal, harsh, ringing. At times their sputa are abundant, of muco-purulent nature. Toward morning particularly they will cough almost continuously, and a large quantity of viscid material is rejected after intense and painful efforts of cough. During the day we see them occasionally when they cough two or three minutes, and only bring up a small quantity of viscid muco-pus after each violent paroxysm. The reason of their difficulty of expectoration is sufficiently explained by the loss of pulmonary elasticity and also of power in the expiratory muscles. Now and then the sputa are slightly tinged with blood which comes from an altered capillary vessel which has given way in their severe efforts. These patients may, or may not, suffer from localized pain in the region of the chest. Usually it is slight and appears to be due to the prolonged coughing-spells. An ordinary site for the pain, if it exist, is at the epigastric region, and is then frequently increased by pressure, or even gentle palpation at this region. We have usually remarked in such cases that there was evident epigastric pulsation which could be accounted for by the hypertrophous dilatation of the right ventricle. When this enlargement of the heart was not present the liver has been enlarged and the localized pain was obviously occasioned by the chronic congestion, or still more considerable organic changes of this viscus. In the lobar form of emphysema the patient, when interrogated, almost invariably replies that he suffers particularly from smothering sensations, and that if he were relieved of these he would feel comparatively well. At his best, however, he always has a certain thirst for air, a certain impression of inability to supply this want. If he attempts to take a full inspiration, his power of breathing into his lungs always falls short somewhat of his desire to gratify his wish—almost his need. At times the face is puffy, sallow, and to such a degree that we are led to suspect chronic disease of the kidneys—still the tint is not that of chronic Bright's disease. It is less pale, not so waxy, nor indeed so much infiltrated. It is more dusky. Sometimes the venous capillaries are markedly engorged and the nose is cold and blue. We suspect cardiac disease, but on auscultation do not find the evidence of it. Although the heart-beats are often distant, muffled, and feeble, especially at the base, it is only occasionally, and in very advanced cases, that we find a mitral regurgitant murmur, or note the pulsations in the veins of the neck, which indicate almost surely the damming back through the tricuspid orifice and the incompetent valvular play at this opening. When the breathing is very rapid and difficult, the alæ of the nose expand with each inspiration; the angles of the mouth are drawn down; the voice is weak, and the whole appearance is one of profound cachexia, and of great physical exhaustion and suffering. In the final stages of this disease, and when the heart has become incompetent by reason of the general venous stagnation, it is not uncommon to find œdematous infiltration of the lower extremities. Indeed, if the liver become enlarged and dense, we have a notable degree of serous effusion into the peritoneal cavity, and increased oppression from the mechanical interference with the descent of the diaphragm during inspiration. The *physical signs* are very numerous and almost pathognomonic.

If the affection exist on both sides, there is considerable bulging of the upper portion of the chest-walls, especially under the clavicle. If the affection is unilateral, the bulging only exists on the diseased side. The supra-clavicular fossæ are sometimes deeper, more excavated than normal. At other times we find them unusually prominent, just as the chest parietes are underneath these bones. The neck appears shorter and thicker than normal. The sterno-mastoid and scaleni muscles are frequently tense, rigid, and stand out like powerful whip-cords on the stretch. The ribs have lost their obliquity in part, and stand out in a marked degree from the chest-walls; the intercostal muscles seem,

and are, more sunken than normal. The entire chest is frequently larger than in health. The movements are peculiar and characteristic. The upper portion does not expand thoroughly, but moves straight up and down in inspiration and expiration. The lower portion of the thoracic parietes may be evidently flattened, and sink in partially with each inspiratory effort. Under these circumstances, the chest is not larger, but rather smaller in circumference at this level than it should be. The back of these patients is often considerably curved in an antero-posterior direction. The shoulders are carried forward. During the night, if they awake with a severe asthmatic attack, their head and shoulders are carried forward, and they lean forward with their elbows and arms resting upon some resisting object, whilst their quick, short inspirations and long-drawn expirations indicate still further the nature of the affection from which they are sufferers. Their abdomen is very prominent, and the movements of this region are much exaggerated.

This is particularly true when the emphysema is generalized. If the emphysema be localized to the upper portions of the lungs, the diaphragm will sometimes be nearly motionless. When the abdominal movements are very marked, and the chest-walls go directly up and down, the appearance arrests the attention immediately. The short, quick inspirations are readily explained by the restricted expansion of the lungs. The long, slow, jerky expirations, accompanied frequently with râles, show the deficient elasticity of the lungs. Although the cough is often loud and ringing, it is also quite as frequently very feeble, and the sputa are expectorated with the greatest difficulty. If there be, under these circumstances, a severe attack of intercurrent acute bronchitis, the danger to the patient's life is very great. The secretions may accumulate to such a degree as to completely fill up the bronchial divisions, a violent paroxysm of cough may be thus occasioned, and during the extreme efforts to throw off the viscid and profuse phlegm from the lungs the patient may be rapidly exhausted, and succumb from apnœa thus occasioned.

If we recur to our physical methods of exploration, we readily recognize signs which, taken together, give indubitable evidence of the existence of emphysema. Percussion of the chest anteriorly, and more especially in its upper portion, reveals marked hyper-resonance. This exaggerated sound is usually found also over the præcordial region. When it is not present here it sometimes points to the fact that adhesions have formed between the layers of the pleura, thus restricting the expansion of the pulmonary air-sacs at this level and preventing the overlapping of the heart by the lungs. The apex-beat cannot in advanced cases be recognized by mere inspection, and at times palpation, even at this level, remains negative in its revelations. Over and beneath the ensiform cartilage we recognize more or less marked epigastric pulsations. They may, indeed, be quite forcible. In place of resonance, dulness exists at this region. Even though the heart-sounds are heard with distinctness over the lower portions of the sternum, the pulse may be quite feeble and depressible. In the mitral area the heart-beats are feeble and obscure. At the base they are at times distinguished with difficulty, and are invariably more distant than they should be. Whenever the heart-beats, both at the apex and the base, are scarcely audible, it shows that the heart has been pushed directly backward. When the dulness is pronounced in the lower sternal region and the epigastric pulsations are exaggerated, it shows that the heart has been carried to the right of its normal position in the chest, or, indeed, that already there is present some hypertrophous dilatation of the right ventricle. The respiratory sounds are characteristic. The inspiration is short and feeble, the expiration prolonged and noisy. Sometimes the respiration is very feeble.

In this weakness of the respiratory sounds we have a valuable sign of emphysema, even though percussion does not as yet reveal any appreciable degree of hyper-resonance. Occasionally, and when the posterior portions of the lungs near the bases are affected with emphysema, exaggerated resonance is carried further down the back than is met with in healthy patients. A dry râle, somewhat resembling the crepitant, has been described by Laennec as existing in emphysema. Without doubt such a râle at times exists, but it cannot be readily separated from a small sub-crepitant which we frequently hear in bronchitis.

Most all the symptoms, signs, and sequelæ of emphysema are clearly explained when we are already familiar with the pathology of the disease. On account of the limited amount of air which enters the chest, inspiration is short and feeble. On account of the loss of pulmonary elasticity in the lungs and the numerous perforations of the walls of the air-sacs, there are many side-currents, and expiration is prolonged and noisy. There is but a slight difference in the size of the chest when we compare it at the end of inspiration and of expiration. Moreover, there is small latitude of more considerable expansion, for so soon as the patient makes, through exercise, a greater call upon the activity of his lungs, immediately marked dyspnœa is produced. This is explained by the diminished area of aërification of the blood, owing to the different perforations which exist in the walls of the air-sacs. Besides imperfect respiration, there is imperfect circulation. At first the circulation is interfered with by the lung changes, afterward, owing to the absorption or rupture of the capillaries, the lungs are anæmic, their nutrition endangered, and for these reasons their liability to acute inflammation (pneumonia) becomes much less. The temperature in emphysema is lowered, owing to the deficient amount of blood in the arterial circulation, and also to the more limited area of lung in which the blood is oxygenated. The general aspect of these patients is marked by pallor, torpidity, and dulness. All these symptoms indicate the diminished aëration of the blood and show the special liabilities of this disease in regard to complications and sequelæ. It is infrequent for emphysema to last any considerable time without being complicated with bronchitis. This bronchitis is not, as a rule, of the inflammatory, but rather of the congestive type. Quite rapidly sputa are formed which are frothy or purulent in character, and fill, to a great degree, the entire bronchial tree. They are thrown off with much difficulty, and occasionally the patient runs a risk, and an imminent one, of dying from apnœa.

At the autopsy the mucous membrane of the bronchial tubes is not always very red, but, on the contrary, shows a tendency to anæmia. This is especially evident in the larger divisions, and when the attacks of bronchitis have been frequent. In the intercurrent attacks of bronchitis, if they be of severe type, unless they are properly and speedily cared for, the tendency to become graver is very obvious.

If the patient die, the bronchi are discovered to be full of spumous or purulent sputa, and fibrinous coagula obstruct the pulmonary arteries and the right side of the heart. Death is manifestly due, therefore, to these combined conditions. During life we can occasionally observe a heart in which the pulsations are rapid and forcible, and yet the pulse remains weak and depressible. In such examples, coagula are frequently found, and the post-mortem examination confirms the belief adhered to during life. Of course, when the dyspnœa is intense during life, we have occasion to remark the anxious countenance, the cyanosed lips and extremities, the cold hands, the short, quick inspirations, and the long, labored expiratory efforts. The breathing is noisy, and expectoration is accomplished with great difficulty. From time to time the permanent interference with aërification is rendered more painful still by repeated paroxysms of cough, accompanied with intense oppression. These are, indeed, real asthmatic attacks. They are more frequent at night than during the day, and are apparently due to the greater congestion of the bronchial mucous membrane which exists at this time. The congestion itself is brought on by the recumbent position and the relative inactivity of respiration during sleep. Finally, a spasm of the bronchial tubes is produced, owing to the reflex irritation, and the patient's condition is for a while more serious. The frequent repetition of these attacks is apt to occasion increase of the muscular layer around the bronchi. When emphysema has been of long duration it is accompanied by organic change of the cardiac structure. The walls become thickened and the cavities enlarged. There is hypertrophous dilatation of either ventricle accompanied or not by valvular incompetency. Owing to the obstructed circulation in the pulmonary arteries the right heart has more that its share of work to do, and whilst it may struggle to overcome the obstacle to its efficient action, it finally yields to backward pressure, and tricuspid regurgitation is thus effected. When the general venous system is stagnant, œdema of the lower extremities and effusion into the abdominal cavity sometimes become manifest. The left ventricle is also involved in the pathological process. By reason of being pushed over toward the right by the left lung, the axis of the ventricle does not correspond with that of the aorta. Hence the efficient contractions of its muscular walls are in a measure prevented. Moreover, from the stagnation of the blood in the general venous system there is another considerable obstacle to be overcome, and, in consequence, the evident forcible cardiac systoles are not revealed by a corresponding strong pulse. Besides being weak, the radial pulsations are small. This, too, is easily accounted for by the insufficient supply of blood which flows into the left ventricle from the lungs and by the large amount of it which constantly remains in the veins throughout the body. Emphysema finally affects the general nutrition of the whole organism. The patients become very thin, the body wastes, fat disappears, the muscles are found to be small and flabby; the face is pale, puffy and sallow. To look at it we might suspect the existence of chronic renal disorder.

We should not regard the disease as trivial, although remedies sometimes occasion decided beneficial results. The primary indication is to avoid the accidents which can either develop complications or augment the existing bad symptoms. In this way alone can a life for several years of comparative comfort be anticipated. Cases are occasionally seen in which extravasated air which started at the root of the lung has extended itself to the mediastinum, the neck and cellular tissue of the trunk. Such a condition is serious, although capable of cure in many instances. Emphysema is more serious in adult life than among old people, because they have greater need of the respiratory function, and at the former period, on account of the amount of blood in circulation, there is more probability of an attack of severe bronchitis. Emphysema often accompanies pulmonary phthisis. It is then found between the lobes or in the interior of the lungs. According to Waters we may find tubercles in the emphysematous lobules. In phthisis emphysema is due to the severity of the cough. Pleuritic adhesions may exist over the surface of the lung and prevent the underlying vesicles from dilating. It is somewhat rare to find pleuritic adhesions in emphysema if it be generalized. In the *treatment* it is essential to consider, first, the treatment of the disease itself and then that of its complications or the affections which depend on it. To those who are of opinion that emphysema is mainly occasioned by *bronchitis*, and that this affection is, when present, a constant menacing source of further injury to pulmonary structure, the primary indication is to avoid or cure the bronchial attack. To do this we shall, of course, be obliged to consider climatic conditions, telling our patient to go South in the winter, and duly to come North with the spring when already well advanced, and to take such medicinal preparations as are most suitable to subdue, if not wholly cure the cough, at the time when it becomes an annoyance, or even a great suffering.

To persons who look upon vesicular emphysema as a *dyscrasic affection*, under the influence of certain constitutional tendencies, such treatment is not sufficient. We must do for the patients thus affected what we do for those suffering from analogous diseases—such as Bright's disease, or fatty degeneration of the heart. Of course, we appreciate, when the disease is far advanced and there is already present not only perforations of air-cells in different points, but even rupture and almost complete disintegration of tissue, that we can effect very little by the use of any remedy. But when we have a case at an earlier stage in which there is merely loss of elasticity in the air sacs we can be of unquestionable service. The remedy which is followed by the greatest benefit, especially when it is given during a long period of time, is iron. The form in which iron is exhibited is not essential. The tincture, the sulphate, the carbonate, all are good and may be varied in accordance with some individual peculiarity of the patient, or the habit of the practitioner. According to Waters, it would appear that the tincture of the acetate (Br. Ph.) in ten- to twenty-minim doses largely diluted with water is specially efficacious in those instances of emphysema where there is accompanying bronchitis.

While iron is being given careful attention should also be directed to diet and regimen. Formerly it was thought there was real paralysis of the bronchial tubes, and in view of this condition strychnine was prescribed. Never, however, has it been of decided advantage, nor is this to be wondered at since we know that the condition, formerly considered as paralysis, is indeed a condition of spasm. But the spasmodic affection of the bronchial divisions is not a primary one, but is secondary to the emphysema.

Breathing compressed air has been highly recommended by many writers on this disease, principally among the Germans. It may be of temporary use and give great relief for a time, but soon its advantages are less apparent and we should not expect from its continuance any durable results.

The diet of the patient must be nutritious and easily assimilable. It is not desirable, however, to give such a quantity or kind of food as notably to increase the amount of blood. Aërification is not sufficient always for the blood which is present, and any increase of it in bulk would necessitate greater power of oxygenation than the patient could exert without augmenting his dyspnœa. The dyspnœa in such case would be occasioned by more frequent respiratory efforts. The main object under this head to hold in view is the necessity of securing for the patient through proper care a blood of *good quality*.

If these patients be attacked with acute bronchitis we should be chary of the use of many of the anodyne or depressing cough-mixtures. The component parts of such a mixture should be ether, ammonia, and squills. Alcohol should be given in moderate and quite frequently repeated doses, particularly if the pulse be feeble and rapid. Very soon we shall perceive its good effects, for the patient will become less anxious and oppressed. Counter-irritation of the chest-walls by means of mustard-poultices, tincture of iodine, or turpentine stupes is not to be lost sight of as a valuable adjunct to treatment. When you order a mustard poultice be careful *not* to have it made with too large a proportion of mustard, first, because it would irritate the skin at the time too rapidly, and hence not produce the good results we wish to obtain from its application, and second, because if the chest-walls be rendered red and sore from mustard we cannot afterward use any other method of counter-irritation during one or more days without causing an undue amount of suffering to the patient. What is most to be desired in these and similar cases, is a continuous slight irritation of the cutaneous surface. The blood must be drawn away as far as may be in this manner from the internal viscera, and also stimulated in its onward flow by what there is of reflex stimulus through peripheral nerve-fibres. If turpentine be employed, I know of no better preparation for external use than that of Stokes' liniment, in which there is a certain amount of acetic acid, the whole emulsified by means of yolk of egg. The vapor which rises from the turpentine liniment is, I am satisfied, of value from its local action upon the mucous membrane lining the bronchial tubes. Whenever there is more or less sanguineous expectoration, it doubtless tends to arrest it by its styptic influence. Tincture of iodine is not so useful an application as the ointment of iodine, as it very soon hardens the skin, makes it tough, more or less parchment-like, and probably incapable of absorption.

The ointment, on account of the grease which enters largely into its composition, and the absence of alcohol, keeps the tissues softer for a longer period, and probably benefits the patient not only by its irritant quality, but also by its resorbent action. At times a more powerful local irritation is required. This may be accomplished by dry cupping, a thapsia plaster, croton-oil paint, or fly-blisters. The croton-oil paint, known as Corson's paint, is usually to be preferred. The proportions are as follows: one drachm of croton oil, one drachm of sulphuric ether, five drachms of tincture of iodine.

This may be painted over a limited area of the chest-walls with a camel's-hair brush. In eight or ten hours afterward a myriad of little miliary vesicles with a red, inflamed base, will occupy the region which has been covered with the paint. These vesicles are sometimes accompanied by severe, harassing itching, which may be relieved by local applications of sweet oil, or glycerine and water. Care should be taken not to bring the fingers into contact with the eyes or face after using this pigment, as a red blotch, or still more irritation might thus be occasioned. Washing the hands will of course be the proper precaution to take so as to avoid a like possibility.

Many of these remarks seem almost infantile, gentlemen, until a little experience in actual practice makes you appreciate that even they are not unworthy of a passing consideration.

With these patients it is important to move their bowels every few days by means of extract of colocynth and rhubarb, rhubarb, aloes, and mercury, or some other equally effective laxative or mildly purgative combination. Too often all the means indicated fail to help your patient, and his condition grows steadily worse, sometimes by slow degrees, sometimes with a more rapid march. Now is your time to make use of turpentine internally. You may give it in the form of gelatine globules, or French "perles" as they are called, and in this way all the disagreeable or unpalatable properties of the medicine are lost sight of. You may give it in a more assimilable form, perhaps, as an emulsion, with gum and some aromatic water, like fennel, cinnamon, or peppermint. A formula I frequently use is this:

℞. Olei terebinthinæ..... ʒ ij.
Syrupi acaciæ..... ℥ j.
Aquæ cinnamomi.....ad. ʒ iv.
M. S.—A dessertspoonful every three hours.

The proportion in the above of the oil of turpentine may of course be increased, and much larger doses of it be given. This I can scarcely advise as a rule, since I have remarked by actual experience that larger doses do not answer our purpose so well. Frequently they are followed within twenty-four or forty-eight hours by symptoms of very painful dysuria, that the medicine has to be greatly lessened in amount, or its exhibition completely suspended for a time. I have known quite abundant hæmaturia to be occasioned by drachm doses given every four hours. The good effects of small doses of turpentine in generalized vesicular emphysema are sometimes very remarkable, and that too, in a few days. I have known patients who were breathing noisily and laboriously, whose pulse was feeble and rapid, whose extremities were cold and cyanosed, whose chest was filled with moist and sonorous râles, return after a few days' trial of it and report the most evident improvement.

Normal heat had returned to their extremities, the cardiac pulsations were slower and stronger, the power of expectoration was greatly increased, the quantity of the sputa was diminished, and the chest was freer of its obstructive fluids, as shown by auscultation and by the audible and visible relative quiet breathing.

But this glowing account is by no means always true. Some patients get no benefit from the use of the turpentine. In these I have been led to believe either that the changes of the walls of the air-sacs have already passed beyond the limit of possible great benefit, or that the heart-walls are al-

ready degenerated. To test this matter thoroughly, and especially where we are in great doubt as to the precise condition of the muscular tissue of the heart, I give frequent small doses of tincture of digitalis, combined with some stimulating expectorant, or by itself. In a day or two we may notice the good effects. The heart may gain strength little by little, and the ability to throw off the viscid and foamy sputa which stifles the patient may be greatly increased. Now and then even cardiac stimulation seems utterly to fail of good effects. Then, gentlemen, is your time, if ever, to try what you can obtain from an emetic dose of powdered ipecac. Give it in ten-grain doses, and repeat once or twice every ten or fifteen minutes, until free emesis is produced. Make the patient drink freely of tepid water between each successive dose of the ipecac, and if much depressed after vomiting, give two ounces of hot whiskey or brandy in the form of a strong toddy.

I have seen more than one patient who appeared to be literally in the jaws of death dragged forcibly out of them by the adoption of what seemingly is an heroic method of treatment, but which in reality is one of the best with which I am familiar.

What, indeed, do we fear in these cases? Apnœa, and an apnœa which is inevitable if the bronchial tubes be allowed to become more and more choked up with viscid or spumous sputa, or both combined, so that the function of hæmatosis is almost completely abolished.

Expectorants, stimulants, heart tonics are no longer of any use. We must literally galvanize the peripheral fibres of the pneumogastrics in the only way it can be done effectually, and that is by the immediate use of an emetic. Be careful of one thing, however, to use an emetic which is not followed by depressing effects, and for this reason, if for no other, tartar emetic should never be either counselled or employed.

Among other disastrous consequences which might proceed directly from such an ill-advised course would be the formation of intra-cardiac or intra-pulmonary fibrinous coagula. I need not add that rapid, or even sudden death, would be an almost necessary consequence of these products. In the event of vesicular emphysema being accompanied by persistent chronic bronchitis, we must still make use of the stimulating expectorants already mentioned, but we shall also find advantage, in certain instances, in giving ten- to fifteen-minim doses of oleoresin of cubebs, or one or two capsules of copaiba every four to six hours. The bronchial mucous membrane will be thus modified and secretion diminished. If the general tone of the system is under par, it must be raised up by iron, quinine, and nux vomica. In this way doubtless we get the better of certain cases, which otherwise would resist indefinitely all usual methods of treatment.

In a preceding lecture I have pointed out that essential asthma is a rare affection; that ordinarily we can trace its connection with some preceding organic change in the lungs, or in the heart. Of these none, perhaps, are met with so often as vesicular emphysema. Therefore, it is that sometimes turpentine, cubebs, counter-irritation, tincture of the acetate, or some other form of iron, will relieve asthmatic attacks when the antispasmodic remedies so frequently indicated will fail to produce desirable effects. Yet we should not throw aside too completely the use of so-called anti-asthmatics like stramonium and belladonna leaves, nitre paper, tincture of lobelia, and the like. If, after ignition, smoke of the former be inhaled, or the latter be taken in proper doses before retiring at night, they will frequently prevent an otherwise imminent attack. In very low conditions, where the vital forces are at a complete ebb and where food and drink, except in the smallest quantities, are taken with difficulty, I know of nothing in the way of a general stimulant equal to strong black coffee, with about one-third old brandy. Some physicians believe such a mixture may be given during the day-time with advantage, but not at night, because they fear it will prevent sleep, and thus take from the patient one of his most reliable restorers. This is not true, for many times when the blood is stagnating in the brain and a condition of wakefulness is in a measure continued by its presence, black coffee will not only break up the spasmodic closure of the bronchial tubes, give renewed vitality to the general system, but also actually cause sleep by its stimulating action upon the cardiac contractility and the direct influence upon the activity of the cerebral circulation.

THE HISTORIES OF SOME UNUSUAL CASES OF LABOR,

TAKEN FROM THE OBSTETRIC RECORDS OF

EDWARD L. PARTRIDGE, M.D.,

INSTRUCTOR IN OBSTETRICS, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; ATTENDING PHYSICIAN, NURSERY AND CHILD'S HOSPITAL; ATTENDING OBSTETRICIAN, NEW YORK INFANT ASYLUM; ATTENDING GYNECOLOGIST, OUT-PATIENT DEPARTMENT, NEW YORK HOSPITAL; FELLOW OF THE NEW YORK OBSTETRICAL SOCIETY.

I.—*Twins—Hemorrhage from partially detached placenta before birth of second child—Ante-partum hour-glass contraction—Version.*—Mrs. K——, aged thirty, was delivered on August 5, 1881. The pregnancy was the sixth, two preceding ones having resulted in miscarriage. Nothing abnormal occurred in connection with previous labors. This delivery took place at term. After a stage of dilatation, lasting twelve hours, a child wrs born, which presented by the vertex. Within a few moments an alarming hemorrhage took place, and I was summoned by her attendant.

I found a large amount of blood in the bed, the flooding still continuing. The abdomen happening to be uncovered, I observed some peculiarity in its shape, in that a large-sized, firm tumor was present quite high up, and chiefly on the right side, while from the lower border of this enlargement downward to the pubes, the uterus was less defined and less firm.

My hand passing upward from the vagina entered a cavity, which proved to be the lower segment of the uterus, filled with clotted blood, and containing also a placenta three-fourths separated from its attachment. After scooping out clot after clot I was able to recognize that the partially detached placenta was situated on the right side of the uterus below its middle. Introducing my arm still farther, I distinguished another child packed, as it were, into the right upper corner of the uterus, and at once recognized an obliquely situated constriction of the uterus separating that portion which contained the second child from the flaccid lower cavity. I was able to pass my fingers through the ring and

touch the child's side and abdomen, feeling the lower extremities lying against the latter. Thinking delivery of this child to be an easy matter, I was surprised to find that traction upon a foot effected no change in its position.

Feeling that the danger from hemorrhage from the lower segment of the uterus—with its partially detached placenta—to be extreme, I applied, for the next ten minutes, as powerful and varied traction as I was capable of, for the purpose of dislodging the child. It availed nothing, producing *absolutely no* change in the relation of the parts. Finally catching both feet between my fingers, and pulling violently downward, they engaged in the constriction, and strong traction completed delivery. Full chloroform anæsthesia by Dr. F. W. Merriam had been kept up during my efforts. Both placentæ followed birth of second child, subsequent examination showing them to be distinct and separated by a broad space of intervening membrane.

The children, which were males, and large for twins, were dead—the death of the second, I think, resulting from the tetanic spasm of the upper corner of the uterus.

The exsanguination and exhaustion of the patient were very great, and her recovery of strength was slow. Even this termination was fortunate as compared with results in many similar cases.

In the *American Journal of Obstetrics* for April, 1882, Dr. T. C. Smith, of Washington, has made a study of thirty-three cases of antepartum hour-glass contraction of the uterus. The forceps proved of no value in meeting the difficulty, and so serious was the dystocia that craniotomy was performed in no less than ten cases. Anæsthetics and opium accomplished but little, and of the thirty women who were the subjects of the thirty-three labors, eight died, while the mortality among the children was twenty-five.

II.—*Pulmonary congestion and œdema from organic heart disease, complicating pregnancy and labor.* —Mrs. R——, aged twenty-six, was first seen by me in November, 1881, when about six months advanced in her first pregnancy. Her previous health was always good, she had never had rheumatism or scarlet fever, nor was she conscious of any cardiac disease, though she had suffered at times, beginning two years before, from palpitation of the heart. This symptom had never been sufficiently severe to lead her to consult a physician. My first visit upon her was owing to an attack of dyspnœa. She was expectorating frothy, bloody mucus in moderate quantity, and the ear to the chest discovered abundant fine mucous râles, chiefly on the left side, with slight dulness. Digitalis and stimulants relieved her after a few hours.

Subsequently a satisfactory examination of the heart, when pulmonary œdema was absent, disclosed a loud mitral regurgitant, and a very distinct presystolic murmur. There was in addition a marked purring thrill over the apex region of the heart. The apex-beat was in the seventh intercostal space on a line with the nipple.

In January she had a similar attack, not differing essentially as regards symptoms or severity. Her condition was markedly anæmic, the renal function being properly performed.

On March 3d (the proper time for term-labor), at 2 A.M., slight but regular labor-pains began. An hour later she was seized with a severe attack of œdema of the lungs.

On my arrival, I found the patient with pulse of 120, upright in a chair, with much difficulty of respiration. Expectoration characteristic—profuse and bloody. Fine and coarse râles were abundant over both lungs. The cervix admitted one finger, regular uterine contractions being present. The first stage of labor lasted eight hours, and the second an hour and a half, the child being born at noon: presentation and position normal.

The pulmonary œdema continued throughout. Digitalis, stimulants, and dry cups were in constant use, with care to maintain a proper surrounding temperature. An amelioration of the cough and expectoration could be obtained from time to time, yet the pulse could never be brought lower than 120, and it continued at that rate for four hours after completion of delivery.

At no time, from the beginning of labor until eight hours thereafter, was the expectoration of bloody mucus absent. There would be intervals of half or three-quarters of an hour, occurring every two or three hours, when the secretion would be considerably diminished.

The patient being unable to lie down, or even take a semi-recumbent position, two wooden chairs were placed with sufficient space between them to allow of the passage of the child, and its birth took place with the patient in the upright position. The labor was natural, the child being of average size. The second stage would have been of less length if she had not been directed to abstain, as far as possible, from voluntary effort.

After delivery of the placenta she was placed in the sitting posture in bed, it being, of course, impossible to apply a bandage, and it was after nine o'clock in the evening that her pulmonary embarrassment was sufficiently removed to permit her to lie down. The unusual manner of delivery did not bring about an undue loss of blood nor syncope.

On March 4th her pulse was 100; cough still present, expectoration having ceased. She had been able to sleep some. Convalescence was normal from this time. Contrary to my advice, she nursed her child.

Six months later she was looking very well, having gained in weight, though still nursing her child. She had experienced no cardiac symptoms beyond occasional hurried respiration upon the exertion of fast walking.

The case is of interest chiefly because of its unusual clinical features. It serves also to illustrate the increased liability to pulmonary œdema when chloro-anæmia exists, the latter, with hyperinosis, being the usual concomitant of pregnancy.

Another thought which occurs to one, is the great embarrassment to which the operator would have been exposed had the case called for forceps or version.

III.—*Forceps delivery, and physometra.* — Mrs. O——, aged thirty-three, had been married twice—to her first husband, twelve, to the second, two years. In general she had good health, never having uterine disease to her knowledge. Ten years ago she acquired syphilis, though for several years there had been no active manifestation. She felt well during pregnancy, and stated that she felt the movements of the child up to the commencement of labor.

Her labor began at 1 P.M., September 6th, terminating September 8th, 3 P.M., the unusual length depending upon a prolonged first stage.

The early uterine contractions were short and inefficient, though regular. No fetal heart could be heard. After twelve hours had elapsed, the os was

as large as a half dollar and the membranes then ruptured, the liquor amnii being small in amount, dark colored, containing vernix caseosa and macerated epidermis. The os had a rounded and very thick margin. Digital dilatation of the cervix was then attempted with but slight benefit, owing to its rigidity. The pains had less force and frequency, so that I desisted from these efforts.

During the next eighteen hours, there was no improvement in the uterine action. Morphine secured some sleep for the patient, but did not assist in relaxing the cervix, there being no element of spasm in its rigidity. At this time another attempt was made with the fingers to dilate the os and excite uterine activity. It was soon apparent that such forcible manipulations would be necessary that the integrity of the cervix would be endangered.

On September 8th the pains became stronger, though still very short. Dilatation took place from the jamming of the head into the cervix. This more readily resulted as the head was very compressible, there being ample signs of advanced decomposition. The anterior lip of the cervix became greatly œdematous, which may be explained, perhaps, on the theory of Professor King, for the patient insisted upon keeping the dorsal position and the anterior lip was consequently directed forward, being compressed between the pubic bones and the head of the child. Finally, in the afternoon, short forceps without handles easily delivered the head, which was well descended; no chloroform being given, nor the patient's position in the bed changed.

Immediately upon the birth of the child, a large amount of foul gas was discharged from the uterus with a succession of loud reports. The liquor amnii which had remained behind the child contained most foul-smelling, decomposing cuticle and vernix caseosa.

The placenta not following for some time, it was removed manually without difficulty, though still attached to the fundus. There was no hemorrhage. The child was far advanced in putrefactive changes. At no time did the lochial discharge become offensive, and convalescence was normal. Disinfectant injections were freely used. Two weeks after labor the cervix was examined and found to be without laceration.

I am inclined to believe that during the manipulations attending the attempts to dilate the cervix, a small amount of air found its way into the uterus, the membranes being ruptured. The contents of the uterus were already in a condition favorable to, and the amount of time amply sufficient for, the development of the gases produced by decomposition.

Lest it might be thought that the discharge of gas came from the rectum and was erroneously attributed to the vagina, I would add that when pressure was made upon the uterus previous to the delivery of the placenta, I saw the separation and movements of the vulva incidental to a noisy escape of some of the gas.

IV.—*Forceps delivery—Posterior position of the occiput—Fracture of child's humerus.*—Mrs. K——, aged thirty-eight, had her first child at the age of thirty-seven, after a difficult instrumental delivery. Her second labor occurred May 24, 1878, at term. I was called at 5 A.M. (this being my first attendance upon her), and found the os well dilated, the head presenting in the L. O. P. position. She was a short, thick-set woman, with a pelvis small in all its diameters, most markedly shortened antero-posteriorly at the outlet—a condition readily permitted by her child-bearing so late in life. The size of the uterine tumor was unusually large.

At 5.30 A.M., the head was well engaged and the os widely dilated. The pains were excellent, the patient aiding much by voluntary efforts. The head did not advance nor show any disposition to perform anterior rotation, manual efforts to bring the occiput anterior being without benefit.

The head was well flexed.

Two hours later I applied the forceps, and after forcible traction delivered the head, the occiput emerging posteriorly.

Progress was now interrupted owing to obstruction to the passage of the shoulders, the right one impinging above and against the pubis. Uterine action was vigorous, and almost immediately the child's face became purple. Exercising as much caution as possible to avoid injury to the perineum, I employed every variety of tractive and manipulative method during the next five minutes, without any effect, though the uterus was aided and stimulated by strong pressure upon the fundus. Finally, having lodged my finger firmly in the axilla of the left arm, I made most forcible, continued traction downward and slightly backward. The effect of this was to disengage the shoulders and they were at once expelled, though only upon strong traction. This was not all that I accomplished, however, for my finger recognized the sensation caused by a breaking bone.

The first result of the finger in the axilla was to throw the child's elbow away from its side, and when the elbow was thus brought against the pelvis, the downward traction produced a fracture of the humerus at the junction of its upper and middle thirds. The child was of large size.

Delivery occurred at eight in the morning, and in the afternoon of the same day I applied a plaster-of-Paris splint. Forty-eight hours after birth, abundant callus was present. The splint was removed in three weeks, though at the end of seventeen days firm union seemed to exist.

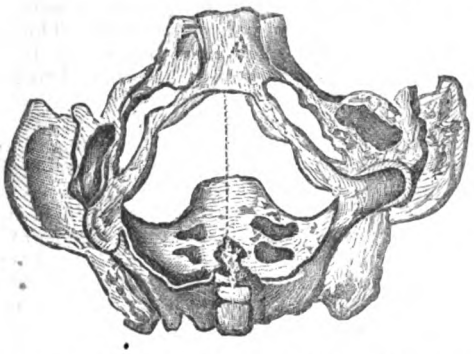
The child is now in its fifth year, the development of the extremity has been perfect, and nothing would indicate to the careful examiner that any injury had ever occurred.

This history does not differ from those common to such injury except that usually fracture of the humerus takes place during attempts to bring down an arm in breech cases.

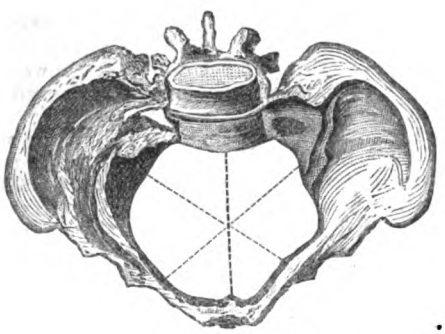
V.—*Deformed pelvis—Induction of premature labor on three occasions.*—Mrs. K——, aged twenty-six, was first seen by me in her third confinement in March, 1877. I then assisted Dr. J. W. Wright in the management of her delivery, he having been engaged by her without receiving any detailed previous history of her case. Her labor was exceedingly difficult, occurring at term. The dystocia resulted from an imperfectly developed left half of the pelvis, as indicated in the diagrams on next page. The presentation was L. O. A., the parturient forces being normal. The stage of dilatation was short. The head being engaged, the posterior fontanelle could not be reached, the anterior one was touched with difficulty, the sagittal suture was crowded far over to the mother's right side, and the *left* parietal bone lay within the circle of the os. The fœtal heart was strong.

After an hour and a half, no descent being made, the forceps was used. Half an hour of very firm traction was required to bring the head to the pe-

rineum, the instrument being once re-applied. As the head descended, it rotated into the *left* oblique diameter, which was the longer, finally presenting



in the R. O. A. position. The child, which weighed nine pounds, lost its life from compression of the cranium during delivery. Convalescence was good, there being no pain or loss of power in the right



leg, nor any necessity for employment of the catheter. There was a numb sensation present in the right leg for two weeks.

Information, meanwhile, was obtained from her as follows. Six years before, after a prolonged labor, she was delivered of her first child, which weighed four pounds and lived a short time. Four years before, her second child was still-born, dying in the birth. Labor continued sixty hours. After the first labor, her right leg was paralyzed for six weeks; after the second the same leg was similarly affected for three months. The catheter had to be used for a long time after both labors. When a child she sustained "an injury about the left hip" which caused her to be lame for some time.

The occurrence of the paralysis in the *right* leg is readily explained by a crowding of the head against the sacral nerves of that side. The pelvic deformity was of that character which results from an anchylosis of the sacro-iliac synchondrosis during childhood, and is attended by a partial arrest of development in the corresponding half of the pelvis.

The *fourth* pregnancy of this patient dated from menstruation occurring May 18 to 23, 1878. Pregnancy was natural and term labor would have occurred about February 22d. By my advice she submitted to the induction of labor on February 1st. Barnes's dilators effected dilatation of the cervix, and by the time of its accomplishment regular and frequent uterine contractions were excited. The position was R. O. A. The pains were not expulsive and after a delay of two hours I applied the forceps. Delivery was not difficult, though considerable traction was required. The child was vigorous, and at the date of this report is well and strong. Convalescence normal. While nursing this child she again became pregnant, the last menstruation occurring April 30th to May 4th.

On January 15th, three weeks before term, I again induced labor, Dr. J. West Roosevelt aiding me. Fetal heart and movements were strong. The first examination showed the os, admitting two fingers, and the *head, readily perceived, presenting.* Palpation demonstrated the breech in the right hypochondrium, while the head could be taken between the fingers just above and a little to the left of the pubes. In an hour the largest dilator had completed its work, and the head was again noticed presenting. Some trifling pains were present. Three-quarters of an hour later, on looking incidentally at the abdomen, its appearance was found entirely changed. The head could not be distinguished above the pubes, and there was no long axis to the uterus, its outline being circular. Suspecting a change of presentation, I examined and found the *left foot presenting*, the right being detected on a little higher plane. The pains improved, and at 11.15 I ruptured the membranes. The descent of the child was gradual, the arms were brought down with great difficulty, owing to the narrowed pelvic diameters, while the head became caught at the *brim* of the pelvis. For a moment or two manual efforts were unsuccessfully employed to deliver the latter, then Elliot's long forceps was applied. Five minutes of powerful traction were required before delivery.

The child did not survive, there being no action of the heart at birth, or during half an hour occupied by measures undertaken for resuscitation. The child was slightly larger than the last, yet if it had presented by the head I am confident that it would have lived. The mother did well, having no unnatural sensations about the right leg.

This delivery, let me repeat, occurred on January 15, 1880.

On February 5th and 6th she had a discharge, which she thought to be menstrual. She experienced quickening July 23d. It seemed so highly improbable, if not impossible, that she should become pregnant at menstruation in February (three weeks after delivery), and the time of quickening being taken in consideration also, I believed that impregnation took place just preceding the time at which menstruation should have occurred in March. The induction of labor was advised, therefore, for November 20th. Accordingly, on that date—which I thought to be three weeks prior to the time for term labor—the operation was performed. The head presented, the bones of the cranium being noticeably more firm than on either previous occasion. Fetal heart, 148.

The labor occupied two hours, delivery taking place by the aid of Barnes's bags and the forceps, the latter instrument insisting upon rotating as before, so as to bring the blade on the mother's right side on a plane anterior to that occupied by the blade on the left side. Considerable traction was necessary, with slight compression.

The child was strong, well developed, though of less than average size, and is now as healthy as could be desired. Convalescence was normal.

The histories of these three labors illustrate certain of the benefits conferred by induction of premature labor, while they fairly demonstrate the

simplicity and ease of its performance, with reference to the mother.

This patient being kept more or less under the influence of an anæsthetic from the commencement of the measures for her delivery, has no suffering during her child-bearing, and regards the *beginning* of her labor as the *termination* of evils.

13 West Ninth Street.

FOREIGN BODY IN THE AIR-PASSAGES.

Rupture of the Trachea from Cough—Surgical Emphysema—Tracheotomy—Death.

By GEORGE M. LEFFERTS, M.D.,

Clinical Professor of Laryngoscopy and Diseases of the Throat, College of Physicians and Surgeons, New York.

The *résumé* of the history of an unusual and interesting case is given in the above title: it remains but to add the details. The young child, of not more than three years, was brought to me with the story of having, while playing upon the floor, two days previously, placed something that he had picked up in the mouth, which a moment later caused violent cough and strangling. The latter, with its attendant cyanosis, passed away, but the former remained and became progressively more distressing, more or less paroxysmal in character; each attack, according to the mother, seemed as if it would suffocate the child. On the second day a sudden swelling of the neck and face was noticed, and the respiration became labored. At the date of my examination, the little sufferer, wan and exhausted, presented a curious appearance, the tissues anteriorly and laterally over the neck being markedly swollen or bloated, and giving a distinct emphysematous crepitation to the touch. The same condition, in lesser degree, existed over the upper parts of the chest. The respiration was hurried, labored, and slightly stridulous, while the paroxysmal attacks of cough were violent and prolonged. Auscultation of the lungs, rendered difficult by the constantly recurring cough, gave diminished respiratory murmur on both sides, with numerous subcrepitant and a few coarse râles over both bases. An examination of the throat and larynx was negative in its results.

Tracheotomy was at once decided upon, but owing to the objections of the mother, was not allowed by her until the following day, when it was performed by Dr. Satterthwaite.

The child's general and pulmonary conditions were unfavorable. The delay had been prolonged, but the surgical indication was clear and imperative.

The upper third of the trachea having been reached by a dissection that required, on account of the swollen and infiltrated condition of the overlying tissues, all of the surgical skill that it received, a slight hissing of escaping air, and the presence of air-bubbles in the deep layer of fascia adherent to the windpipe, located the point of rupture of the trachea at a little to the left of the median line, at about the point of juncture of its middle and upper thirds. The rings appeared to be intact, and the laceration, therefore, must have been of the tissues between one or more of them, the tube now being opened by an incision extending upward through three or four rings and the cricoid cartilage, and the wound held open by retractors. No evidence of the presence of a foreign body was immediately forthcoming, although a probe was introduced downward into the trachea for a short distance, but a tracheotomy tube being introduced during the resultant paroxysm of cough, it was both heard and felt to ascend the trachea and strike against the tube. This was at once removed, and with the next explosive cough the offending substance was forcibly expelled far out into the room (the lower pear-shaped portion of a common jet earring). The edges of the wound were now brought together by sutures.

The immediate result of the operation was to materially relieve the distressing cough and cause a rapid subsidence of the emphysema. The child died, on the third day, from a broncho-pneumonia.

Remarks.—An interesting point in the history of my case is the definite localization of the point of rupture in the wall of the trachea itself. This I believe to be unusual. As a rule, undoubtedly in such cases as I have described, a weaker structure will give way before a stronger, under the great pressure caused by the powerful expiratory efforts in the form of cough; and Wyatt (*Lancet*, April 15, 1882) is probably right in his explanation of the production of emphysema of the neck and chest in many, perhaps the majority, of cases where it follows violent cough—viz., that the breach through which the air escapes occurs in some small or terminal bronchus, rather than in the trachea itself. In such a case, the air would track along the connective-tissue sheath of the bronchus until it reached the root of the lung; then diffuse itself through the mediastina, passing up out of the thorax into the neck, and downward possibly over the muscles of the chest.

The Appearance of Medicinal Agents in the Bile after Absorption from the Rectum.—Dr. E. Peiper publishes the results of some experiments undertaken by him to determine the passage of certain metallic salts into the bile from the blood. The experiments were made upon dogs with biliary fistulæ, the medicaments being injected in solution into the rectum. The following are the results obtained by him: 1. *Iodide of potassium* was detected in the bile in from six to eight hours after the injection of half a gramme in solution into the rectum. 2. *Salicylate of sodium.* No results were obtained with the injection of half a gramme of this salt, but when three grammes were administered in one dose it was found in the bile within thirty minutes. 3. *Carbolic acid.* As the dogs with biliary fistulæ were too weak to bear even small doses of this substance, the experiments were made upon rabbits, the animals being killed a few hours after the carbolic acid solution was administered. In every case the acid was found in the bile, though in very small quantity. The amount injected was in the different experiments from thirty-five to seventy centigrammes. 4. *Ferrocyanide of potassium* (yellow prussiate of potash) could be detected neither in the bile nor in the urine five hours after the administration of a three-gramme dose. The same negative result obtained with the red prussiate of potash. 5. *Sulpho-cyanate of potassium* was found in the bile three hours after the injection of one gramme in solution.—*Schmidt's Jahrbücher*, August 22, 1882.

A Bon Mot of Arago's.—"What are comets made of?" asked a French lady of the distinguished savant. "Madame, I do not know." "Then what is the use of being an academician?" "Madame, that I may be able to say I do not know."

Progress of Medical Science.

CURATIVE ACTION OF ERYSIPELAS.—According to Dr. Dauchez (*L'Union Médicale*, October 5, 1882) erysipelas may exert a beneficial effect upon a number of diseased tissues by exciting in them a healthy action through active inflammation. It modifies favorably some ulcers, especially phagedenic chancre and lupus. Fungous tumors are destroyed, old suppurations dried up, and elephantiasis cured. This action is indeed rare, yet it is sometimes observed, and the possibility of its occurrence should be borne in mind.

STRANGULATED HERNIA OF THE VERMIFORM APPENDIX.—Dr. E. H. Bennet relates the following case in the *Medical and Surgical Reporter* of October 7, 1882: The patient, a man sixty-four years of age, was suddenly attacked with violent pain in the hypogastric region. Examination revealed the presence of a tumor the size of a hen's egg, hard and painless, in the right groin. The patient had noticed a lump in this region for three years, but it had never given him any trouble. Although it resembled an enlarged gland rather than a hernia, attempts were made to reduce it, but without success. The bowels were confined and could not be acted upon by cathartics or enemata. Vomiting set in and soon became stercoraceous. On the third day an operation was decided upon. When the strangulated portion was reached it was found to oe the free end of the appendix vermiformis. As it was gangrenous it was removed, a ligature being previously passed around the appendix in the healthy portion. At the end of four weeks the wound was healed and the patient made a good recovery.

TO HASTEN THE ACTION OF QUININE.—Dr. Starke, in *Berliner Klin. Wochenschrift*, advises that before swallowing powder or pills of quinine, a weak tartaric acid lemonade be taken. This procedure not only greatly accelerates the solution and absorption of the quinine, rendering its physiological action much more prompt, but also obviates that unpleasant gastric irritation so common after the administration of large doses of this drug.

A PUPILLARY PHENOMENON OBSERVED IN CERTAIN MORBID CONDITIONS IN CHILDHOOD.—Dr. Parrot records in the *Revue de Médecine* for October, 1882, a number of observations made by him in regard to a reflex dilatation of the pupil, occurring in certain pathological conditions in young children. In these affections, dependent or not upon evident lesions of the nervous centres, accompanied or not, by convulsions, but always by coma, if the skin of the epigastrium or of any other part of the body be pinched, there follows a momentary dilatation of the pupil. Among the affections in which this phenomenon is observed are tubercular meningitis, hemorrhage beneath the pia mater, some cases of chronic hydrocephalus, and certain other undefined conditions in which the contents of the cranium are increased out of proportion to its capacity. In other comatose conditions, usually without convulsions, there is no response of the pupils to even violent pinching of the integument. In these cases there may be œdema or marked congestion of the pia mater, but the factor of cerebral compression is absent. From his present observations the author is unable to determine the precise diagnostic or prognostic value of this phenomenon, but he formulates one conclusion, viz.: In a child in a comatose condition, whether there be convulsions or not, if the pupils do not respond to peripheral irritation in the manner indicated, we can exclude meningitis and hemorrhage beneath the pia mater—the child is suffering from asphyxia and his death is imminent.

THE INTESTINAL ORIGIN OF CERTAIN ALKALOIDS FOUND IN THE URINE.—In a previous paper read before the Société de Biologie, Dr. Bouchat announced the discovery by him of certain alkaloids in the urine during the course of infectious diseases, and expressed the opinion that they were vegetable alkaloids originating from the infectious agents rather than any product of the animal-cells. At that time he had found none in normal urine. Since then, however, he has succeeded in determining their presence in the urine in health, but believes that they are elaborated in the alimentary canal by vegetable organisms, the agents of intestinal decomposition. Those diseases, as typhoid fever, which increase intestinal putrefaction, augment proportionately the quantity of alkaloids in the urine; and in proportion as this process is controlled by charcoal or other agents, the alkaloids in the urine are diminished. Hence he concludes that they are generally found in the intestine (though possibly also in the tissues), are absorbed in part by the mucous membrane, and excreted by the kidneys.—*Revue de Médecine*, October, 1882.

THE TOLERANCE OF POISONS.—Prof. Rossbach, from a very extended study of this subject, draws the following conclusions: 1. Tolerance of poisons is established very rapidly (except in nervous and hysterical subjects), and it is thus that at the third or fourth cigar symptoms of tobacco-poisoning cease, and that the quantity of alcohol necessary to produce intoxication increases with its use. When atropine is given to dogs daily, certain symptoms are observed at first which disappear in the course of a few days—such as hyperæsthesia of the skin, trembling of the body, etc. The animals then became as lively and vivacious as unpoisoned animals. 2. The organs of man and of animals become equally habituated to poisons, and in the same organism each organ behaves differently toward these. 3. There are organs which never become habituated to poisons, in the sense that they always behave toward them as at the beginning of the administration. It is thus that morphia, always administered in the same dose, induces sleep for weeks or months; that the smoker, consuming a uniform quantity of tobacco, feels, at the end of years, the same beneficial influence continued. It is the same with tea and coffee. Certain organs are influenced by the use of atropine after long usage as at the commencement—the pupil always dilates, the salivary secretion is diminished. It is precisely those organs which are most impressionable which are least influenced by habitual use of poisons. 4. Nevertheless those organs, by the prolonged use of a poison, remain influenced by it for a period of time which progressively diminishes; hence drunkards, and those addicted to morphine, experience the need of more and more frequent doses of alcohol or of morphia. 5. Another series of organs reacts differently toward the same poison, according as it is administered for the first time or after a lengthened interval. Thus atropine acts at first upon the heart by paralyzing the vagus, while at a later period it

paralyzes the motor nerves and the muscles of that organ. 6. Again, there are organs which become habituated to certain poisons (tobacco, alcohol, morphia), so that after a certain time they present no functional derangement. 7. These propositions are not valid, except where the dose remains the same. When the dose is increased, however slowly, a time comes when the poison again exhibits its action. 8. In an organism accustomed to a certain dose of the poison, a much larger dose acts in the same manner as a small dose on an unhabituated organism. 9. In general, the symptoms of chronic poisoning are extended to more organs and functions than those of acute poisoning. Thus in chronic morphia-poisoning we observe restlessness, insomnia, hyperæsthesia, neuralgia, an exaggeration of reflex movements, anorexia, malaise, vomiting, palpitation, albuminuria, malnutrition; whilst in acute morphinism purely nervous symptoms alone are observed. 10. In man and animals, if the dose of the poison be not continually augmented, but be kept at medium quantity, this amount may be supported with impunity for the rest of life. The proof of this is, that thousands of persons arrive at an advanced age who have taken for long periods tobacco, alcohol, coffee, or opium. 11. If the use of the poison be broken off at the end of a relatively short time—weeks, months, or it may be, in exceptional cases, years—health is restored in the course of a few days. But if the cessation take place after a more considerable period of use of the poison, certain morbid phenomena are observed, such as trembling, acute delirium, intellectual feebleness, and lowness of spirits. If now the use of the poison be recommenced, these symptoms rapidly disappear. 12. There is an epoch at which reparation of tissue is still possible, and one when this is no longer possible. In this last case, there is a notable change in the chemical composition of the substratum of the tissues; and this modification is appreciable by the microscope in certain organs, as, *e.g.*, the liver. 13. In order to explain the effects of chronic poisoning, we may say that the organs are not more impressionable to normal stimuli (carbonic acid, ferments), but only to the poison; failing this, the body is deprived of excitants, and a profound depression of most of the functions is produced. 14. The fact that certain organs end by being no longer impressionable to poisons, is comparable to the immunity which certain organisms enjoy toward certain organized poisons (those of infectious diseases) when once they have been the seat of their action.—*Archiv für die Gesammte Physiologie*, 1882.

The Bacterium of Pemphigus.—M. Paul Gibier has found micro-organisms in the serum which fills the bullæ in acute pemphigus and in the urine of the patients. The parasite is found in chains of rounded elements, which show active movements. It is reproduced by cultivating the serum of the urine. The author has not found it transmitted by contagion, and attempts to propagate it by inoculation have so far failed. The affection is easily cured by the usual anti-parasitic remedies. —*Annales de Dermatologie et de Syphilographie*, No. 2, 1882.

How far may the Alcohols be Used in the Treatment of Pneumonia?—In the treatment of either croupous or catarrhal pneumonia, alcohol must, by all means, be used with caution. There are, for example, cases of pneumonia where the employment of alcohol to prevent paralysis of the heart, not only disturbs the regular course of the disease, but has a directly injurious tendency. This is to be noticed: 1. In all light cases of pneumonia. By this we mean those cases in which the temperature does not rise above 104°, where the dyspnœa is not very great, where the pulse is strong and the pulmonary trouble in general shows no tendency to rapidly increase. The employment of alcohol in such cases can only have a dangerous effect, for through the increased action of the heart more blood is thrown to the lung and the disease is increased. 2. The above treatment of pneumonia is further contra-indicated in people who are otherwise strong and healthy, who have not passed forty-five years of age. In children and young people alcohol exerts no favorable influence on the course of the disease. 3. In those cases of pneumonia where there is a valvular lesion of the heart alcohol is to be avoided; for through the increased action of the heart collapse is sooner to be expected. On the other hand, indications for the alcohol treatment are—1. In those patients in whom there is thought to be a degeneration of the heart-muscle, but when there is no valvular lesion. This is mostly the case in chronic alcohol drinkers, in whom an unexpected paralysis of the heart may occur at any time. 2. In those who have passed fifty years of age, if they possess no heart lesion. 3. In the so-called hypostatic pneumonia where the appeal impulse is in position, for the purpose of supplying the sound as well as the diseased lung with fresh, healthy blood, and to protect the sound parts of the organ from stasis and the diseased part from the further consequences of the stasis which has already occurred. 4. In every pneumonia, if only the heart is not affected with a lesion of the valves, after the crisis has passed, so as through the increased impulse to the circulation to more rapidly promote the absorption of the exudation. 5. Finally, alcohol cannot be avoided without regard to the condition of the heart in persons having a tendency toward collapse, where paralysis of the heart or œdema of the lungs may occur at any moment. When, however, œdema is already present, then alcohol is no longer of use, for by this means will the patient, who is now without hope, be unnecessarily maintained in the death-agony. The thoughtless, unrestricted treatment of every case of pneumonia with alcohol is not only unscientific, but indeed blamable.—*Cincinnati Lancet*, October 21, 1882.

Oxygenated Water as a Dressing for Wounds.—At a recent meeting of the Société de Médecine Pratique, M. Brochin reported some experiments made by MM. Paul Bert and Becquard, on the use of oxygenated water in the wards of M. Péan for the dressing of wounds. Excellent results had been obtained in cases of purulent cystitis, ozæna, and ringworm. It had also been employed internally in uræmia and diabetes with good results. Its use had not been so successful in obtaining union by first intention as carbolized water. M. Jolly drew attention to the fact, that to preserve oxygenated water, it must contain an acid. This is more frequently hydrofluoric acid, otherwise it may decompose with an explosion; that used by MM. Paul Bert and Becquard contained sulphuric acid, a fact not to be lost sight of. A certain amount of oxygen is liberated from this water in the form of ozone, and it is in this way that it acts.—*British Medical Journal*, September 23, 1882.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, November 25, 1882.

EXPERT TESTIMONY REGARDING PROFESSIONAL FEES AND SKILLED TREATMENT.

A RECENT decision of Judge Campbell, of the Supreme Court of Michigan, in a suit for the recovery of fees for surgical services, is of much importance to the profession. The action was brought by M. W. Wood, Captain and Assistant Surgeon United States Army. The defendant, as is usual in such cases, made a counter-charge of malpractice. The plaintiff was called to attend the defendant on account of compound complicated fractures of both legs, the result of injuries. The latter were so severe and extensive as to cause the surgeon to advise double amputation. The patient objected to the removal of more than one limb; the other limb was dressed, and in the face of great risk an attempt was made to save it. Happily this attempt was successful to the extent of giving the patient a somewhat crippled extremity. The patient was, however, not satisfied with this unlooked-for result, and not only claimed to prove that the surgeon's judgment was originally at fault, but that his skill was defective in not giving him a perfect leg. Hence, instead of paying for such services the patient sues for damages. It is unnecessary to say that the charges were not sustained, although the usual attempts were made to influence the jury in deciding upon matters which they could not necessarily understand.

The questions on which the controversy appears to have turned were, as stated before, the value of the services and the propriety of the treatment. In regard to the first point, the charges for services were reasonable and just. It was intended, however, to reduce the fee in accordance with the want of skill shown in the subsequent management of the case. Hence, the second point as regards propriety of treatment was necessarily presented.

The ruling of the court completely covers all the considerations in this case, and practically establishes a long hoped-for precedent, by judicially recognizing the principle that physicians alone are competent to testify to the value of a physician's services, and that they alone are qualified to give opinions on methods of treatment.

The decision was as follows:

"There is no presumption of law as to the value of a surgeon's services, nor that a jury can ascertain their value without testimony from persons knowing something about it. Nor has a jury a right to reduce the compensation claimed for such service where undisputed testimony shows it to have been appropriate, and on their own unsupported notions that the treatment adopted should have been different.

"A jury has no right to ignore testimony that has not been discredited, and form independent conclusions, without testimony, on matters that require proof beyond their conjectures or opinions.

"The fact that a surgeon changes a course of treatment adopted by another does not in itself show that the former course of treatment was not proper at the time; nor is the patient's failure to recover perfect soundness of limb in itself evidence of malpractice, nor is the fact that he survived, although he refused to allow a particular course of treatment, evidence that such course might not have been proper under the circumstances.

"The jury in an action for the value of surgical services has no right to find malpractice without testimony from persons who are qualified to give opinions on the method of treatment."—Wood *v.* Barker, filed October 18, 1882, Supreme Court of the State of Michigan, Campbell, J.

A PECULIAR BILL.

THE Vermont Legislature has recently had before it a bill which adds to the studies of common schools physiology and hygiene. Furthermore, these sciences are to be taught in such a way as to "give special prominence to the effects of stimulants and narcotics upon the human system." This bill excited much discussion, as well it might, but it was finally passed by the Senate.

Aside from its railroad judiciary and legislature Vermont is one of our model States, as evidenced by the morality of its people and the bareness of its civil and criminal dockets. It has, also, a most stringent prohibition law. Nevertheless, the State is seized upon by the temperance party as though it were a stronghold of sin, and a particularly proper field for its literary and legislative activities. The present bill is doubtless one of the offshoots of the State temperance agitation.

We highly approve of youths and maidens having some lucid and correct ideas about their livers and

their stomachs. But such knowledge is not easily gained. The study of physiology means also a study of anatomy, which latter must come first. And anatomy, physiology, and hygiene are too advanced and comprehensive studies for common schools. Children, says a medical philosopher, first want to know about the stars—last of all about their bodies. As regards this latter subject, the growing youth are obstinately dull. It is wonderful how even medical students mix things up in attempting to master physiology. It is well, therefore, for educators to know that that science is not an elementary one. The average child gets no clear or rational notions regarding it. This has already been abundantly shown by examination papers. The difficulty is increased by the fact that the teachers themselves know almost nothing of what they are compelled to teach.

Again, a knowledge of physiology does not necessarily make one more prudent in hygienic matters. Witness the doctors. A child should be taught at home those habits that will secure his health. The enforcement of such habits is better than the most learned expositions of the laws of hygiene. With children, as with nations, art comes before science, the act before the reason why. Will a boy refrain from going behind the barn and smoking a cigarette because he has been taught that one drop of nicotine will kill a cat?

With reference to the proposed Vermont law, we fear that a just application of physiological science will not help the cause of teetotalism so much as is hoped. For this science teaches that alcohol in moderation, though dangerous to youth, is only risky to manhood, and may be helpful to age. So, for tobacco; it is, indeed, absolutely pernicious and hurtful to the immature, but not necessarily so to the adult, and no State should allow or compel its teachers to pervert physiological science and accepted hygienic truths to the purposes of ultra reformers.

THE CUTANEOUS DISEASES OF CHILDREN.

Dr. Robert J. Lee recently read a paper upon the "Cutaneous Diseases of Children" before the Medical Society of London. The paper was based upon a clinical experience with about two thousand cases of this kind, and contained some points of practical interest.

Dr. Lee said that children were liable to cutaneous diseases to a larger degree than adults. In the wards of a children's hospital and dispensary, five per cent. will have some form of skin trouble. Children are also peculiarly liable to a certain form of skin disease. This form the writer chose to consider simply as a dermatitis, which affects particularly the scalp, face, and neck. Under this head of dermatitis are included the diseases generally known as strophulus, ecthyma, eczema, and impetigo. In thus using the generic name of dermatitis, Dr. Lee adopts a method which is in accord with the views of many others. It shows, says Dr. Lee, a feeble apprehension of the true spirit in which we should regard the subject of skin diseases to try to find a separate name for every case we see. Every fresh student is appalled at the multiplicity of forms and names associated with eczema; and it at once strikes one as better, where possible, to use a word which implies no specific process other than inflammation.

Dermatitis, as thus understood, of the head, neck, and body, makes up about two-thirds of the cutaneous diseases of children. This disease takes on various forms, and may properly enough be defined as serous, scaly or epithelial, purulent, tubercular, etc.

Dr. Lee insists upon the fact that this form of dermatitis belongs to children exclusively. The fact that it affects so large a per cent. of children in hospital is evidenced in favor of this view.

The dermatitis of children is in a very small proportion of cases (two per cent.) the result, apparently, of hereditary tendency. Our author's theory of the pathology of this trouble was stated by him some time ago, and is a plausible one. The presence of any local sore may be followed in children by a dermatitis of the head or other part. This fact explains the skin affections that sometimes follow vaccination, herpes, varicella, etc. It is thought by some to be due to a nervous influence; by Dr. Lee to local absorption of some product of inflammation yet unknown, and a poisoning thereby of the blood. Such morbific agent may result from disturbances in digestion or dentition, as well as from various lesions of the skin.

Among the remaining one-third of children who have not this dermatitis, the skin troubles are variously divided. The syphilitic cutaneous cases occur in the ratio of about five per cent. on all cutaneous cases. The syphilitic eruptions were found to have a distinct character according to the history of the parents. Thus, if the father's disease is recent and the mother has suffered, the infant presents a skin profoundly diseased, the nasal and oral orifices being also affected. If the father's disease is of older date and the mother escaped, the infant (at twelve months) shows only condylomata, or perhaps gummata which have softened till they became like furuncles, painless and soft.

Of the remaining diseases, about six per cent. on the whole were tinea tonsurans, of which nothing especial need be said.

From three to three and a half per cent. were cases of herpes. This disease less frequently affects the abdomino-dorsal region (herpes zoster) in children than in adults. Such affections as scabies,

congenital disease of the skin—which latter has a curious relation to the health of the mother during pregnancy—scrofulous and tuberculous disease, together with a few pathological rarities complete the list.

THE TYPHOID EPIDEMIC IN PARIS.

The prevalence of typhoid fever in Paris has excited much attention, in part, as it seems, because there was not sufficient accommodation in the hospitals for the new cases.

The epidemic was announced in August. But it was two months before proper preparations were made for it. The official statistics show that on October 2d there were in the hospitals of Paris 1,166 typhoid fever patients. A week later this number had increased to 1,845, with a daily admission of 137 cases.

In the succeeding week the number of hospital patients increased to 2,156, but the daily admissions were somewhat less. Since that time there has been a steady decline in the daily admissions until on October 25th the number was only twenty-five. The epidemic seems, therefore, to be on the wane. The mortality rate is not very creditable to French therapeutics, assuming that the disease had no especial malignancy. In one week the admissions were 740, the deaths 116; during the next week there were 407 admissions and 92 deaths. One may ask what has become of the antiseptic treatment or the antipyretic treatment, by which the mortality may be reduced, we are told, to six per cent. or less.

Despite the large number of typhoid fever cases, the total mortality for the city was not unusually great. In the week ending October 8th the number of deaths was 1,111, of which 244 were from typhoid fever.

THE COMMITMENT OF LUNATICS.

Much sensation has been created in this city by the recent removals of alleged sane men from the City Insane Asylum. We are informed that within a few months nine patients confined in the Ward's Island Asylum have been declared sane and removed. The public press, especially the sensational weeklies, have utilized the occasion to make sport of medical experts, and to intimate that dark deeds are being constantly done by these gentlemen and the asylum superintendents. We are told that the "medical profession is spotted with scoundrels" who are willing to send sane men to asylums for the sake of a bribe from the relatives. Other "scoundrels," under like persuasion from conspiring consanguinity, keep these poor victims in the asylums.

It is needless to say that a great deal which has been written and spoken of late about incarcerating the sane is sensational and untrue. People do not reflect that there must be a very carefully arranged combination of circumstances in order to get a sane man into an asylum and keep him there. The relatives or friends must be conspirators; the two examining physicians must be in league with them, or else extremely incompetent. And we would here remark that it requires no extraordinary or special skill to recognize most cases of insanity. Further, the judge must be very negligent (which is, perhaps, likely enough); and finally, the asylum superintendent and his assistants must all be bribed or deceived. Now it is really quite rare for all these things to happen regularly together. We do not deny that they occasionally occur, and that in small or private asylums the opportunities are possibly greater.

In some of the cases that have recently been discussed, there has apparently been gross carelessness and stupidity, but we very much doubt the "conspiracy."

Our present law regarding the commitment of the insane is a tolerably good one. Yet there is dissatisfaction with it, and some changes are needed in order to relieve public distrust and apprehension. In all matters pertaining to the commitment and care of lunatics, there should be the fullest guarantees of fair play. The past history of asylums has made people suspicious of them, and not without cause. In the present law of commitment there is a temptation to haste and carelessness, as well as a chance for wrong-doing. The proposed amendments would make the process of commitment more cumbersome and tedious, yet this would be worth while if it gave a greater confidence to the public.

The Subcutaneous Insertion of Laxative Remedies.—The following preparations have been used hypodermically at Berlin for therapeutic purposes: Aloïn, colocynthine, alocynthinum purum, (Merck's) catarthine, citrulline, extract colocynth, leptandrine, euonymin, baptisin, and elaterium. Most of these substances being only slightly soluble in water are not appropriate for hypodermic application. Aloïn and the preparations of colocynth proved themselves most worthy of use. Aloïn 1 to 8 of warm glycerine, injected in quantities of 60 to 120 minims produces a mild laxative effect in from six to eight hours. The same quantity administered internally expresses an effect in the same time. Citrulline and colocynthinum purum in doses of 5 to 10 milligr. act in even a drastic manner. Citrulline is a resinoid of colocynth. This resinoid injected per anum in the same quantity as hypodermically acts in much shorter time. This same was found true in the use of other preparations employed. Therefore applications of laxative remedies are for the most part preferably made per anum. The preparations of colocynth administered hypodermically produce tenesmus and sometimes catarrh of the rectum. Conclusion: The hypodermic injection of laxatives does not diminish the dose nor shorten the period before the effect appears, nor is there greater safety in thus administering such remedies, so that powders, pills, and infusions of these agencies are much to be preferred.—*Therapeutic Gazette.*

Reviews and Notices of Books.

A System of Human Anatomy, Including its Medical and Surgical Relations. By Harrison Allen, M.D., Professor Physiology University Pennsylvania. Section I. On Histology, by E. O. Shakespeare, M.D. Section II. On Bones and Joints, by Author. 4to. Philadelphia: Henry C. Lea's Son & Co. 1882.

We have received the first two sections of this work, the one comprising Histology, by E. O. Shakespeare, and the other, by the author, treating of the bones and joints of the human body. Each is contained in a portfolio, is of quarto size, double columned, and is supplied with full-sized page plates specially prepared from dissections by the author. The work is an entirely new one, on a comparatively new plan, for which reasons it commends itself to the special notice of anatomical students. The design of the author is to present the facts of anatomy in the manner which shall appear to be best suited to the requirements of the student and the practitioner of medicine. In a word, it is to be considered a study of applied anatomy in its widest sense—a systematic presentation of such anatomical facts as can be applied to the practice of medicine as well as of surgery. An attempt to fulfil such a promise brings with it many responsibilities. It implies a wide grasp of a very comprehensive subject. Our author has, however, proved in many ways his peculiar fitness for the task. He is concise, accurate, and practical in his statements, and succeeds admirably in infusing an interest in the study of what is generally considered a dry subject.

Dr. Shakespeare has also justified the wisdom of the author in the assignment of the department of histology. This latter topic is treated in a masterly manner, and the ground is travelled over by one thoroughly familiar with it. The illustrations are made with great care, and show very satisfactorily the different histological conditions of the various grand divisions of tissue-structure.

It would be impossible, except in a general way, to point out the excellence of the work of the author in the second section, that devoted more particularly to the consideration of the bones and joints. There is as much of practical application of anatomical points to the every-day wants of the medical clinician as to those of the operating surgeon. In this respect it is different from the many excellent works on anatomy, and in so far deserves special and meritorious recognition. The physician has as much need of the knowledge of the relations of the internal organs, their variations of position, structure, and size, within the limits of health, as does the surgeon of such parts as are subjected to the various operations. The physician, by this kind of knowledge, is as well prepared for the interpretation of symptoms, and the exact localization of diseased action, as is the surgeon by a like proficiency in his anatomy enabled to guide the knife safely in dangerous localities. And our author has done his best to secure for his work a corresponding range of adaptability. In fact, this has been so successfully done that few general practitioners will read the work without a feeling of surprised gratification that so many points concerning which he may never have thought of before are so well presented for his consideration. Saying thus much for the sections before us, we have striven to be within the bounds of conscientious conviction. We wish, however, we could include in this statement an equal commendation for the plates. But, in reality, they by no means do justice to the text. Although evidently got up at considerable expense, they fall far short of what one might expect in a work of this sort. They are, as a rule, very bad, and their general appearance decidedly unartistic. It is a matter of surprise that any artist, having a proper conception af outline and shadow, should allow many of these specimens to escape from his pencil. The general impression they convey is that of confusion of parts, and general indistinctness of the whole If one faculty more than another is required in such drawings, it is that of working up details. This can only be done by correct outlines, proper shading, and due attention to perspective. We are sorry to say that there is a manifest failure in all these particulars. In many instances the names of the parts are so mixed up with loose and sketchy shading as to be almost entirely useless for ready reference. This is to be regretted the more, as these names are in many cases the only indications of the artists intention. As an offset to this criticism, we are happy to state that the illustrations in Dr. Shakespeare's chapter are simply superb.

It is to be hoped that in the remaining four parts of the book yet to come, that the defects noted will be remedied, for it is to be deplored that a work which is destined to be the best of its kind in any language should not be perfect in every respect.

The Change of Life in Health and Disease. By Edward J. Tilt, M.D., Past President of the Obstetrical Society of London. Fourth Edition. Philadelphia: P. Blakiston, Son & Co. 1882.

Except in the matter of a new preface, containing spasmodic strictures on the barbarous tendencies of American gynecology, the fourth edition of Tilt's treatise does not differ materially from its predecessors. Hints of great practical value abound in the work, but there is also a large admixture of rather unprofitable theory. Still the book has no rival in its special field. It will certainly be read with profit and interest by all who are called upon to treat disease as modified by the factor of climacteric life, which is equivalent to saying by the entire profession. The American edition is printed on good paper, with excellent type, and our copy is furnished with neat paper binding, which insures convenience of handling.

Essentials of Vaccination. By W. A. Hardaway, M.D. Chicago: Jansen, McClurg & Co. 1882.

In this little volume the author has endeavored to place before the profession a *résumé* of the more essential facts relating to vaccination. The text is made up of ten chapters, beginning with the history of vaccination and inoculation, animal pox, and particularly vaccinia in the cow; its communicability, differentiation, etc., and its relationship to variola in the human subject, receives much interesting consideration. The symptoms and course of an inoculation (chapter iv.) are then detailed, together with certain deviations considered to be normal, in regard to appearance of the lesion, delay in the progress of the vesicle, a relatively lengthened period of incubation, insusceptibility, etc. Various abnormal modifications, so-called spurious vaccinia, certain complications and irregularities, their causes, and the influence of other diseases, are then dis-

cussed, followed by a chapter devoted to the subject of re-vaccination and the questions thereby suggested. Certain general considerations are afterward presented, relative to the merits of the different viruses, and the degenerative influence of many removes upon the prophylactic power of the vaccine lymph. Chapter viii. affords much useful information in detail, on the various and most approved methods of obtaining and storing the virus, both humanized and bovine. The subject of operation is then taken up, together with the several influences affecting it; notably the age, condition of the person, the value of vaccination after exposure, as well as the minor details of the procedure itself, which though apparently a simple one, nevertheless receives many observations that are commendable to all. The book finally closes with a general consideration of the objections to vaccination, the protection afforded, and the alleged attending dangers. In presenting his work, the author gives evidence of much valuable research, which not only the young practitioner, but likewise the more experienced, may receive with profit to himself, and possibly with incalculable benefit to his patients.

THE PHYSICIANS' VISITING-LIST FOR 1883. Philadelphia: P. Blakiston, Son & Co.

LINDSAY & BLAKISTON'S Visiting-List, having enjoyed thirty-one years of uninterrupted popularity, may safely rest on its own merits. It will be found, as usual, to contain some improvements and modifications, among which we notice a new table of poisons and their antidotes.

A MANUAL OF THE DISEASES OF THE EYE. By C. MACNAMARA, F.R.C.S., Surgeon to the Royal Westminster Ophthalmic Hospital. Fourth Edition. 12mo, pp. 520. Philadelphia: P. Blakiston, Son & Co. 1882.

IN the fourth edition of this work the author has rewritten the chapters on errors of refraction of the eye and also those on diseases of the choroid, optic nerve, and retina. As a whole the book is well written, is practical in character, and, for its size, contains more valuable information for the practitioner than any similar work we have seen.

SPEECH AND ITS DEFECTS: Considered Physiologically, Pathologically, Historically, and Remedially. By SAMUEL O. POTTER, M.D. Lea Prize Thesis of Jefferson Medical College. Philadelphia: P. Blakiston, Son & Co.

ALTHOUGH Dr. Potter attempts to present his subject from a rather large number of standpoints, he has succeeded in making a compact and interesting little work. There are practical hints for the treatment of stuttering, etc., which will be found particularly valuable to the medical reader.

WHAT TO DO IN CASES OF POISONING. By W. MURRELL, M.D., M.R.C.P. Detroit: Geo. S. Davis. 1882.

As the author very justly remarks, the practitioner can imagine "nothing more painful than to be called in to a case of poisoning and not to know what to do." This little work, already in its second edition, presents, in a short and concise manner, directions for the treatment of the various poisons. The author supplies the contents of an "antidote bag," for ready use in emergent cases, the value of which is self-evident. The various emetics, their actions, doses, etc., are then cited, following which the chief part of the text is devoted to the several poisons and their treatment, arranged alphabetically. Besides complete revision, an addition has been made to the text in the matter of fatal dosage. It is an exceedingly useful little book, not only offering instruction but guidance to the practitioner in what might otherwise prove an hour of great trial.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 16, 1882.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

EXCISION OF CHANCRE AS A MEANS OF ABORTING SYPHILIS.

DR P. A. MORROW read a paper on the above subject in which the question was asked, Is it possible by excision of the initial lesion to destroy the syphilitic virus and so prevent infection of the general system? The author of the paper then presented the theories and practice of Bell, Hunter, and Ricord concerning the treatment of chancre, and stated that it had been an almost universal practice until a comparatively recent date to destroy the primary sore with caustics as soon as it was recognized. In 1877 Auspitz first excised the initial lesion, and since that date this method of treatment had been practised by numerous surgeons and with apparent success in quite a number of cases. In Germany the current opinion was largely in its favor. In France it had by no means received the same approval. In England the operation had been practically ignored. In this country excision had not been extensively practised, and the general sentiment seemed to have been averse to its adoption as a means of cure.

Dr. Morrow then gave a *résumé* of the claims of the partisans of excision, and described the manner of performing the operation. The method consists in lifting the indurated mass and, with a knife, making a clean incision through the healthy tissue immediately surrounding it. The loss of tissue was rarely followed by unfavorable results, such as cicatrix, deformity, etc. Subsequent induration in the cicatrix might require a secondary excision. The claims for the method had been that it prevented the development of syphilis, or that the virus was attenuated by the procedure, and even if its abortive effects were negative, it was to be recommended as a local adjuvant, thereby converting what might prove to be a troublesome ulcer, into a sore which frequently healed by first intention. Secondary adenitis had not been regarded as a contra-indication to excision, and when performed in time the claim had been that it prevented the appearance of the secondary symptoms of the disease.

Of course, if the local lesion be evidence of a constitutional affection it was impossible to arrest or modify the effect of the general disorder by excision or other methods of treating it.

The author of the paper then presented an outline of the ordinary evolution of syphilis. The first appreciable phenomenon was always manifested at the point of infection, and after the lapse of a certain period of time an eruption of secondary symptoms took place, etc. Here the question arose, At what

particular time does the generalization of the virus occur? And the views entertained concerning the nature of the chancre were given; that is, whether it was a purely local lesion or the manifestation of a general disease. The conclusion reached was that the teachings of analogy and the deductions from experiments were opposed to the theory that the chancre is a purely local affection.

Turning to the clinical aspect of the question, reference was again made to the views and practice of Bell, Hunter, and Ricord, and the teachings generally in the French and German schools. Under this head were studied inoculation experiments which had been performed, and also some of the sources of error, in forming an estimate of the value of excision were pointed out, such as the fact that all syphilographers recognized the impossibility of determining positively the exact nature of a suspicious sore until induration had developed, and also that medical literature was full of cases in which the most energetic treatment practised early had failed to prevent or retard constitutional symptoms.

Dr. Morrow believed it to be the opinion of most syphilographers that destructive cauterization of the primary lesion was absolutely useless as an abortive measure. Even Ricord had been converted to the belief that cauterization or excision was inert as a prophylactic measure.

With reference to excision and its results, he had collected the records of 222 cases, of which 60 had been reported as successes; by success meaning the non-appearance of secondary manifestations of syphilis within a period varying in length from four months to four years.

Criticisms upon the report of the sixty successful cases were then made. A certain number had been reported by unicists, and were open to the objection that the sore excised was not chancre, the initial lesion of syphilis. Some cases, also, had been reported as successes where the operation had been performed before the time had arrived at which it was possible to determine exactly the character of the lesion.

The conclusions reached by the author of the paper were substantially as follows:

First.—That the facts of clinical experience, as well as the deductions from analogy and experiments, were opposed to the theory of the local nature of chancre upon which the practice of excision was based.

Second.—That the practice of excision of chancre as a means of aborting syphilis was condemned by the results of clinical observation.

Third.—That the sources of error in recorded successes were comprehended under doubtful diagnosis, and insufficient observation.

Fourth.—That in cases where secondary accidents failed to appear after excision there was no positive evidence that the result was due to an abortive influence of the operation.

Fifth.—That there was no evidence that excision of chancre attenuated the syphilitic virus or modified the general symptoms of the disease.

Sixth.—That it could not be recommended as a local adjuvant, because it was opposed to the principles of sound conservative surgery.

[The paper will be published in the December number of the *Journal of Cutaneous and Venereal Diseases.*]

The paper being before the Academy for discussion, Dr. E. L. Keyes expressed his entire assent to the conclusions reached by Dr. Morrow concerning excision of the chancre.

With reference to the physical peculiarities of the chancre, he believed that it might be of the most malignant character possible, and yet have no induration.

With regard to malignancy, he thought that the syphilis of the present day was not nearly so severe as the disease described under that name as far back as the fifteenth century. Syphilis, as he saw it in patients in this city, was a comparatively mild affection. Certain forms of treatment afforded a greater guaranty than others that the patient would recover completely; but it was an indisputable fact that persons suffering from the malady did not uniformly die of the disease, as was at one time supposed to be the inevitable result. A person might have syphilis and the disease progress with the greatest possible mildness. It was the uncertainty and the irregularity of the phenomena of the affection that constituted the chief charm in its study. He had not had any personal practice in excision of the primary lesion.

Dr. E. B. Bronson concurred with the conclusions reached by Dr. Morrow. He had performed excision of chancre a sufficient number of times to satisfy himself that the operation was feasible, and, in the cases in which he had operated, induration of the glands did not develop. Whether or not syphilis developed he was unable to ascertain, because the patients were dispensary patients who soon passed from under observation.

Dr. G. H. Fox accepted the general conclusions reached by the author of the paper. He had performed the operation in only two cases; in one no symptoms of syphilis followed, in the other evidence of syphilis did follow, although the disease seemed to pursue a milder course than the average.

He was inclined to believe that chancre was a local lesion and theoretically its complete removal should prevent general infection. Practically, however, the theory failed, and therefore it could not be recommended as a measure of treatment for the prevention of syphilitic infection. The impossibility of making a positive diagnosis of chancre in every case was perhaps the most important source of error, and that being the case it would be impossible to determine that excision had a beneficial effect or any effect whatever in preventing the development of syphilis. He believed, with Dr. Keyes, that syphilis in this city was usually a mild affection. He was also inclined to think that the reports of cases observed in the fifteenth century were those of selected cases, as naturally the physicians of those days selected cases which presented the most striking features. Although its ravages could not be overestimated, it should not, at the same time, be overlooked that many persons who contracted syphilis recovered even without any treatment and lived to a good old age.

Dr. F. R. Sturgis supplemented Dr. Morrow's criticism upon cases of excision which had been reported as successes, by referring to several in which it had been stated that adenitis was absent at the time of the operation and no subsequent symptoms made their appearance. The absence of adenitis he thought would throw suspicion upon the character of the sore in those cases. In addition there were certain cases, reported as failures, in which it was said that adenitis was present.

Still further, in examining the French and German cases, it would be found that in the former adenitis

was present, and in not a single one had success been obtained. That fact would lead to the inference that there was some error in the German statistics. To strengthen the inference it was stated that Auspitz did not distinguish between a simple ulcer and the chancre the accepted initial lesion of syphilis. Dr. Sturgis regarded induration of the lymphatic glands as an important factor in deciding as to the character of the sore, and believed that when absent the diagnosis of initial lesion of syphilis was vitiated. He heartily concurred in the conclusions reached by the author of the paper.

Dr. L. D. Buckley theoretically and practically accepted the conclusion reached by Dr. Morrow. He had performed excision of chancre in one case, and the operation was followed by severe syphilis. If, however, the wound healed without complication, he thought the surgeon might be justified in resorting to it for the purpose of preventing bad cases of chancroid.

Dr. R. W. Taylor agreed with Dr. Keyes concerning the benignity of syphilis. With a tolerably good constitution, a docile patient, and an intelligent doctor, syphilis could easily be robbed of all its terrors.

He also believed that there were cases in which conservative surgery would recognize the justifiableness of excision of chancre. For example, a chancre existed upon the end of the prepuce and produced phimosis, there were two procedures offered, one was excision and the other the internal administration of mercury. The first finished the matter at a stroke, decorated the organ, and avoided by circumcision unpleasant results. The other permitted delay, and the cases did not do so well as those in which the mercurial treatment was begun at the evolution of the secondary lesions. He believed therefore, that in certain cases conservative surgery would be advanced by excision.

He had resorted to excision in fifteen cases of ordinary hard chancre, and in none was syphilis aborted. In a few cases, however, the operation was followed by an apparent attenuation of the virus; that is, the secondary manifestations were postponed until the seventy-sixth, seventy-ninth, and eightieth day. Dr. Taylor then cited one case in which there was a little excoriated papule not larger than four times the size of the head of an ordinary pin. It was deep red and slightly elevated. The man had sexual connection twenty days previously. The woman was examined, and close by the fourchette an excoriation, not a mucous patch, was found, and upon her body was a declining roseola. He told the patient that his pimple was probably the initial lesion of syphilis. Excision was practised as follows: First the penis was washed with carbolized water. Then he cauterized the sore with carbolic acid and dusted the top of it with calomel. Next he transfixed the papule with needles, lifted it up and cut away the tissue to the distance of one-fourth of an inch all around. The wound was left open and it healed kindly within ten days. The patient went on without enlargement of the inguinal glands, and at the end of forty-five days a distinct syphilitic roseola developed, which was followed by other evidences of the disease. At this point Dr. Taylor said he was willing to go upon the record as believing that syphilis is not always attended early by enlargement of the inguinal ganglia. He claimed for the operation of excision that it was a failure as a prophylactic against syphilis, but as a cure for chancre it was sometimes beneficial.

Dr. F. N. Otis believed that in order to form an intelligent opinion with reference to the desirability of excising the initial lesion of syphilis, we should first inquire concerning the real nature of the true chancre, and the manner in which systemic infection takes place. He believed there was sufficient authority to warrant the statement that the beginning of syphilis was in an infecting cell which did not differ in appearance from the ordinary white-blood corpuscle; that syphilis was a process of proliferation; and that it might go through its entire course without open lesion of any kind. That there must be a point of abrasion for the introduction of the virus was well understood, but that such abrasion would heal as if no inoculation had taken place was well proven. Competent observers had determined by microscopical examination that there was an accumulation of cells first at the point of inoculation; that these cells gradually moved along in the lymphatics, and after a period varying from four to six weeks the general manifestation of syphilis announced themselves in a roseola. Up to that time there might be nothing to show that the patient had been diseased. There was, then, unquestionable evidence that the disease had been local. He would therefore say that it might be considered reasonable to remove as many of these cells which possessed an infecting property as possible, and so far as his experience went, wherever the initial lesion was situated so that it could be removed without incision into the glans or the body of the penis, excision should be performed, but he would never substitute the operation or expect it to take the place of legitimate subsequent treatment. Practically he had performed the operation in at least fifteen cases, and the result had been that great benefit had accrued as a matter of personal convenience to the persons affected. According to his experience, removal of the requisite amount of tissue had not been followed by any deformity, and as a rule it had been difficult to determine where the tissue had been removed when examination had been made some time afterward. It had seemed to him that in the cases operated upon, the disease had been milder in its manifestation than in those where excision had not been adopted. That there were yet sufficiently severe cases of syphilis, he thought could be satisfactorily demonstrated to any one who would visit the venereal wards in Charity Hospital.

Dr. Morrow, in closing the discussion, said that if by the term benignity of syphilis, it was meant that there were benign cases of syphilis he consented, but if it was meant to be understood that syphilis was a benign disease he dissented. He would ask Dr. Keyes if syphilis, according to his observation, had been shorn of its malignancy with regard to heredity.

Dr. Keyes said he wished to be understood as saying that syphilis, as he saw it, was comparatively benign, although he had seen no evidence that its hereditary effects had been especially influenced.

The Academy then adjourned.

SECTION IN OBSTETRICS.

Stated Meeting, October 21, 1882.

Dr. H. E. Crampton, Chairman.

Dr. J. Lewis Smith reported a case of

PERNICIOUS REMITTENT FEVER AFTER PARTURITION.

The patient was a primipara, aged twenty, of a strongly marked nervous temperament. Her labor was prolonged to forty hours, and finally, when the

head of the infant nearly pressed on the perineum, was easily terminated by the short forceps with very little injury. Dr. Smith, appreciating the fact that there was inertia of the uterus, now administered ergot, which, however, was vomited. The patient's general condition was good, but the pulse, which had fair volume, was accelerated. After uterine contraction was secured by kneading, and while waiting for the expulsion of the secundines, with one hand compressing the abdomen, and the other lying within the vagina, so as to detect any undue hemorrhage, which might occur, and while the placental mass was felt pressing upon the fingers, the patient, without a moment's warning, ceased breathing, her head dropped upon the chest, and her hands and fingers were strongly flexed. The placenta was fully detached by lateral movements with the fingers, and immediately removed. It was afterward examined by Dr. Smith and the patient's mother, and found to be unbroken. The epileptiform attack lasted only about one-fourth of a minute, when she immediately and fully recovered her consciousness, and was talkative and cheerful, on account of the favorable termination of her long labor.

On the following day, May 23d, no unusual symptoms were observed, except that the pulse was constantly above 100. The flow was normal, and there was the prospect of a good recovery. During the night of May 23d the patient did not rest well, and the flow of pure fresh blood was so abundant that Dr. Smith was sent for early on the following morning. When he arrived the patient had vomited, and at same time had expelled a mass of fresh-looking clots as large as a goose-egg. To the fact of a free flow of blood at this time, which must have washed out the uterine cavity, the doctor attached much importance in the way of diagnosis, for within eight hours of the time of this flow the symptoms were unquestionably present of the disease of which the patient perished.

At 2 P.M. on May 24th, a rigor occurred, accompanied by some headache, and followed by a moderate febrile movement. On the 25th, the patient was comfortable, but somewhat feverish. On the 26th, the second chill occurred, and from this time a chill followed by fever and perspiration took place each day, with remissions, but not an apyrexia, unless on one occasion, after free perspiration, when the thermometer, in the axilla, registered the normal heat. During the remissions the temperature was usually about 100° to 101½° F.; in the exacerbations during the first week the temperature did not rise above 103½° F., but toward the close of life it reached 104°, 105° F., and finally 107° F. The febrile movements were more and more protracted, remaining so long in the last days that it seemed as if the disease would have assumed the type of a continued fever had the patient lived longer. In the last days the perspiration occurring in the remissions of the fever, was more profuse than at first, drenching the underdress and the pillow, and so cooling the surface that while in the hot stage cloths wrung out of ice-water were freely applied to the face, head, and arms to allay the pungent heat, the surface now became so cool, that after the limbs were wiped dry, warm applications were plainly indicated. Professors Lusk, Barker, Otis, and Metcalf attended the case in consultation, and these gentlemen could detect nothing wrong in the uterine system. Professor Barker saw the patient but once, on the eve of his departure for Europe, but the others made several visits, and concurred in the diagnosis of pernicious remittent fever.

Thirty, and afterward sixty, grains of quinine were administered daily. The sulphate was given by the mouth, the bisulphate per rectum, and the bimuriate of quinia and urea hypodermically, seven to ten grains at a time, and yet day by day the paroxysms became more severe, and the febrile movement more intense and protracted. On the seventeenth day muguet appeared over the faucial surface, a sure forerunner of death, and on the eighteenth day death occurred in a state of exhaustion. The patient in the last week had become considerably emaciated. Two weeks after the death of the patient, the wet-nurse, who had been previously healthy, never having had any symptoms of malarial disease, and who almost constantly, night and day, occupied the same floor with the patient, contracted a tertian intermittent fever, which was allowed to continue a week, until the fourth paroxysm, when the appropriate remedies were employed. An autopsy was not permitted.

The only doubt as to diagnosis was obviously whether the patient had septic or malarial poisoning. That it was the latter was believed for the following reasons:

First.—The complete removal of the placental mass, the normal lochial discharge, the normal condition of the uterine system from beginning to end, so far as could be ascertained, and the free flow of blood, or hemorrhage, as mentioned above, so that the doctor was sent for to arrest it, and which must have thoroughly washed out the uterine cavity eight hours before the disease of which the patient died began. This flow, and the expulsion of fresh looking clots, which occurred at the same time, could have removed the conditions for septic poisoning, had they been present in the uterine cavity.

Second.—The occurrence of a malarial disease on the same floor where the patient resided. The conditions of malarial poisoning were certainly present, while those of septic poisoning were probably absent.

Third.—The symptoms resembled very closely those in reported cases of pernicious remittent fever, and of the so-called typho-malarial fever, in which quinine, though largely administered, fails to arrest the malady. Dr. Smith quoted authorities and cases to show that the malarial disease is apt to be severe in parturient women, assuming the pernicious type, and expressed the belief that the remark made by Trousseau in reference to Paris applied also to New York. Trousseau, in his remarks on pernicious intermittent fever, states that this malady, rare in Paris, has become more frequent by excavations and disturbances of the surface of the earth (*les mouvements de terrains*).

DR. C. A. LEALE then reported several cases of marked malarial poisoning traceable to excavating for building purposes and the upturning of saturated soil. He also referred to cases in which it seemed established that the serious sickness was due to exposure to emanations from human excreta and sewer pollutions.

These communications were discussed at some length and several cases were cited that illustrated different phases of malarial poisoning, and the opinion was expressed that, in absence of post-mortem examination, the diagnosis of septicæmia in Dr. Smith's case had many points in the clinical history in its favor.

The Section then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 25, 1882.

DR. G. L. PEABODY, VICE-PRESIDENT, IN THE CHAIR.

POPLITEAL ANEURISM — LIGATION OF THE FEMORAL ARTERY.

DR. J. W. HOWE presented a patient with the following history: James L——, aged fifty, engineer, admitted July 8, 1882. Previous history: Has always enjoyed good health; has had gonorrhœa and chancroid; has always freely indulged in stimulants. About three years ago he noticed a swelling in right popliteal space which increased gradually, but caused him no pain or inconvenience until about one year ago, when he felt pain on movement, and found that his right leg was getting weak. The tumor increased in size up to the time of his admission. On examination a tumor filling the popliteal space was found. It had a heaving pulsation, with a double bruit, and a marked thrill was communicated on palpation. The femoral artery was found dilated and all the arteries showed evidences of marked atheromatous changes.

The patient was treated by Tufnell's method, and diet restricted to meat only and small amount of liquids. The medical treatment consisted of the administration of kali iodidi, 20 gr. t. i. d. During the first month in the hospital the pain became less and the œdema of leg was reduced—foot and leg became somewhat warmer.

About August 10, 1882, the tumor began to increase in size and œdema and pain returned. The pain was so great that Magendie's solution of morphia had to be used constantly. A change was made from pressure by tourniquet to that of a lever, to the long arm of which a weight of six pounds was attached. The pressure was kept up for a week and then was discontinued, as the integument at the point of pressure began to slough. The tumor had now increased to twenty-five inches in circumference, and at one point the integument was very red and œdematous. On September 4, 1882, the femoral artery was tied in Scarpa's triangle, with catgut ligature; wound sewed up and drainage-tube inserted. The limb was enveloped in cotton and the wound dressed with carbolized oil. At no time had there been any change in color of the limb, and only a slight coldness of the toes was noticed. Œdema of the foot and leg rapidly diminished; tumor became gradually smaller and firmer. Wound healed rapidly except over the site of the ligature, where there was a small sinus, from which a few drops of pus could be pressed. The circulation in leg was perfect, the leg was very weak and the patient was compelled to use crutches. Circumference of leg at the site of tumor, on the day of the patient's discharge, was seventeen inches.

MULTIPLE FIBROMA OF THE UTERUS.

DR. BOZEMAN presented the uterus and its appendages, together with the vagina and rectum, removed from the body of a woman from whom the fibro-myoma was discharged which he presented at the stated meeting September 20th. At the time he presented the first specimen the patient was doing well. She continued to progress favorably for two or three days, when evidences of pelvic abscess developed, and on October 1st rupture occurred into the vagina with the discharge of a large quantity of offensive pus. Her temperature immediately fell from 104° to 100° F. The patient then progressed favorably until October 7th, when she was seized with general peritonitis, which, under the ordinary treatment, terminated, but with the reappearance of the discharge into the vagina. From that date the case progressed favorably until October 19th, when the patient began to vomit greenish fluid, and on the 20th she became markedly prostrated, suffered from extreme dyspnœa, with great rapidity of the pulse, and on the following day she died. The specimen exhibited the three varieties of fibroma—the submucous, the intramural, and the subperitoneal. Another interesting feature in the specimen was the fact that Douglas's pouch extended about an inch and a half below the cervix. The anterior wall of the vagina became very much thickened during the time of the occurrence of the disease, and gave rise to an immense cavity, which could be recognized distinctly during life with the finger introduced into the rectum, although its exact explanation was not made out until the post-mortem examination was made.

COLLOID CYSTOMA OF THE OVARIES WITH THE TRANSFORMATION OF THE OMENTUM INTO A SIMILAR COLLOID TUMOR.

DR. BOZEMAN also presented specimens accompanied by the following history: They were removed from the body of a woman, aged thirty-five, the mother of one child, two years old, who was operated upon at the Woman's Hospital, October 1, 1882. She had always been in good health up to last February, when she got her feet wet and took cold. About the beginning of April she first noticed an enlargement in the left side of the abdomen. After the first of July the increase in size was rapid, and soon the enlargement was symmetrical upon both sides. Then began a loss of flesh about the face, arms, and chest, which continued up to the time of his first examination, made October 10, 1882, when he detected distinct fluctuation throughout nearly the entire mass. A solid substance was noticed in the epigastric region, which was thought to be in the wall of the cyst. The uterus was slightly retroverted, turned toward the right, movable, and measured three inches. There was flatness on percussion over the lumbar region to the left of the spine, pointing to the left ovary as the seat of the enlargement. The girth of the abdomen was forty inches. The diagnosis was multilocular ovarian cyst. When the abdomen was opened it was found that the tumor was extensively adherent, but the adhesions were broken up without difficulty, the pedicle of one large tumor reached, a ligature applied in the usual manner, and the mass removed. The second tumor was then brought into view, also filled with colloid material. The entire omentum had undergone the same colloid degeneration, and it was removed. The weight of the ovaries and the omentum was twenty-seven pounds. The right kidney was also involved, especially the suprarenal capsule. In front of the right kidney there was a patch of this peculiar cystic degeneration seen in the mass of the omentum. The removal of the kidney was deferred for the present. Up to the fifth day after the operation the progress of the case had been most favorable. As soon as the patient came from under the influence of the anæsthetic the supporting plan of treatment was begun, consisting in rectal alimentation and the administration of quinine and opium. The specimen was accompanied by the following report, made by Dr. W. H. Welch, Pathologist at the Woman's Hospital:

There are two tumors of similar structure, one growing from each ovary, and one much larger than the other. With each is connected a small piece of the abdominal extremity of the Fallopian tube by means of a distinct meso-salpynx. The tumors are multilocular cystomata; the walls of the cysts are thin. The cysts are filled with extremely thick colloid material. The cysts are all lined by columnar epithelium, both granular and in the form of goblet-cells.

The omentum is converted into a large thick mass, preserving more or less the form of the original omentum, but consisting of myriads of cysts, mostly minute, some as large as a pea or walnut, each filled with the same colloid material as that present in the ovarian tumors, and each lined by cylindrical epithelium of the same character as that met with in the ovarian cysts. On section tubes lined with cylindrical epithelium, extending from the cysts into the adipose tissue of the omentum, can be seen. It is doubtless by the growth of the tubules, and by their dilatation, that the cysts are formed. There is no doubt, therefore, that the omental tumor is a proliferous cystoma, in all respects like that growing from the ovaries.

DR. FERGUSON presented specimens as follows:

PERSISTENT FRONTAL SUTURE.

Male, aged nineteen; Italian; sailor. Cause of death, multiple fractures. In the median line of the frontal bone there was a suture which divided the frontal bone into halves. The other cranial sutures were abnormally loose. The skeleton in other respects was well developed.

ARTHRITIS DEFORMANS.

The right hip-joint was involved in the diseased process. The preparation was obtained from a male, aged forty-nine; German; hotel-keeper. Cause of death, tuberculosis. The head of the femur was elongated, rough, not covered in the recent state by cartilage, and fitting into the acetabulum, which was much widened and deepened. The inner surface of acetabulum was rough, not covered by cartilage, two and three-fourth inches in depth, and two inches in diameter. There was no motion in the joint. The brim of the acetabulum and the neck of the femur were surrounded by ridges of osteophytes.

The scapula and humerus, from the body of a male, aged sixty; United States; coachman. Cause of death, tuberculosis. He gave a history of rheumatism in the early part of his life, but never had any severe attack, confining him to bed. After he grew up he remained quite free from sickness of any kind until his symptoms of tuberculosis developed. The shaft of the right humerus was shortened, and its head was almost entirely absorbed; it was concave and polished. The glenoid cavity was changed; its brim was rolled out, forming a lip-like projection which surrounded the neck of the bone. The head of the scapula was slightly convex, and polished from contact with the head of the humerus.

FRACTURE OF THE CLAVICLE.

There was an old fracture of the inner third of the clavicle, the fragments being held together by bands of fibrous tissue. At the seat of fracture there were several smaller fragments which were separated and surrounded by bundles of white fibrous tissue. This, in the recent state, formed a tumor two inches by one and a half inches in diameter. There were ridges of osteophytes surrounding the fractured end of each fragment. There was no history of the case.

PAPILLOMATOUS TUMORS OF THE LARYNX.

DR. ELSBERG presented two specimens of tumors of the larynx, accompanied by the following histories:

In the first case the tumor occupied the anterior commissure, and was so extensive that the chink of the glottis was very narrow and was transverse. It was removed from a boy eight years of age. The patient had been seen by Dr. Mackenzie, of London. The boy wore a tracheotomy tube, which was inserted in January last. There was absolute aphonia. The growth was papillomatous in character.

The second specimen was removed from a young man who had formerly been under the care of Dr. L—— of Milan. It occupied about the centre of the left vocal band, at which point there was a spindle-shaped elevation, and from the centre of this there arose a small stem, which was surmounted by a little button-like mass, giving the whole growth the appearance of a mushroom. It was in the posterior commissure of the larynx. There was hoarseness in this case, but not loss of voice. In both instances the growths were removed by means of the intra-laryngeal forceps.

VESICAL CALCULUS.

DR. J. W. HOWE presented a vesical calculus weighing 3,541 grains, which he removed from the bladder of a boy, sixteen years of age. There was a history of vesical trouble existing for seven years. He attempted to remove the stone by the median operation, but finding it too large to remove in that way he attempted to crush it, but failing to accomplish this he then performed the supra-pubic operation. The vesical walls were thick and contracted, and at one point they were slightly adherent to the calculus. Quite a quantity of urine flowed from the bladder when it was entered from the perineum. At the present time the patient was doing very well.

PAPILLOMA OF THE UVULA.

DR. L. E. HOLT presented a tumor which he had removed from the uvula of a patient fifteen years of age. It had existed two years, was painless, but gave rise to a constant desire to remove some foreign body from the throat. There was no history of injury, and the patient was free from any exciting disease. The mother was suffering from probable cancer of the omentum. The specimen had been examined by Dr. W. H. Welch, who pronounced it to be a papilloma. The tumor was removed by the forceps and scissors.

THE RATIONAL SYMPTOMS OF ORGANIC CARDIAC DISEASE WITHOUT VALVULAR MURMURS.

DR. B. ROBINSON presented a heart removed from the body of a patient who entered Charity Hospital. On admission there were present all the rational symptoms of organic cardiac disease, such as general anasarca, more or less serous effusion into the abdominal and pleuritic cavities, etc. Physical examination failed to detect any valvular murmur. The patient died two days after admission, and at the autopsy a double lesion was found in the left ventricle. There was some stenosis at the mitral orifice, the valves were extremely thickened, and probably permitted regurgitation during systole. The aortic orifice was decidedly smaller than it should have been, the cusps of the valves were

thickened and indurated, and doubtless permitted of regurgitation. The left ventricle was somewhat hypertrophied. The special point of interest in the specimen and the clinical history of the case was the existence of the rational symptoms of advanced cardiac disease without the existence of valvular murmurs, and at the autopsy such conditions were found as rendered it almost certain that regurgitation both at the mitral and aortic orifices had occurred. In this case the heart-beats were sufficiently forcible to give rise to murmurs, but no murmurs were detected.

CHEESY DEGENERATION OF THE KIDNEYS.

Dr. Robinson also presented a kidney removed from the body of a patient who had died from advanced catarrhal phthisis. There were large cavities in the lungs, and there was cheesy degeneration of the left kidney. In some places there were almost a semi-liquefaction of the cheesy masses.

ATROPHY OF THE KIDNEY.

Dr. Robinson also presented two kidneys in the advanced stage of cirrhotic change. The right weighed two ounces, the left four ounces. Both kidneys exhibited the atrophic change, particularly in the cortical substance. No albumen was detected in the urine before death, nor was it found in the urine which was removed from the bladder at the autopsy. These specimens also illustrated the clinical fact that the kidneys may be far advanced in atrophic change without albumen being present in the urine.

Dr. Van Santvoord referred to a case in which the only active tubercular process consisted in a peritonitis which took rise from a caseous spot in the kidney.

CEREBRO-SPINAL MENINGITIS.

Dr. J. Lewis Smith presented the spinal cord removed from the body of an infant ten weeks old, which was first brought to the service of Dr. H. D. Chapin, at the out-door department at Bellevue Hospital, when about one month old. It was an eighth month child, but was well developed at birth. When it was two weeks and four days old red blotches appeared upon the buttocks quickly followed by all the usual signs of infantile syphilis. Snuffles appeared when it was one month old. When it was nearly two months old the syphilitic eruption had nearly disappeared under specific treatment, and the child seemed in a fair way to recover. On October 11th it began to vomit, and the vomiting was projectile in character, its bowels were somewhat constipated and from that time until its death, eight days later, it had the characteristic symptoms of cerebro-spinal meningitis: head retracted, clenched fingers, thumb bent over the hand, etc. Temperature 102° F., head not hot, anterior fontanelle not at all prominent. Eyes not attracted by a lighted match; no rash and no apparent sensitiveness of the skin. The child died in convulsions October 19, 1882. The diagnosis was between the sudden development of syphilitic affection of the spinal axis and cerebro-spinal meningitis.

At the autopsy, made by Dr. Chapin, the spinal cord for its entire length was found encased with a pseudo-membrane, with the exception of about half an inch upon the anterior aspect. The exudation, as was the rule, was thickest upon the posterior surface. The cauda equina was also covered with exudation. There were patches of thick exudation upon the under surface of the brain and along the fissures of Sylvius. There was abundance of serum in the ventricles, a fact which was interesting especially in connection with the absence of elevation of the fontanelles. The vertex of the brain appeared to be normal; all the other organs were healthy. It seemed to Dr. Smith that cerebro-spinal meningitis had almost become endemic in this city.

Dr. Amidon believed that the existence of fever would exclude syphilitic disease of the central nervous system.

EXSECTION OF THE CARPUS AND METACARPUS—AMPUTATION OF THE HAND.

Dr. Wyeth presented the carpus and metacarpus removed from a boy fifteen years of age who had a tubercular diathesis. He also suffered from necrosis of the fifth rib which also gave rise to abscess. The left wrist was the one involved, and at the time he first saw the patient last May it was greatly swollen. At that time the question was whether the hand should be amputated or whether an exsection should be performed. After consultation exsection was performed, and the carpus and the posterior portion of the metacarpus were removed. The result of the operation was unfavorable, and amputation was performed two months afterward by Dr. Gerster, after which the patient made a good recovery.

PRIMARY CANCER OF THE BLADDER.

Dr. G. L. Peabody presented a specimen with the following history: N. H——, fifty-seven years of age, a Swede; married, and a hatter, was admitted to the New York Hospital September 16, 1882. He said that twenty-five years ago, he was afflicted in a manner similar to that which at present caused him to seek admission to the hospital, but that the condition passed away, and had left him in comparative health until recently. Ten months ago he began to be troubled with difficult, scanty, and frequent micturition. His urine has been high-colored, and looked to him as if it might contain blood. Recently he had had swelling of the legs and gastric disturbance (anorexia with occasional nausea and vomiting). He has felt feverish, but had had no headache or visual difficulties. He had had slight dyspnœa, but no cough or other signs of pulmonary trouble. Lately his urinary troubles had abated somewhat, though micturition was still painful, especially at the end of the act. He gives a history of syphilis, but denied gonorrhœa.

On admission, at 2.30 P.M., his temperature was 101.1° F.; respiration, 20; pulse, 86. He was well nourished. There was some œdema in the feet and ankles. The circulation in the skin was fair. The heart's action was regular, and there was no murmur. He was given a mixture of acetate and citrate of potash with digitalis.

The day after admission his pulse, respiration, and temperature were normal. Examination of his urine revealed these facts: specific gravity 1,002, reaction acid, contains albumen and pus, but no casts.

He continued to suffer a good deal in urination, especially at the end of the act, and the character of his urine soon changed, it becoming strongly alkaline. A steel sound, No. 26, was passed into the bladder with difficulty, and subsequently his bladder was washed out daily with a solution of borax in water. The prescription above mentioned was soon discontinued and he was given infusion buchu *ad libitum*.

September 27th.—The operation of washing out

the bladder caused great pain, and the residual urine removed was intensely fetid and loaded with mucus, pus, and desquamated epithelium. It was strongly ammoniacal.

September 29th.—Bladder was still washed out. The patient now complained of pain in the chest, but his condition was not otherwise changed.

September 30th.—This afternoon the patient's symptoms suddenly became aggravated. He had a sudden and profuse pulmonary hemorrhage which severely prostrated him. The usual treatment was resorted to, and in spite of active stimulation, etc., he sank steadily, and died at 2.30 A.M., on October 1st.

Autopsy eight hours after death. He omitted all notes that did not seem essential. The lungs were rather loosely bound to the chest-walls by old adhesions. Both of them were congested and œdematous. Near the apex of the right lung was a cavity large enough to hold three ounces of water. Water injected into the arterial branches leading into the upper lobe of right lung readily filled this cavity. It was surrounded by a thin wall of connective-tissue, which did not seem to contain any tubercles.

The kidneys were both hard and white; normal in size; capsules not adherent, surfaces smooth, markings obscure. Reaction to iodine well marked in them both.

Spleen, intestines, liver, peritoneum, and brain were normal.

The bladder contained a large, soft, fleshy mass, firmly attached to the mucous membrane. It was ovoid in shape, with a long diameter of three inches and a short diameter of one and one-half inch. It was situated just behind the position of the trigonum, and there was more of the mass on the left of the median line than there was on the right. It was attached by a broad base, over part of which the wall of the bladder was destroyed. The growth surrounded the entrance of the left ureter into the bladder and extended half an inch into the ureter, partly occluding it. The urine from the left kidney must therefore have trickled through this mass of morbid growth. The occlusion was only partial, and the dilatation resulting was but slight.

The microscopic examination of the mass showed it to be an epithelioma. It had large branching spaces surrounded by a stroma of newly formed connective-tissue and filled by masses of flat and cuboidal epithelial cells. The stroma was but slight in amount. It contained blood-vessels of large size.

A microscopic section of the growth was exhibited.

The condition was a rare one. Secondary cancer of the bladder was not uncommon, especially among women. By reference to Mr. Stein's very interesting work upon tumors of the bladder, published last year, Dr. Peabody found the statement that in 4,777 autopsies made at the Charité, in Berlin, only 7 cases of primary cancer of the bladder were recorded.

Dr. Peabody also reported a case of

CONGENITAL ABSENCE OF THE RIGHT KIDNEY,

with the following history: Philip S——, sixty-one years of age; born in Germany; married, and a brush-maker, was admitted to the New York Hospital suffering from retention of urine due to traumatic stricture caused by a fall that injured his perineum thirty years ago. His general condition was bad. He was operated upon September 21, 1882, but did not do well, although he passed daily about twenty ounces of urine through the opening then made. The urine was acid, had a specific gravity of 1.026, contained albumen, pus, and vesical epithelium. The patient died five days after the operation.

At the autopsy it was discovered that the body contained only one kidney. It was about double the usual size. The capsule was not adherent, the surface was smooth, the markings were indistinct, and the pelvis was lined by a thick phosphatic deposit, part of which still remains adherent. This kidney was situated in the usual position of the left kidney, and did not appear to have resulted from a fusion of the two organs, but simply to be in a condition of hyperplasia. There was no trace of a kidney on the right side, nor was there a ureter on that side. This kidney was supplied with two renal arteries, both of which were short, and there was no renal artery on the other side of the body.

The testicles were normal. The renal plexus on the side of the missing kidney consisted of only a few filaments of the sympathetic without a ganglion. The renal ganglion on the other side was normal in size and position.

The suprarenal capsules were normal, both in size and in position, on the two sides.

The bladder was much hypertrophied. In places its mucous membrane was black and necrotic, and in others it was covered by a layer of phosphatic deposit.

He brought for inspection the kidney, the aorta, the bladder, and the penis. He also presented microscopic sections of the organ, which showed that the capsules of Bowman were somewhat thicker than normal, and in some places were seen aggregations of young cells, indicating an inflammatory condition of the interstitial tissue. As an interesting incident it might be mentioned that the sections had accidentally passed through a partly decolorized hemorrhagic infarction of small size, which contained many crystals of hæmatoidin.

Last year he had the opportunity of presenting a case of this kind occurring in a female, and giving certain other anomalous conditions. In connection with that case he looked up the literature of the subject.

[See report of proceedings of Pathological Society in New York MEDICAL RECORD for June 11, 1881.]

Since that time he had seen records of three similar cases in the New York MEDICAL RECORD for March 12, October 8, and November 18, 1881. In two of these cases the kidney was missing on the left side, in one on the right side.

Proneness to disease in the kidney in these cases was certainly remarkable.

DR. WYETH said, with reference to the vascular anomalies, that he placed in the Wood Museum four specimens of double and multiple renal artery. He thought the abnormality was not so very uncommon.

The Society then went into executive session.

VIBURNUM OPULUS IN DYSMENORRHŒA AND UTERINE PAIN. Dr. A. E. M. Purdy, in the *New York Medical Journal and Obstetrical Review*, reports several cases in which viburnum opulus was found very efficient against dysmenorrhœa and uterine pain. He gave the drug in doses of five grains of the abstract (powdered drug), which is equal to ten minims of the tincture. Previous observers (Hale and Meyer) had found this drug a powerful uterine sedative.

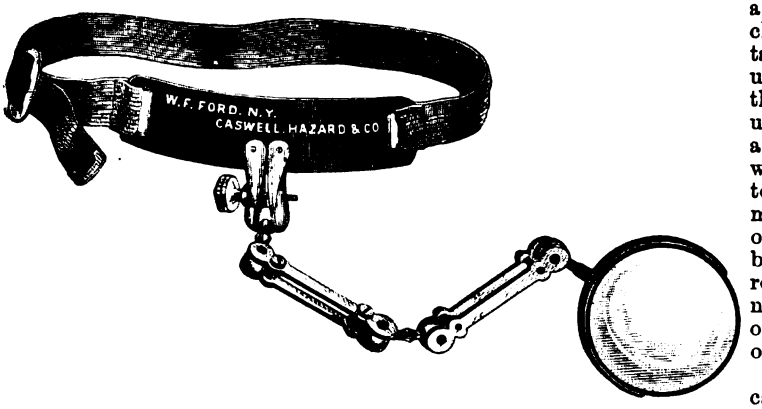
New Instruments.

AN IMPROVED MEANS OF OBLIQUE ILLUMINATION—A CORNEAL CONDENSER.

By E. G. LORING, M.D.,

NEW YORK.

Since the introduction of the elevated railroads the frequency with which foreign bodies are found impacted in the cornea has increased so much that hardly a day passes that the ophthalmic surgeon is not called upon to remove one or more of these painful and oftentimes dangerous particles. This may occur not only at any hour of the day, but of the night as well, and in this latter case it is extremely



difficult, if not impossible, for the surgeon, without the aid of an assistant to hold a condensing-lens, to accomplish his object. This difficulty has, it is true, been obviated in a great measure by an ingenious contrivance described by Dr. Noyes, which consists of a lens so mounted that it can be worn by means of a spring clamp on the end of the first finger on the left hand of the operator. The amount of movement, however, is small, while to chock the eye successfully with the index finger so encumbered, and at the same time keep the cornea illuminated, is a difficult operation and requires considerable practice and skill.

Mr. J. E. Adams, of London, described in the *Lancet*, February 7, 1880, a useful and ingenious little instrument, which consists of two lenses attached to a head-band, the plate of which is worn in the centre of the patient's forehead.

The modification of that idea consists, as shown in the drawing, of an arm, broken at the various points by ball-and-socket joints, so as to give a perfectly free adjustment to the lens in any direction, and at any distance up to the extreme length of the arm. This leaves both hands of the surgeon unencumbered, permits the use of fixation forceps if necessary, and does away with the necessity of an assistant to hold the lens.

The arm is attached to an elastic head-band precisely like the head-band of an aural or laryngoscopical mirror. When in use the band is slipped over the head of the patient in such a way that the hard rubber support comes at the temporal region and on the side of the eye to be illuminated, the lens then being swung into the position desired. By having the plate at the temporal region instead of in the centre of the forehead, as is Mr. Adams' instrument, and the lamp well at the side instead of directly in front, we get rid of annoying reflections of the lens in the cornea, and avoid the irritating effects of the light from a strong condensing lens thrown directly through the pupil upon patient's retina. If the lens is so arranged as to be a little within or a little without its focal length from the eye the section of the cone of light is large enough to keep the cornea covered, even if the eye makes considerable excursions, while as the lens is attached to the patient's head, this latter can be moved to a considerable degree without displacing the illumination from the eye. I have found it of great service in operating upon delicate membranes in the pupillary space, as it gives a much steadier illumination, and one which is more easily controlled than when an assistant holds the lens.

By removing the lens from the clip and supplying a mirror, the instrument, from the character of its joints and the mutability of its position, can then be used as a fixed ophthalmoscope for the upright image, and can thus be used in demonstrating the fundus to a class or in making a sketch of it without the observer being compelled to take up and lay aside the instrument at every look; or the upper half of the ordinary ophthalmoscope can be inserted instead of a simple mirror, and then any optical combination that the refraction of the observed eye may require can be obtained.

I have had a band made which carries two lenses, one on a shorter arm, which is then used as a magnifying lens, but the single one answers every purpose, and for ordinary occasions is the most convenient.

The instrument is also very useful in magnifying small hairs, thus rendering their detection and removal much easier, or in performing any operation at night or whenever the light is poor. When, however, the light is sufficient, and only an increased enlargement is desired, the surgeon, by wearing the band on his own forehead and extending the arm to its utmost, can obtain a large amount of magnifying power, while by slight movements of the head he can successively inspect and keep in front any portion of the anterior surface of the eye or lid.

The instrument can be obtained of W. F. Ford, New York, and A. Keune, New Haven R. R. Building, Franklin Street, New York.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from November 11, 1882, *to November* 18, 1882.

Gardner, Edwin F., Captain and Assistant Surgeon. Ordered to Fort Walla Walla for duty. S. O. 161, par. 3, Department of the Columbia, October 26, 1882.

Moore, John, Surgeon. The leave of absence granted by S. O. 145, C. S., Department of Colorado, extended one month. S. O. 175, par. 2, Military Division of the Pacific, November 3, 1882.

Owen, Wm. O., Jr., First Lieutenant and Assistant Surgeon. To proceed to Astoria, Oregon, and

report to First Lieutenant E. B. Rheem, Twenty-first Infantry, for duty with his command. S. O. 164, par. 5, Department of the Columbia, October 30, 1882.

REED, WALTER, Captain and Assistant Surgeon. Relieved from duty in the Department of the East, and assigned to duty in the Department of the Platte. S. O. 266, par. 4, A. G. O., November 14, 1882.

WILLIAMS, JOHN W., Major and Surgeon. Assigned to duty at Fort Cœur d'Alêne, Idaho. S. O. 161, par. 3, Department of the Columbia, October 26, 1882.

WYETH, M. C., First Lieutenant and Assistant Surgeon. To report to Fort Snelling, Minn., for temporary duty. S. O. 185, par. 3, Department of Dakota, November 9, 1882.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — **Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending November 18, 1882.**

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Nov. 11, 1882.	0	26	36	7	13	37	2	0
Nov. 18, 1882.	0	17	25	1	9	47	0	0

THE Lying-in Asylum (85 Marion Street) is in need of District Physicians for the lower part of the city. Applications can be made to Dr. Allen at the Asylum.

THE LATE DR. J. FOSTER JENKINS.—At a meeting of the New York Obstetrical Society, held November 7, 1882, the following report was made by the committee appointed to draft resolutions in regard to the death of Dr. J. Foster Jenkins:

We, the members of the New York Obstetrical Society, mourn with heartfelt grief the death of Dr. John Foster Jenkins, for sixteen years an honored fellow of the society.

With pleasure we recall the purity of his character and the sweetness of his life.

Highly cultivated, by nature a lover of books, and endowed with rare native ability, he represented the highest type of the scholarly physician.

Faithful in his attendance at the meetings of this society, and an active participant in its discussions, his loss from our ranks will be keenly felt, and his memory will ever be regarded by us with honor and affection.

Therefore be it *Resolved*, That we express our sympathy to his family in the time of their affliction, and convey to them our appreciation of his high personal worth, and of his generous and noble qualities.

WILLIAM T. LUSK, M.D.,
ROBERT WATTS, M.D.,
Committee.

On motion, the foregoing report was accepted, and a copy was ordered to be sent to the family of the deceased, to the *New York Medical Journal*, and to THE MEDICAL RECORD.

EX-SURGEON-GENERAL BARNES is reported to be quite recovered from the long sickness which followed his attendance upon President Garfield.

AN EPIDEMIC OF TRICHINOSIS occurred recently in Braunschweig. One hundred and ninety persons were made more or less seriously ill from eating raw pork.

DR. SAMUEL WHITE THAYER, of Burlington, Vt., recently died at his home. Dr. Thayer was born in Braintree, Vt., in 1817. He graduated at the Woodstock Medical College in 1838. He practised medicine successfully in Woodstock, Northfield, and finally in Burlington, to which place he moved in 1853. Dr. Thayer was one of the founders of the Medical College in Burlington, and was at first Professor of the Theory and Practice of Medicine in that institution. He subsequently held other chairs. He was Surgeon-General of Vermont during the war, and after the war was breveted captain. He organized the medical department of the Northern Pacific Railroad.

Dr. Thayer was a member of numerous medical societies, and was held in high esteem by his fellow members in the profession.

THE STATE CHARITIES AID ASSOCIATION AND INFANT MORTALITY.—At the recent annual meeting of the above Association the Standing Committee on Children reported that they had investigated the causes of infant mortality in the city during the hot months, and had found it to be largely due to the adulterated milk supplied to the poor.

It was suggested that there be established depots in the poorer quarters of the city, where good milk can be obtained.

There is already an organization, the New York Kitchen Diet, which might undertake some such plan as this.

THE PREVALENCE OF EXPLOSIVE KEROSENE OIL.—At the quarterly meeting of the State Board of Health, held November 18th, a report was made upon explosive oils. This showed that among one hundred and eighty-one samples of kerosene oil obtained and examined in different parts of the State, only eight came up to the required standard. There is plainly something wrong somewhere. The law is now uniform for all parts of the State except the city of New York. The charter of the city directs the Fire Commissioners to fix a standard which shall be used in testing oils. Michigan, Ohio, Illinois, Iowa, Missouri, and Tennessee, now have laws regulating explosive oils.

RIDES FOR INVALIDS.—A Boston Society engages itself in the work of providing free rides for invalids during the warm months. From last May to the present month, 1,343 persons were given rides. In addition, 1,400 car tickets, and 640 round tickets on the harbor steamers were distributed.

GANGRENE OR A BOIL.—It is known that the Hon. Thomas A. Hendricks has been reputedly suffering from senile gangrene. His life was despaired of, but he is said now to be recovering. The following not very probable story is going the rounds of the press: "On the very day, the tale runs, to which the medical prophets in attendance had limited his life, a blunt old granger—also a doctor, after a fashion—called to pay him a farewell visit. After a pathetic interview, the country practitioner thought he would take a look at the 'gangrene' which was about to terminate his illustrious friend's life. He did so; stared at it, open-mouthed, for a moment,

and then, with a derisive grunt, and an indignant, thumping oath, roared out: 'Nothing but a boil!' Sure enough, Mr. Hendricks was very soon rushing along the high road to recovery, and the able physicians who attended him are keeping moderately quiet."

PREPARATIONS OF ACONITE.—Dr. Squibb, in his *Ephemeris*, writes concerning the value of the different preparations of aconite and its alkaloid. He concludes that the fluid extract of the root is the best preparation for internal use. The dose is one minim, which may be given every three hours, or oftener if needed. For external use, he says, there is probably no form better or more convenient than an oleate of aconitia, made by dissolving two grains, or 130 milligrammes in 98 grains of oleic acid. A fluid ounce of oleic acid, weighing 412 grains, requires 8.25 grains of aconitia to make a 2 per cent. solution. Each minim of this oleate contains about $\frac{1}{50}$ of a grain, and this quantity applied locally and repeated according to circumstances, should be an efficient dosage, and should in a short time produce constitutional effects by its absorption. It should be applied to the surface by the cork of the vial, or by some non-absorbent, without friction, and about the head and face it needs no covering; great care must be taken that it does not get into the eye. In using it around the eyes this caution must never be forgotten. If applied under the clothing it should be covered with oiled silk or rubber tissue. Local neuralgias are much better reached by the dermic or epidermic method of treatment.

POISONING FROM RED STOCKINGS.—Dr. J. Woodland writes to the *Lancet* that, having had his attention directed to several cases of great irritation of the feet and legs, causing small pustules to arise and the skin to subsequently exfoliate, and suspicion being fastened upon red stockings which the patients wore, he carefully analyzed them. He found a tin salt which is used as a mordant in fixing the dye. He succeeded in obtaining as much as 22.3 grains of this metal in the form of the dioxide, and as each time the articles are washed the tin salt is rendered more easily soluble, the acid excretions from the feet attack the tin oxide, thus forming an irritating fluid.

NEW YORK'S MEDICAL COLLEGES.—The Philadelphia *Medical Times*, in an able and temperate criticism of ourselves, observes incidentally: "To be sure, a city which claims to be a medical metropolis, and yet has not a single first-class medical school within its wide domains, needs tergiversation sorely. With Harvard on the one side and the University of Pennsylvania upon the other, we wonder there is not pride enough in New York to start one school upon the higher plane. On second thought we cease this wonder, for New York did start one such school not long since, and maintained it just one year, when its stock of pride and conscience was exhausted."

Having the highest esteem for the *Times*, we regret to find that it has plagiarized us as above. We have on numerous occasions tried to excoriate the commercial institutions here which teach didactic medicine. Despite these, however, New York, we still insist, is a medical metropolis, because there are here 5,000 hospital beds, dispensaries that treat 200,000 patients yearly, and 2,000 medical students, with gentlemen who are thought competent to teach them.!

THE PROGRESS OF MEDICAL WOMEN.—The committee in charge of Blockley Hospital, says the Philadelphia *Medical Times*, recently compelled one of the attending physicians to resign for no other reason than to give his place to a woman physician.

AN AID IN PERCUSSION.—Dr. E. C. Huse, of Rockford, Ill., writes to the *Chicago Medical Journal and Examiner*: "If a couple of feet of small rubber tubing be attached to an ordinary 'finger-stall,' such as is found in most drug stores, and its tip, sewed to an elastic band, be pushed into the ear, the stalled finger will convey sounds, in percussion, where nicety is requisite, far better than the ordinary way. It is to percussion what the stethoscope is to auscultation. An apparatus (cost twenty-eight cents) which I devised yesterday worked nicely."

A STRINGENT HEALTH ORDINANCE has recently been passed by the City Council of Baltimore. The *Maryland Medical Journal* questions whether it does not go too far, and asks: "Will public sentiment submit to the removal of inhabitants of infected dwellings to more salubrious structures; to the removal of the sick to temporary hospitals; to enforcement of vaccination whenever the Health Commissioners may deem it necessary; to the report of cases of infectious diseases?"

Such ordinances may be too radical, but they at least show how awakened the lay mind has become to the demands of sanitation.

THE MEDICO-LEGAL SOCIETY held its regular monthly meeting on November 15th. Dr. J. Clarke Thomas read a paper entitled, "Death by Drowning Medico-Legally Considered." In treating of drowning from the standpoint of medical jurisprudence Dr. Thomas mentioned the Malley trial, and after reading the testimony of the various experts in the case he stated that in his opinion Jennie Cramer's death was caused by suicide, and resulted from drowning. The arsenic found in Miss Cramer's system might have been taken as a cosmetic, or possibly with intent to commit suicide. In his opinion Jennie Cramer had more motive for suicide than the Malley boys had for murder, besides which all appearances indicated death by drowning.

Nominations for officers to be elected next month were then made. Among the nominees for President were Calvin E. Pratt, of Brooklyn; Dr. William A. Hammond, and Mr. Clark Bell, the present incumbent.

THE EMPEROR OF GERMANY is reported to be suffering from a malady of a nephritic character.

TELEPHONES AS A MEANS OF PROPHYLAXIS.—It is suggested that persons wishing to visit friends who are suffering from infectious diseases in hospitals, be allowed to communicate with them only through telephone.

DENTAL.—It may not be generally known, but it is a fact worth remembering, that a small quantity of the unbleached sulphate of quinine mixed with any ordinary tooth-powder, forms an excellent quinine dentifrice, which not only preserves the teeth sound, and the gums healthy, but is found to be wonderfully efficacious for preventing toothache and neuralgia.—*Student's Journal.*

DEATH OF DAVAINE.—The well-known pathologist, C. J. Davaine, died in Paris, on October 23d, in the seventy-first year of his age. Davaine is remembered by his work on "Human Entozoa," and especially by his experiments with the anthrax-germs.

Original Communications.

NERVOUS DISEASES CONNECTED WITH THE MALE GENITAL FUNCTION.

By GEORGE M. BEARD, A.M., M.D.,
NEW YORK.

(Concluded from page 201, No. 537, February 19, 1881.)

VII.

TREATMENT OF SEXUAL NEURASTHENIA.

The treatment of sexual neurasthenia is of a threefold character.

First.—General or constitutional treatment.

Second.—Local or medical treatment.

Third.—Operative or surgical treatment.

In the majority of cases, both local and general treatment are needed; they may be employed at the same time or in alternation, and failures that attend these cases are in part due to this, that the measures used have been one-sided—the constitutional treatment to the exclusion of local treatment, and *vice versa*. The most common error is to look solely to local treatment, medical or surgical. Different cases differ very much in regard to the necessity for local or general treatment, but the law is that the general treatment, including, of course, hygiene and mental therapeutics, should constitute about three-fourths, and the local treatment about one-fourth; but this general law is only to be understood as applying to the average of a very large number of cases. There are cases not a few, where the proportion is the reverse, where treatment must be only local and incidentally constitutional. There are cases—a very small minority to be sure—where only local operative treatment is needed. These cases are indeed so rare that I am not quite sure that I have ever seen one case, but I am quite willing to admit the possibility of their existence.

The general or constitutional treatment of sexual neurasthenia is not different in principle from the other constitutional treatment of the other varieties: exhaustion of brain, of the spine, of the digestive system, are benefited by carrying out the same principles.

The general rules that are to guide us in our constitutional treatment are, as indicated in my work on "Neurasthenia," as follows:

First.—Not to place dependence on any one medicine or any mode of treatment. There is no specific for sexual neurasthenia. The cases are to be treated as cases rather than as diseases. In no form of disease, probably, are idiosyncrasies against drugs and therapeutical procedures more common or more severe than in this disease; they overthrow all our ideas of medicine and greatly disturb our prognosis. Remedies that are most familiar and most uniform in their action, and on which we are wont to rely, play tricks with us in our treatment of these states; the bromides may keep them awake or make them nervous; quinine and strychnine may depress them, while baths, cold and hot, and even massage and electricity, unless given with very great caution indeed, may irritate and weaken, rather than soothe and strengthen.

This fact, however, should be known and noted: that these idiosyncrasies undergo change with the progress of the patient from disease toward health; as they get stronger they can bear varieties of drugs and varieties of food that had been intolerable.

Second.—Frequent change of treatment is needed. The common idea that patients can wear out a mode of medication is correct, and it accords with all we know of physics, of physiology, and of pathology; patients often need a new kind of treatment as they need a new suit of clothes. In taking even milder medicines these cases should be under the, at least, occasional observation of their physician.

Third.—Occasional suspension of all treatment. The very act of treatment itself tends to keep the minds of some patients constantly on their disease, so as to interfere with their recovery; in other words, the treatment interferes with the treatment, however judicious it may be; the constant directing of their attention to their symptoms by dosing and doing, is a stronger force for keeping symptoms alive than is the action of the drugs for removing the symptoms. This is not true of all cases of this disease; it is probably not true of the majority, but it is true of some; and it is a fact to be studied in our analysis of this subject that there are persons for whom it is well for this reason alone to defer or suspend, or to modify, at least, our local procedures.

Fourth.—The recognition of the fact that hygiene and medicine are identical, and that those portions of medicine which have been classed under hygiene are more difficult to manage than medical or surgical procedures, partly on account of their inherent complexity and partly because they are more exclusively in the patient's own hands.

In my studies of this subject I find patients usually willing to co-operate with the physician in hygienic suggestions, and that the only difficulty is to find out exactly what is best and most wise for each case under all circumstances.

Under what is called hygiene come diet, work, rest, travel, marriage, change of climate. Of these it is needful to remark here only of work, rest, and marriage.

Work.—For such cases, work and the prospect of work are remedial forces; their sufferings are genuine; their pain is real pain; their weakness and depression and fear are no more imaginary than the pitting of small-pox, or the crepitus in a broken leg; but like all real physical troubles, they can be made worse by turning the mind upon them; they can be relieved by turning the mind in some other direction. For such cases employment is mental counter-irritation, acting like blisters, dry-cupping, or cautery, electricity, hot and cold baths. We are, therefore, justified in urging these persons that they continue in their business, whatever that business may be, provided it suits them; and to seek occupation if they have none, with the assurance that they will be able to fulfil the duties required of them. Short vacations, or even long ones, are not inconsistent with systematic employment; the need is to have something to look for. Giving up one's profession and business, and running off indefinitely to Europe or around the world, is usually one of the worst prescriptions that is or can be given. Very many have I seen who, in measureless despondency, have traversed seas, and mountains, and continents, sacrificing therefor property, and home, and promise of usefulness, and seeking thereby health and finding it not. Such persons are not so much diverted by travel as undiverted; they stand as watchdogs over their symptoms, never allowing them to get out of sight; counting, or trying to count, their healthward progress from day to day, like sailors throwing the log; they are inevitably disappointed, and return home oft-times broken

and helpless. Patients of this kind are allowed to take vacations, but for pleasure more than health. In travel and in all treatment, the seeking of health, though systematic and persistent, should be incidental, not the main issue—secondary rather than primary; here, if not elsewhere, he who would save life must lose it; an over-earnest and fiery desire to get well keeps us from getting well.

To all forms of neurasthenia and allied states, these general principles apply, the only exceptions being cases of exhaustion so profound that they need absolute rest in bed.

Marriage.—Marriage, like travel, is recommended for these cases by wholesale, without consideration for the claims and wants of idiosyncrasies. Marriage and non-marriage are really but two out of a large number of factors that enter into the causation and treatment of these maladies. As bad cases of sexual neurasthenia as I have ever seen have been in those who are healthily married, while in other cases marriage has been the direct exciting cause. Quite an important percentage of my cases have been married for years, and in age range between twenty and seventy. In their relation to marriage, sexual neurasthenia may be divided into the following classes:

First.—Those who are positively benefited—perhaps cured—by marriage, whether resorted to as an incident to treatment, or as the main and only dependence.

That there are such cases—that there are many such—cannot be questioned; but they are not the majority; probably, rather, they are the minority of the neurasthenic patients that are specially affected in or through the sexual organs. Every physician has seen instances illustrating this, but the inference that marriage is a specific for sexual neurasthenia is as far outside of warrant in experience, as the inference that travel is a specific for the same cases because now and then one has been profited by travel.

Second.—Those who are positively injured by marriage, or indeed, by sexual indulgence, even rarely.

With the increase of modern sensitiveness the list of this order of neurasthenics is growing longer and longer. Such temperaments are not only disappointed in the remedial power of coitus, they are directly and severely harmed by it; and if married they must live platonically if they would live in health. With these persons intercourse, frequent or rare, has no apparent effect that is salutary, and very many effects, apparently, that are annoying. These bad effects sometimes follow at once, sometimes after an interval of one or two days; in some cases they are purely local, in other cases general—reverberating through the whole body.

MEDICAL TREATMENT.

Local sedatives.—Among the remedies that have a more or less sedative effect on the genito-urinary tract, and which may therefore be employed in connection with the constitutional treatment, are the following:

Hydrastis, epigea repens, triticum repens, stigmata of maize, rhus aromaticus, eucalyptus, digitalis and digitalin, alkalies, cantharides in very minute doses, belladonna, atropia, ergot and ergotine, lupuline, camphor, bromide of camphor, gelsemin, cimicifuga.

It is not to be understood that these drugs, when they enter the system, intelligently avoid every other part of the body and rush directly to the prostate gland. It is probable that these remedies have affected the whole body more or less, but their effect can be demonstrated in some cases more readily and satisfactory on the genito-urinary tract, when it is in a condition of inflammation, congestion, irritation, and exhaustion.

The differential action of large and small doses is very noticeable in the use of cantharides and belladonna, large doses of these remedies being, as all know, very irritating at the neck of the bladder, while small doses are soothing.

General sedatives.—Among the remedies which have a general sedative effect in neurasthenia, but no special sedative effect on the genito-urinary tract, are:

Physostigma, the bromides of sodium, ammonium, lithium, potassium, calcium, and hydrobromic acid, glonoin, scutellaria, cypripedin, cannabis indica, lactucarium, hyoscyamus and hyoscyamin, conium, convallaria.

Substitutes for bromides.—It is quite important in many cases to find some sedative remedy or combination of remedies that have the good effect of the bromides, in a more or less degree without their injurious effects. The above list contains good substitutes.

There are two classes of patients for whom it is not well to prescribe bromides. First, those who are kept awake instead of being put to sleep by them, or with whom in some way they do not agree. The number of those who cannot get some benefit of a temporary character from bromides is small. Second, those who have already taken the bromides too long—who have been thereby weakened and impoverished. The bromides, like all the other great remedies, are abused on account of their very value; they do so much that they are ordered to do everything. In this respect the history of the bromides is like that of mercury, counter-irritation, opium, and the like.

General tonics.—To depend on general tonics, even the very best, for the cure or important relief of sexual neurasthenia is to make disappointment sure. If iron and quinine, salicine, phosphoric acid and muriatic acid, and strychnine, arsenic, coca, quassia, calumbo, phosphorus in all its forms, the salts of zinc and silver could cure this trouble, then all cases would be quickly cured; for almost all use some of these remedies, or all of them, often in large doses and for a long time; and sometimes with a degree of benefit up to a certain point, sometimes with clear evidence of injury.

There is, indeed, no specific, or any approach to a specific, for sexual neurasthenia any more than for the other varieties; it is not by any one remedy or by any prescription, simple or compound, that we obtain the result. All the above-named tonics are good; some of them are most excellent, but none of them can be trusted as even a chief means of cure; these tonics are to be used oftentimes in connection with sedatives or in alternation with them; they are in some cases to be withdrawn absolutely, in other cases the dose must be reduced very greatly; there are persons who are made worse at once by the use of these tonics, at least when given in the average dosage.

In most cases of neurasthenia and in all varieties the stomach suffers first or last, and this fact must be considered in giving medicine. I usually give both tonics and sedatives well diluted, and begin with small doses. Where large doses are given it is with the understanding that they are to be taken a short

time, with intervals of rest for the stomach and nerves, and at the outset, at least, one must be ready always to give up even a choice and favorite prescription when it does not agree, or seem to agree; doubts are often best solved by withdrawal and then returning again, carefully watching the effects.

I have faith in the objective power of drugs apart from the action of mind on body—the expectation of the patient. I believe we can relieve and cure, or aid in the cure of disease by medical substances introduced into the system, just as we can induce disease in the same way, even when the patient does not know he has taken anything or just what he has taken or just what effects to look for. This creed is inconsistent in no way with the admission and declaration for which I have always contended, and the truth of which I have demonstrated by special experiments, that mental therapeutics is the most important of all therapeutics, and that mental force is the strongest single force that nature gives us in our conflicts with bodily disease.

I have faith, justified by observation, in very large doses of some remedies for some patients, in some conditions, for a short time and for an effect that small doses, though repeated often, cannot give; and have also faith, justified by observation, that often repeated very small doses of some remedies, for some patients in some conditions for a short time or for a long time, have an effect quite different, radically different, from the same remedies in large doses, and it is not inconsistent at all that in the same patient both large and small doses should be given.

Mental therapeutics.—There is no form of neurasthenia and no form of disease, nervous or inflammatory, where mental therapeutics, under the vague and elastic and unfortunate phrase "moral treatment," is so often tossed off as a prescription as in sexual neurasthenia.

Mental therapeutics, the turning of the patient's own mental force on his body for the purpose of relieving or curing disease, is important in this disease as in all other diseases, but there is no proof that it is of more or greater value in sexual neurasthenia than in other varieties of neurasthenia or in other forms of functional nervous disease. Even in organic disease of the brain or of the spinal cord, mental therapeutics is a powerful and an almost incredible means of temporary relief.

The mind of the patient in sexual neurasthenia can be therapeutically utilized both positively and negatively.

In the first place, we can assure such patients that their disease is relievable and curable. This assurance, which is based on the history of cases, is itself a curative force co-operating pleasantly and powerfully with whatever else we may do.

The history of these cases gives us a right to predict a bright future—which they especially fear will be impossible—provided they break up any evil habits and conform in a reasonable way to the local and hygienic treatment required. Some cases of a milder sort recover spontaneously under time and hygiene. In bringing, therefore, the element of hope to bear in these cases we are simply making use of experience, and the larger one's experience, the longer we keep sufferers of this disease under observation, the more hopeful on the whole we become, and in acquainting our patients with this fact we are both giving them information and helping to cure them. The prophecy is an aid to its own fulfilment. There are, probably, few forms of disease where symptoms are so distressing and so long standing that are so sure of relief as these cases, under right management, even in the most hopeless forms of the disease. Where there is, or appears to be, a wreck of all the faculties, and the whole man seems to be going to pieces, help can be secured in time by patient and sensible use of therapeutical measures—a relief that is both agreeable and tends to become more prominent with age.

Second, drawing off the mind of the patient from his disease by mental or physical work.

There are cases of neurasthenia in both men and women that need entire freedom from physical or mental toil, but the victims of this special form of neurasthenia do better, as a rule, to be employed in something that at once sustains their ambition, engages their thoughts, and gives them visible encouragement that they are not wholly disabled, nor likely to be. Better to stop the safe side of fatigue; but occasional excessive exertion is preferable to sustained, moody, and hopeless inaction, since one can more quickly rally from a single indiscretion than from a steady course of evil hygiene.

Muscular exercise is better than mental; it draws off more thoroughly from the sexual centres; it is sedative, where sometimes intellectual exertion is exciting. For man or for woman muscular exercise of some kind, or of many kinds, is, indeed, the best known relief for the irritating and morbid sexual desire that so often attends sexual debility.

LOCAL TREATMENT.

The methods of local treatment of sexual neurasthenia are quite numerous. Many which I have tried and discarded, because they either failed or are less useful than other methods, I shall not mention here.

Those which I use and commend are the following:

Localized electrization by external and internal applications.—General electrization in the forms of central galvanization and general faradization is of the highest value as a general sedative and tonic, and as such belongs under the head of general treatment. On this I have nothing to add beyond what has already been said in other writings on this subject in this country and in Germany and England.

Electricity may be applied to the male genital organs in various ways, and by both currents—galvanic and faradic.

First.—One electrode in the rectum and the other in the urethra, both insulated nearly to their tips. In this method *very mild* currents must be used, since the tips of the electrodes come very near together, the tissues are very moist, and there is but slight resistance to the current. This is good treatment for gleet and prostatorrhœa.

Second.—One insulated electrode in the rectum and the other externally at the perineum, or between the penis and scrotum, or over the pubis, and on the inner side of thighs. In this method very strong currents can be used.

Third.—One pole connected with an uninsulated sound in the urethra, and the other on the thighs or on the spine. Strong currents can be borne in this method also.

In this method the mechanical effect of the sound is combined with the special effect of the electricity. I have devised a clamp for connecting the electricity with the sounds.

Fourth.—Purely external applications, one electrode pressed firmly on the scrotum, the other on the spine or the back of the neck, or on the inner

sides of the thighs, the nerves of which affect reflexly to the general apparatus in a powerful way.

Fifth.—One electrode at the perineum, the other up and down the spine.

In the above method of application, both currents may be used. I use the faradic more than the galvanic. For the gleety blennorrhœal discharge that often accompanies sexual neurasthenia, I prefer the insulated electrode and the galvanic current.

Sixth.—Drawing off sparks on the spine and the genital region by statical electricity (franklinization).

The use of statical electricity (franklinization) is necessarily felt all over the body, and is really a form of general electrization;[1] but it is especially more powerfully felt on or near where sparks are drawn, and by this method very powerful local impression may be made. In these applications the patient sits on an insulated stool, and there are a variety of electrodes that I employ in the applications. I make frequent use of the electric wind in these as in other forms of nervous diseases.

Comparing franklinization with galvanization and faradization, I should say that the average results of faradization are preferable; but there are individuals who are specially benefited, or seem to be specially benefited, by franklinization, and *vice versa*. I therefore make considerable use of it as an alternate to general faradization. It is certain that most sensitive persons can be franklinized without discomfort and without fear, and without any unpleasant after effects.

In using any form of electricity, we have to guard against too long, too strong, and too frequent applications; but we are not to be alarmed if a drop of blood should appear after an internal application, and we are always to abandon or suspend or modify the applications when they seem to disagree.

Soluble bougies and cupped sound and powders.—The familiar devices have never fulfilled my hopes; and as the other plans described here do better, I have fallen into the habit of making less use than formerly of even such a good remedy as iodoform in the shape of soluble bougies, or in an ointment for the cupped sound. The more common remedies, such as sulphate of zinc, seem to do but little except for some intercurrent attack of urethritis.

The powder of iodoform can be introduced into the urethra by a tube with a sliding wire and bulbous extremity.

Sound.—The history of many of these cases is a history of disappointment in the use of sounds. Treatment that is only local, however varied, most usually fails; but exclusive dependence on the introduction of sounds is, of all measures, disappointing for all cases of general sexual neurasthenia—that is, cases in which the brain and spine and digestive system have become involved, as well as the genital organs. That the sounds, by their mechanical influence, are a help in some cases, mainly of a local character, even when there is no stricture, has been shown long ago, and by many observers; but they do very little that is desired or promised of them. Now and then a good and strong effect is noticed after large sounds have been used; but this is often temporary, or is appreciated only in some one symptom, as impotence; whereas large numbers of persons use the steel and flexible sounds faithfully without profit, and sometimes to considerable harm.

Very sensitive urethras cannot bear steel sounds, even when introduced cautiously and kept in but a short time; increase of the sensitiveness, and sometimes discharge, are the results. Not only for the patient, but for the physician, the flexible sounds are less irritating.

All of these criticisms apply mainly to the treatment of those cases where there is no stricture.

Local baths and douches.—From cold sitz-baths I see little good in the class of cases to which these papers are devoted. The experiments are made on an extensive scale; almost every one tries them.

Hot sitz-baths, taken at night, injure less and help more, but some are so sensitive as to be weakened by them, while in other instances the effects are negative or doubtful.

From douches to the spine and back of the neck, with hot water or cold water, or an alternation of hot and cold, there is more satisfaction than from bathing. These douches, however, should be managed with prudence; the chief point being to avoid using them too long at a time. Some are made chilly by a very short douche of cold water; a minute is a long time when a stream of cold water is falling from a height on the back; a fraction of a minute is all that many nervous patients can bear.

Horse-hair mittens used thoroughly and daily all over the body are a good substitute for baths and douches, and may well follow all water applications.

Rectal treatment.—The prostate gland, when in an irritable condition, can be affected through the rectum, in some cases with less disturbance than through the urethra. Injections of ergot, of aqua bismuthi, of hamamelis, of hot water, and bromide of sodium, are sometimes most useful, not only when piles exist, but when there is heaviness, aching, oppression in the rectum after walking.

Suppositories of many kinds I have used—iodoform, valerianate of zinc, ergotine, belladonna, and so forth, but the injections seem to do better, save in those cases, quite rare, where the rectal pain is severe enough to require morphine.

The irritable rectum requires, in fact, substantially the same treatment as the irritable urethra.

Cauterizing and soothing injections.—The injection of a small quantity of a solution of nitrate of silver, is good treatment for the prostate urethra when used cautiously and occasionally; but it is not a specific or sole dependence for these cases in any sense. I should never think of relying upon it in any case, and there are no cases that require its frequent use. I see no harm, but much benefit, from these injections in my practice: but I do not depend on them only, and in many cases get along without them. The painful urination and desire for urination and discharge of blood that follow these injections, are not serious symptoms. In a day or two they pass away; but if they should be serious they could be relieved by opium and warm sitz-baths.

Lallemand's porte-caustique is not well borne by

[1] The German literature of general faradization is now extensive, and is increasing. Among the more recent writings on this special mode of using electricity are the following: Erb's Handbuch der Electrotherapie; Stein's Allgemeine Electrization des Menschlichen Körpers (including general faradization, central galvanization, the electric bath, and franklinization); Möbius: Ueber Allgemeine Faradisation, Berl. Klin. Wochen.; Fischer: Ueber Allgemeine Faradisation, Arch. Psychi., xii., 3, 1882; Engelhorn: Ueber Allgemeine Faradisation, Centr. Bl. Nervenheilkunde; Maierfisch: Ueber Allgemeine Faradisation, Schweiz. corr., B. xi., p. 221, 1881; Väter: Review of Erb, in Allgemeiner Med. Zeitung. Möbius has just published a *résumé*, wonderfully thorough, even from a German point of view, of the literature of this and other points in electro-therapeutics gleaned from all the languages, under the title Ueber Neuere Electro-therapeutisch Arbeiten. Some of the above references are taken from the monograph of Möbius, which has just reached me. Möbius also gives a *résumé* of the recent and important literature of statical electricity.

the modern nervous constitution, certainly not by the American constitution, but a strong solution of nitrate of silver, even much stronger than one-half a drachm, in *small quantities*, can be tolerated by almost every one.

Besides nitrate of silver I use injections of hot water and the bromide of sodium in the urethra. The hot water is of great value for all mucous membranes, from the nasal passages to the penis and the urethra; it is good for nasal catarrh, or gastric catarrh, or intestinal catarrh—for piles, and for urethral catarrh. The difficulties in applying hot water to the urethra are numerous; first of all the double catheter, with holes near the end, is likely to cause irritation of a mechanical kind by the contact of the edges with the mucous membranes; then the catheter itself with a stream of hot water passing through it soon becomes painfully hot. I had a double catheter of this kind constructed, and soon gave up its use on account of these difficulties, and I now use the flexible catheter above described. With this catheter one can inject a small quantity of hot water into the deep urethra. The quantity of the injections are small, but can at any time be repeated. The bromide of sodium injections I find very excellent for soothing and sedative effects. I use a solution of one part to fifteen of water. For the frequent condition of great hyper-sensitive urethra, the bromide of sodium injections are very excellent and admirable; they can be used frequently, once a day or oftener.

Counter-irritation: small blisters, cupping, and cautery.—There are various ways for using counter-irritation effectively: the use of very small blisters to the spine, as described in my work on "Neurasthenia;" dry-cupping on a large scale, wet-cupping, and the actual cautery.

Counter-irritation to the perineum by means of the nitrate of silver or iodine has disappointed me. If severe, it annoys; if mild, does little good. The judicious and careful use of small blisters is preferred, in the manner elsewhere described,[1] to the perineum and to the under portion of the penis, and is rewarded by a relief of the symptoms of prostatic irritation that cannot always be obtained by other means. The philosophy of this method of treatment in prostatic irritation is the same as in local irritation of other parts, as in spinal irritation, cerebral irritation, nervous dyspepsia, neurasthenic eye, and so forth, all of which conditions are analogous in pathology, in history, in philosophy, to irritation of the prostate, and very often associated with it. On this subject Mr. Milton, of London, writes very intelligently.

The success that follows this mode of local counter-irritation depends largely on the details, on the judgment of the physician, and the good sense of the patient. To do permanent good, the treatment must be kept up, off and on, for some time, and in order that it may be kept up for a long time it should be conducted so as not to severely annoy or interfere in any way with daily duties.

Dry-cupping seems to be useless unless it be carried out with more emphasis and thoroughness than is the custom; but when practised on a large scale, and maintained systematically, like electrization or hydro-therapeutics, it is of much value. It should be applied not only to the spine but to the thighs and perineum. One of my patients has lately constructed an apparatus for dry cupping, which seems to be superior to anything I have seen. If it fulfils its promises it will in time be described and illustrated.

The cautery of the Paquelin or the galvano-cautery I often use just before the application of the small blisters, placing the blister-plaster directly over the parts cauterized.

[1] Neurasthenia, second edition, p. 170.

SURGICAL TREATMENT.

The surgical treatment of that class where surgery is required as an addition to medical treatment has been discussed elsewhere.[1]

Sexual neurasthenia occurs in those who have and those who have not phimosis or redundant foreskin, in Jews as well as Gentiles, in those who have and in those who have not stricture or narrow meatus. In regard to the relation of these conditions to nervous disease, these three propositions are demonstrable:

First.—Persons who have very strong, old-fashioned constitutions are rarely or never injured in the nervous system, locally or generally, in any important degree, at least by phimosis or redundant foreskin, or by stricture or narrow meatus.

Second.—Persons who are only moderately sensitive may in time suffer from these conditions, locally chiefly, and in the different degrees of impotence and spermatorrhœa. With this class of persons, however, years may elapse before even these local effects are noticed.

Third.—Persons who are very sensitive nervously, and especially Americans, living in our American climate, are liable to develop all or many of the symptoms of sexual neurasthenia under the exciting influence of any one of these conditions. The phimosis or the stricture alone could not have excited the nervous disorder, except when co-operating with a temperament previously made sensitive by exhausting climate,[2] work, worry, tobacco, alcohol, traumatism, or excesses.

The consideration of these propositions will help to answer the question, whether, in any case, surgery is to be added to medicine.

Out of 192 of my cases of nervous diseases, including neurasthenia in all its varieties, epilepsy, etc., there were 60 cases of phimosis or redundant foreskin, with or without smegma. Of these 60 cases, 16 were circumcised, but in no case was the operation the only dependence, but was used in connection with medical treatment, local and general.

A NEW VEGETABLE STYPTIC.—During the French expedition to Mexico, a plant was discovered, called by the natives by a name which may be rendered as "Fowlwort" (*trandescantia erecta*). This had the property, when given internally, or even chewed, of stopping hemorrhages. Specimens have been cultivated, says the *Lancet*, at Versailles, and retain their native properties. It is asserted to be the most powerful styptic known.

[1] Medical Bulletin, p. 248, 1882.

[2] In my "American Nervousness," chap. iii., the climate of America as a cause of neurasthenia is considered in detail, with especial reference to degrees of the air and extremes of heat and cold. Very recently an Englishman, Matthieu Williams, has written in confirmation of these views. He speaks of the "desiccated Englishman" and of "Americanitis"—an equivalent to nervousness. In the same line were the results of Mr. Herbert Spencer, on American overwork. The work of Möbius, of Leipsic, on "Neurosität," may also be consulted.

Some of the later writers, including Mr. Spencer, err in assuming that the trouble is only American. The whole civilized world is suffering in this way; the American, mainly for climatic reasons, being only about a quarter of a century in advance of Europe. At the present time there is a larger literature of this subject in Germany than in America.

THE RECORD OF A CASE OF

GUN-SHOT INJURY IN THE CLAVICULO-SCAPULAR REGION,

TREATED BY PRIMARY ANTISEPTIC OCCLUSION, WITH A SINGLE DRESSING.

BY H. I. RAYMOND, M.D.,

ASSISTANT SURGEON, U. S. ARMY.

FOLLOWING in the wake of cases cited in my recent article to THE MEDICAL RECORD on "Primary Antiseptic Occlusion in Military Practice," I desire to record this case, the next in the short series occurring in my military practice in Arizona. Thus the case will not be an isolated one, but will afford confirmatory evidence of the applicability and practical results of the "occlusive method" in gun-shot wounds, as urged in my former article. I report this case without waiting for others to accrue, because the case is exemplary and yet remarkable, in that, although a serious gun-shot injury in a region well supplied with lymphatics and other absorbent vessels, the temperature did not average a degree above the normal, and the primary dressings were not removed or disturbed from the time of their application, at ten o'clock on the night of the shooting, immediately after reaction from shock, until healing of the wound-track was practically accomplished. Six and one-half days after receipt of injury I removed the primary dressings and found the track of the wound filled with granulation-tissue and closed almost up to its mouths. Nature, in such an incredible short space of time, had converted a serious gun-shot wound into two ulcers, one at each end of the track. I dressed these with iodoform and salve, as one would any simple ulcer, and desisted from measuring the depth of the ulcers until the following morning, when Dr. C. H. Allen, my associate at this post, would be present to verify my measurements. Seven and one-half days after receipt of injury Dr. Allen took a Nélaton probe, well carbolized, to determine at what depth in the wound-track it would meet with firm resistance from granulation-tissue. The track of the wound originally was five inches from the entrance to exit, as ascertained by external measurements on a plumb-line. The depths of the ulcers, as ascertained by Dr. Allen and verified by myself, were at entrance of bullet three-fourths of an inch, at exit of bullet, one-fourth of an inch.

The primary dressings in this case were removed as early as the seventh day, as a tentative measure toward determining the shortest time requisite for the process of repair. In the case of a gun-shot wound of the leg, inflicted by a ball from a revolver of 45 calibre, the wound-track being eight inches in length, I removed the primary dressings on the tenth day, and found the track completely filled with granulation-tissue. I would not recommend that the dressings be removed under ten days if no contra-indications arise.

Of course, the progress of repair in any given case will depend largely upon the vascular supply of the part and the quality of the blood, with other conditions which physiological histologists can point out for us.

The history of the case is as follows: Geo. R——, an American, aged thirty-four, by occupation a packer, subject to occasional sprees, was, while intoxicated, shot by a drunken comrade, at close range, about ten o'clock on the night of October 26, 1882. The bullet, projected from a carbine, was of 45 calibre. The wounded man was borne to the hospital, a distance of eighty rods, by two soldiers. On admission into the ward considerable oozing of venous blood was taking place from the wounds of entrance and exit, the former almost immediately subclavicular at the junction of the outer with the middle third of clavicle, the latter immediately supra-scapular and extra-articular. The wounds were on the left side of body.

The numerous lymphatics in the cervical cellular-tissue and the patulous mouths of the injured veins stood like so many eager nestlings, quickly receptive of any infecting entities that might be brought to them by the surgeon's probe or digit, or in anywise whatsoever.

Treatment.—October 26th, 10 P.M.: Hemorrhage, mostly venous, was arrested by compresses to the wounds of entrance and exit, secured by a figure "8" roller bandage about the shoulders. The compresses were soaked in a solution of carbolic acid 1 to 20, and the superficies of the wounds were cleaned with the same before their occlusion by the compresses. This dressing was applied by Dr. Allen before my arrival, and had he not thought that I would probably remove this primary dressing in the morning, he would (as was our custom) have dusted iodoform upon the wounds previous to their occlusion.

Dr. Lloyd, of the army, was present at the dressings. Shock was relieved by external heat, whiskey internally, and ℥x. hypodermically of a mixture of Magendie with a solution of atropine: ℥x. representing ¼ gr. of the former and $\frac{1}{16}$ gr. of the latter. Fearing the lung might possibly be involved, this hypoderm was repeated occasionally during the first three days of treatment.

October 27th (first day), 9 A.M.—Pulse 98, well sustained; respiration 21, of good character; temperature 99½° per orem. No pain in arm or shoulder when at rest. Patient relishes cold rich milk. Ordered a glass q. six hours. Quinia sulph., grs. x., night and morning. Tr. ferri chlorid., ℥xv., t.i.d.

The compresses and two layers of the bandage were found saturated with blood which had oozed out and dried during the night. There being no indication for a removal and reapplication of compresses—the wound smelling sweet, and the temperature scarcely more than a degree above the normal—the primary dressings, though saturated with blood, were not disturbed, but as a precautionary measure the compresses were made to take up an antiseptic wash of boro-glyceride and iodoform.

Memoranda.—October 27th (first day): primary dressings undisturbed, but saturated with an antiseptic wash as a precautionary measure.

October 28th (second day).—Practically nothing done, dressings not touched. Odor sweet.

October 29th (third day).—Nothing done with respect to the wound. Tongue moist; appetite good.

October 30th (fourth day).—Dressings in *statu quo*. No indications to do anything; nothing done; food relished.

October 31st (fifth day).—Absolutely nothing done; tongue moist; appetite hearty.

November 1st (sixth day).—Faint smell to the bandages. The compresses again saturated with a solution of boro-glyceride, 1 to 10, to which was added a little iodoform; dressing not disturbed.

November 2d (seventh day).—Dressings removed for the first time. Entrance and exit of bullet dressed like two ulcers. Wound practically healed.

November 3d (eighth day).—Depth of ulcers at each end of wound-track ascertained. At entrance,

three-fourths of an inch; at exit, one-fourth of an inch. Original length of wound-track, five inches.

November 6th (eleventh day).—The posterior ulcer has granulated to the surface level. The anterior one is gradually filling up with granulation tissue. The temperature and pulse are within an ace of the normal.

Thus it appears that one does less and accomplishes more by this "do-nothing" method, in any case to which it is applicable, than by any other manner of procedure known to the profession.

INFLUENCE OF DOSE ON THE ACTION OF REMEDIES.*

By H. B. HEMENWAY, A.M., M.D.,†

KALAMAZOO, MICH.

It has been observed from very early times that drugs administered in large doses often have apparently the reverse effect from that which is produced by small quantities of the same medicamenta. Many references might be given to substantiate this assertion. One quotation must suffice. Hippocrates gave this prescription for mania: "Give the patient a draught made from the root of a mandrake, in a smaller dose than sufficient to induce mania." Nearly a century ago a German physician, having noticed the apparently conflicting result of large and small doses, propounded that highly erroneous so-called law, "*similia similibus curantur.*" The most common explanation of this law among his followers at the present time is summed up by them in the words "*action*" and "*reaction.*" They say that a drug has a certain action upon the human system. This action the "forces of nature" try to counteract. Large doses show the *action* of the poison. Nature, however, is more powerful than small doses, and when they are given, the *reaction* of nature is seen.

If this theory is correct, there must be one point where the action and reaction are equal and the effect *nil.* On either side of that point the dose would be effective in proportion as it was distant from the point. Since this is not the case, we must of course discard the theory. Moreover, is nature a thinking entity?

The foregoing remarks are called forth by an article by Professor Bartholow, published in the *Medical News*, August 26, 1882, p. 227. He there states the law, "To every action there is an equal and opposite reaction," meaning thereby that as the result of over-stimulation a sedative effect is produced. While recognizing the authority with which he speaks upon such themes, and admitting that there is some truth in the so-called law, the majority of students in the profession must still differ with him as to the breadth of its application.

First look at the oft-mooted subject, *alcohol.* The effect of small doses seems to be stimulant; but is it really so? True, after taking a drink of wine a man will lift a greater weight than before. Though exhausted before, he will return to his work with renewed vigor apparently. The word apparently is used, for in a communication read before the American Medical Association, about 1855, Dr. N. S. Davis clearly demonstrated that this result is reached by its anæsthetic effect. Dr. H. C. Wood says ("Therapeutics, Materia Medica, and Toxicology," p. 118): "It is scarcely doubtful that alcohol acts upon them as does ether," speaking of the nervous centres. A man stops lifting, not because he has reached the limit of his strength, but because pain is produced, showing that should he lift much more he would be in danger of injury. If that pain is deadened, so that he cannot feel it, he will lift heavier weights. After taking a drink he does not mind the cold of winter nor the heat of summer, and as a result, attention is called to the fact that most of those overcome by heat in summer, or frozen to death in winter, come from the class using alcoholic stimulants, so-called. Increase the amount of liquor taken and the sedative effect is seen not only in the æsthesodic, but also in the kinesodic system. Apparently the effect is the reverse with large and small doses. In reality the difference is one of degree only. Professor Bartholow refers to its action on the heart. He says: "Alcohol may increase the action of the heart in two modes: by a reflex impression, having its origin in an excitation of the nerve endings in the stomach; or by its own oxidation or combustion in the organism, yielding a force which is utilized by the cardiac motor apparatus." If the last is the true explanation, it might reasonably be expected that a larger dose would give more strength, which is contrary to fact. Since the inhibitory nerve of the heart and the sensory nerve of the stomach are parts of the pneumogastric, stimulation of the stomachic fibres would cause a slowing of the heart's action. In order to produce quickened pulsations by action on the sensory nerves of the stomach, they must be anæsthetized, not stimulated. In this condition arterial pressure would be greater because of increased heart's action. When a larger dose is given the heart's action is slowed by stimulation of the inhibitory centre. The pulse is weakened by the direct influence of alcohol upon the heart-muscle, as may be proved by injecting it into the jugular vein.

In *digitalis* poisoning is cardiac paralysis due to over-stimulation of the cardiac muscle, as Professor Bartholow implies? The record of experiments with this drug indicates that generally death occurs with systolic arrest. The increased strength of the heart's action is due to the direct influence of the digitalin upon the cardiac muscle. Slowing of the beat is the result of stimulation of the peripheral cardiac inhibitory apparatus, and of the vagi. Rudolf Boehm (*Pflüger's Archiv für Phys.*, 1872), asserts that cardiac arrest in diastole never occurs in digitalis poisoning after the vagi have been cut. I assume this to be true, since I have never been able to find testimony to the contrary. The most reasonable explanation of those rare cases of diastolic arrest, therefore, is not exhaustion of muscular energy, but unusual stimulation of the pneumogastric.

Without doubt, exhaustion is an important element in the production of paralysis in *strychnia* poisoning; but we must not forget that the experiments of Buisson, Martin-Magrow, and others clearly demonstrate that the drug has a paralysant action upon the motor nerves. Now, Professor Bartholow himself says, that when very large doses of strychnia are injected into frogs, there may be *no convulsions.* In such cases, evidently, the paralysis cannot be due to exhaustion of irritability, but to direct paralysis of the motor nerves. The convulsions are generally agreed to be mainly, if not entirely, the result of the action of the alkaloid upon the spinal cord.

Another example of apparently opposite actions of a drug is found in *belladonna.* Small doses increase the frequency of the pulse and cause a *rise* of arterial pressure. Large doses also quicken the

pulse-rate, but *lower* arterial pressure. Small doses increase the action of the heart by paralysis of the vagi, and by stimulation of the accelerator nerve-centres or nerves. The increased vasculur pressure is the result of increased heart-action and stimulation of the vaso-motor centres. The decrease in vascular tension, when large quantities of atropia are exhibited, is due to (1) the continued rapid action of the heart, thereby preventing its complete filling before contractions; (2) the direct depressant effect upon the heart itself, as shown by the experiments of Bezold, Bloebaum, and Botkin; (3) its paralysant action upon the muscular coats of the vessels. That this last is not the result of super-excitation, but of the direct action upon the vessels, may be seen from the fact that atropia applied to the web of a frog's foot causes dilatation of the vessels without their previous contraction, if the skin has been broken.

The foregoing are a few of the many possible illustrations of the fact that to the superficial observer the effects of large and small doses of medicines seem to be reverse, the one from the other; but a more minute examination shows that in reality the differences are those of degree rather than of kind. While this may not be true in all cases, it certainly, so far as our present knowledge goes, is true in very many instances.

In view of these facts, it is greatly to be regretted that our writers of works on the practice of medicine are not at all explicit in stating *exactly* the size of dose, how administered, and how often, as well as the name of the remedy to be used.

It may not be out of order right here to say that, for constitutional effects, in acute diseases especially, small doses given once in one or two hours have more uniform and favorable results than when the same quantity per twenty-four hours is given in three or four doses. Furthermore, very often when small doses are given frequently, it takes less of the drug to produce the desired results than when it is administered according to the old plan *ter in die*. The quantity taken can be better regulated, and after-results are not so likely to annoy the physician as formerly.

PHILADELPHIA HOSPITALS.—The superior skill of Philadelphia surgeons is attested in the following paragraph, which we extract from the *Chicago Medical Review*:

"According to a local paper, a man who had been carried to a Philadelphia hospital while suffering from the effects of a severe contusion, was asked if he had been treated kindly while there. 'Considering all things,' he answered, 'I have no right to complain. They amputated both my feet, removed my clavicle, cut off my right arm, trephined me, took out a piece of my inferior maxillary, sawed my left os innominatum in two, and were about to exsect five or six ribs, when a fire broke out in the establishment, and the police got away with the rest of my body in safety.'"

This simple, straightforward, and temperate statement of facts carries conviction with it; but had it been made by any other than a Chicago man, we could scarcely have credited it. We have also learned that George Washington's hatchet and original cherry-tree are now in the possession of the victim, and will be sold cheap, for cash, for the benefit of his widow, should he die from the original contusion.

Progress of Medical Science.

ALTERATIONS OF THE CORD IN PHOSPHORUS POISONING.—The results of the researches of Dr. Danillo (*Gazette Méd. de Paris*, 1882) on this subject are as follows: 1. The alterations of the spinal cord in phosphorus intoxication must be placed in the class of myelites, either central or diffused. 2. In cases of acute poisoning, the central nervous system contains deposits of pigment of hæmatic origin. This has, heretofore, not been noted. 3. Large doses of phosphorus give rise to a central myelitis, along the whole length of the cord, with the formation of extravasation and pigment. Smaller and repeated doses give rise to a diffused myelitis, affecting the gray and the white matter. 4. Phosphorus thus presents us with a powerful means by whose aid we may excite, at will, an inflammatory irritation in the spinal cord, either localized in the gray matter, or diffused, that is occupying both the white and the gray matter at one and the same time. 5. A certain number of morbid nervous phenomena, observed during life, are to be attributed to the effects of one or the other of these two kinds of myelitis.

THE CEREBRAL SEAT OF SUICIDAL AND OF HOMICIDAL IMPULSES.—M. Voisin has written a memoir in which he endeavors to establish that suicidal ideas in the alienated are due to functional troubles and to lesions, having their seat in the most internal parts of the ascending and parietal convolutions, and moreover that the dangerous impulses to suicide, homicide, and violent acts have their origin in these convolutions.—*Gazette des Hôpitaux*, August, 1882.

THE PROGNOSIS OF DIABETES.—From a consideration of six hundred cases of diabetes, which have come under his personal observation, Dr. Schmitz, of Neuenahr, feels justified in formulating the following conclusions: Prognosis depends upon, 1, the earliness of the discovery and treatment of diabetes; 2, the strictness with which the anti-diabetic regimen is observed; 3, the etiological factors; 4, the age of the patient; 5, the degree of immunity the patient enjoys when he chances to use sugar-breeding food. In early cases the prognosis is favorable. Diabetes depending on central nervous lesions or on grave chronic affections is serious: depending on worry, pain and grief, or on over-use of sugary food, it is less so. Gouty diabetes has the best prognosis of all. After the age of thirty the pronosis grows steadily worse. It is bad if sugar persists on an exclusive diet of fish and flesh. It is decidedly favorable if eggs, salads, and mild cheese can be taken without breeding sugar, which only reappears when fruits, starchy roots, starch, or cane-sugar are taken.—*Wiener med. Wochenschr.*, No. 11, 1882.

THE NUTRIENT TREATMENT OF INSANITY.—"The greater my experience becomes," writes Dr. Clouston (*London Practitioner*, August, 1882), "I tend more to substitute milk for stimulants. I don't undervalue the latter in suitable cases; but in the very acute cases, both of depression and maniacal exaltation, where the disordered working of the brain tends rapidly to exhaust the strength, I rely more and more on milk and eggs made into liquid custards. One such case this year got eight pints of milk and sixteen eggs every day for three months,

and under this treatment recovered. I question whether he would have done so under any other. He was almost dead on admission, acutely delirious, absolutely sleepless, and very nearly pulseless. It was a hand-to-hand fight between the acute disease in his brain and his general vitality. If his stomach could not have digested and his body assimilated enough suitable nourishment, or if he could not have been taken out freely into the open air, he must have died. But to-day he is fulfilling the duties of his position as well as he ever did in his life. All acute mental diseases, like most nervous diseases, tend to thinness of body, and therefore all foods, and all medicines, and all treatments that fatten, are good. To my assistants, and nurses, and patients I preach the gospel of fatness as the great antidote to the exhausting tendencies of the disease we have to treat, and it would be well if all people of nervous constitution would obey this gospel."

Oil of Peppermint in Zoster.—Dr. Meredith says that he has found the oleum menthæ pip. more effective than any other form of anodyne application he has tried in allaying the neuralgic pains so often piteously complained of in cases of herpes zoster. These distressing pains, worse in elderly people, are complained of often when the eruption has disappeared; but painting the affected parts over with oleum menthæ pip. nearly always affords speedy relief. He has painted the oil over the eruption when it was out in a fresh florid condition, and that with great relief to the patient. The value of this application in pains of neuralgic character deserves to be better known than it is.—*London Practitioner*, August, 1882.

Hot Water in Nausea and Vomiting. — Dr. Morton says, in the *Louisville Medical News*, that several years ago he learned from his own personal experience that no agent relieves nausea and vomiting so satisfactorily and promptly as water, as hot as can be drank. Since then he has used it in a large number of cases, and no remedy that he ever administered in any condition has proved more uniformly reliable. He has preserved records of many of these cases, and makes the following classifications: 1, cases in which nausea and vomiting occurred at the onset or during the course of acute febrile disease; 2, cases in which these symptoms were caused by overloading the stomach when its functions had been impaired by protracted disease; 3, cases in which they were produced by nauseous medicines (not emetics) at the time they were taken; 4, cases of acute gastritis caused by the ingestion of irritants; 5, cases in which these symptoms were purely reflex; 6, cases of chronic gastritis; 7, cases of colic in newly born infants; 8, cases of flatulent distention of the stomach in adults.

Burnt Alum in Ague.—Baboo Brojendra Nath Banerjee (*London Practitioner*, August, 1882) states that this is a very cheap, easily procurable, and efficient anti-periodic medicine. The value of alum is chiefly marked in cases of fever in which the attacks come on with clockwork regularity. It usually fails in irregular types of intermittent fever. Two doses are generally sufficient to complete the cure. Eight grains of burnt alum are to be given in each dose. The first dose is to be given three hours, and the next an hour before the expected attack of fever.

Alum may prove an efficient drug for killing the bacilli of malaria, but there seems to exist an inherent potency in Dr. Baboo's full name that will more effectually intimidate rampant malarial germs than any drug yet invented by medical sagacity all the world over.

The Therapeutic Action of Zinc.—Dr. Testa (*Dublin Journal Medical Science*, July, 1882) draws the following conclusions from experiments made with a twenty per cent. solution of sulphate of zinc injected hypodermically: 1. Zinc possesses a marked action on the heart; it diminishes the force of cardiac contraction and reduces blood-pressure. It then causes an increase in blood-pressure by direct action on the blood-vessels, causing their contraction. 2. Zinc acts on the intra-cardiac termination of the pneumogastric nerve; and, 3, causes arrest of the heart in diastole. 4. It diminishes peripheral sensibility up to complete anæsthesia, and causes motor paralysis. 5. Zinc reduces the excitability of the nervous system, and is indicated in convulsive neuropathies; it also reduces utero-ovarian hyperæmia, and is indicated in hysteria. 6. It is also indicated in nervous palpitations.

Tincture of Carduus Marianus in Hæmoptysis.—Dr. Lesenevitch has employed the tincture of carduus marianus (milk-thistle) in five cases of hæmoptysis. The dose is fifteen to twenty drops in a teaspoonful of water every two hours. In three of his cases, in which there was consolidation at the apices, the blood in the sputa was greatly diminished in quantity after six doses, and had entirely disappeared at the end of two days. Digitalis, the mineral acids, and ergot had previously been tried without success. In two other cases, in which cavities existed, no improvement followed the administration of the drug for three days, while ergot subsequently given arrested the hemorrhage in thirty-six hours.—*Journal de Médecine de Paris*, August 12, 1882.

Daily Variations in Stature.—Dr. Merkel states that the height of an individual after a night's rest, measured before rising from the bed, is two inches greater than it is in the evening, measured standing. There is a gradual diminution in height, caused by the yielding of the plantar arches and of the intervertebral discs; and a sudden diminution, when the individual rises, occurring at the articulations of the lower extremities. The sinking at the ankle is $\frac{1}{4}$ inch; at the knee, $\frac{1}{12}$ to $\frac{1}{4}$ inch; at the hip, $\frac{2}{3}$ inch. The shortening at the knee is probably due to the elasticity of the cartilages. At the hip there is, in addition, a sinking of the head of the femur into the cotyloid cavity.—*Journal de Médecine de Paris*, August 12, 1882.

Jaborandi in the Treatment of Pleurisy.—Dr. Dufour relates the case of a child, six years of age, suffering from double pleurisy, in which excellent results were obtained from the use of jaborandi. Several blisters had been applied without result, and at the end of two weeks the symptoms were so serious that it was feared that the effusion would become purulent. One drachm of jaborandi was ordered to be given in infusion. The half of this amount had hardly been taken when the child broke out into a profuse perspiration, but without ptyalism. Dr. Dufour believes that pilocarpine always causes salivation, while jaborandi produces sweating alone. On the day after the administration of the drug the effusion had disappeared, and respiration was normal. The patient went on to a good recovery.—*Journal de Médecine de Paris*, August 12, 1882.

PERINEAL CALCULI.—Dr. D. Molière (*Journal de Médecine de Paris*, August 12, 1882) relates the histories of three cases of perineal calculus. The first patient had had two attacks of gonorrhœa, followed by a stricture. Internal urethrotomy was performed, and the patient was discharged. Three years later he returned to the hospital, suffering from an abscess of the perineum. This was incised and found to contain urine and a quantity of gravel. The second case occurred in a man, thirty-five years of age, who had never had gonorrhœa. A perineal abscess formed and opened spontaneously, giving exit to a calculus the size of an egg, and weighing forty grammes. The only ascertainable cause for the formation of the calculus was a blow on the perineum with the butt-end of a musket twenty-five years before. In the third case there was a urinary abscess, the cause of which was stated to have been a fall upon the buttocks forty years previously. The fall was followed for a time by difficult micturition. The abscess was opened, and found to be filled with a quantity of degenerated pus. Two calculi were removed, one the size of an almond, the other smaller. There was no history of a previous gonorrhœa. The slow formation of perineal calculi is well known, cases having been recorded in which the period of development was fifty years, but those of traumatic origin are rare.

SPONTANEOUS RUPTURE OF THE RECTUM.—A recent number of the *Revue de Chirurgie* contains an interesting article on the above rare occurrence, by M. E. Quénu. The author applies the term "spontaneous" to cases of rupture, in consequence of simple muscular effort, of all the coats of an apparently healthy bowel. The first case of the kind was published by an English author, Sir B. Brodie. M. Quénu has collected six others, one of them having been observed by himself, in the clinique of Professor Richet. The records are not all equally complete. In four out of five in which information on the point is given, there was old and well-marked prolapse of the rectum. The rupture was always produced during an effort—four times during defæcation, once during vomiting, once while lifting a heavy weight, and once in consequence of the patient's straining while the surgeon was endeavoring to reduce a prolapse of the rectum. Excepting for rectal prolapse, the patients were well prior to the rupture. The rupture in each case took place suddenly, at the moment of effort. The patient felt acute pain in the belly, with general malaise, and perceived a voluminous mass protrude from the anus. Sometimes the protrusion was preceded by hemorrhage. The general condition quickly became worse, the face pale and Hippocratic, the voice feeble, the extremities cold; the intellect remained clear. Disappearance of the prolapse immediately followed the protrusion of intestine. The straining of the patient quickly caused the expulsion of more intestine, which formed a mass hanging between the thighs, and soon became congested and inflamed. When examination is made in such cases, the relaxed sphincter commonly offers no obstacle to digital exploration, and the pedicle of the protruded swelling can be followed up to the rent in the bowel, unless the latter should be too high up to be reached. The only treatment at all likely to be of service, of course, is the reduction of the mass. This is very difficult. In two cases laparotomy was performed and the bowel pulled up. In another the protruded intestine was opened and evacuated of fæces and flatus. After the protruded intestine has been reduced, the rent in the rectum should be sutured. If it be possible to reduce the intestine *per rectum*, the laceration may possibly be also sewn up in the same way; or the rectum, if previously prolapsed, may be pulled down and then stitches put in. We would remark, with reference to this proceeding, that in the present day laparotomy is not so dangerous a proceeding as it was in the days when some of the cases which M. Quénu quotes occurred; and hence that probably now, in the presence of so grave an accident, few surgeons would hesitate to open the abdomen, pull up the prolapsed bowel, and suture the wound. To elucidate the pathogeny of this accident, M. Quénu has made experiments to ascertain the resistance which the rectum offers to a bursting force. Having stitched up the anus, he pumped air into the rectum, measuring the pressure. He found that the rectum would bear, without giving way, a pressure equal to that of a column of mercury sixty centimetres high (about twenty-three inches). When the pressure passed that of seventy centimetres, the peritoneal coat began to crack, and the other coats followed. We may add that Schatz has shown that the ordinary pressure within the rectum is equal to that of a column of mercury from twenty-five to thirty centimetres high, and that it sometimes rises to that of fifty centimetres of mercury. He also tried by forcing injections into the veins to rupture the rectum; but the anastomosis was so free that this result did not happen, and, moreover, at a pressure of forty to fifty centimetres, the vein burst in the meso-rectum. The explanation which M. Quénu holds as probably correct, is that the rupture takes place in a bowel in which the veins are varicose, its walls congested by prolapse, and softened by infiltration of leucocytes and inflammatory effusion. He points out that in the three recorded cases of spontaneous rupture of the œsophagus, one occurred in an immoderate drinker, and the other two were preceded by vomiting of blood; from which he concludes that the condition of the œsophagus in them probably resembled that of the rectum in the cases under consideration.—*Med. Times and Gazette*, August 5, 1882.

NORWEGIAN METHODS OF DEALING WITH CONTAGIOUS DISEASES.—The sanitary organization of Norway was fixed by the law of May 16, 1860, which provides that each district, urban or rural, shall have a board of health, to consist of the district physician, an engineer, one of the magistrates, and three citizens. When a parent or householder has in his residence a case of contagious or malignant disease, he must report the fact at once to the president of the board of health. The attending physician is also required to report such cases.

When the board of health considers that the safety of the community is menaced by the presence of contagious disease, it has very great power of interference. It can divide the district into subdistricts, and place any of these under special supervision, can appoint physicians, establish temporary hospitals, and, if necessary, take any building for a hospital, the damages being fixed by a special jury. Each board prepares rules and regulations, which, when approved by the king, become law for that particular district. Taking Christiana, the capital, as a specimen, we find that these rules require physicians to make a daily report of the specially dangerous diseases, including small-pox, cholera, ty-

phoid fever, typhus, scarlet fever, measles, puerperal fever, erysipelas, diphtheria, and dysentery.

The city has the most ample hospital accommodation for each class of the sick. The hospitals for small-pox, cholera, typhus, scarlet fever, measles, being each separate and distinct, besides a hospital where persons suspected of having contracted a contagious disease can be kept under observation without exposing them to danger.

When a case of contagious disease is notified, the physician attending may advise his removal to hospital. In this case an order is at once issued, and the sick man is at once taken to hospital, his clothing, bedding, etc., are disinfected by dry heat, and the room is disinfected by burning sulphur.

In case of typhoid fever, the privy vault, if there is one, is emptied and disinfected. All this is done under the supervision of the city physician of the ward. If the attending physician does not desire the removal of the patient to hospital, he confers with the city physician or health officer, who has discretionary powers. In case of small-pox or typhus, it is rare to permit the patient to remain out of hospital.—*The Sanitary Engineer*, October 5, 1882.

Cotton Seed in Spasmodic Croup.—Dr. G. L. Gray, in *Miss. Val. Med. Monthly*, states that he has used this remedy successfully. Take a handful of seed, bruise them, boil in a quart of water for a few minutes, let it stand a short time, strain, sweeten, and when cool enough give the patient all he will drink, or, if necessary, pour it into the child. The relief is generally prompt, and sometimes without emesis. If persisted in, it produces free emesis. Dr. Gray also states that he has used the remedy with benefit in two cases of asthma.

Tuberculosis of the Heart in Children.—The following case is narrated in the *Louisville Medical News*, October 14, 1882: "A girl, eight and a half years of age, was admitted to the Children's Hospital, suffering from a remittent type of fever. The heart's action was tumultuous, with diffuse impulse; the heart-sounds were distinct, but somewhat dull. The area of precardial dulness was not increased; a rather obscure friction-sound was heard over the cardiac region; the pulse was quick and small. The duration of the disease was fourteen days. On post-mortem examination miliary tubercles were found in the lungs. The bronchial glands were enlarged and in a state of caseous degeneration. The heart was of normal size, and the pericardium contained about two tablespoonfuls of lemon-colored fluid. Miliary tubercles were scattered singly over the heart's surface. Upon opening the left ventricle it was found to contain a tumor five centimetres long and three centimetres broad. It was covered by endocardium, had an uneven surface, and emerged from the junction of the anterior wall with the interventricular septum, so that the greater portion of the tumor projected into the ventricular cavity. A miscropic investigation confirmed the opinion that it was of tubercular nature."

Professor Hirschsprung also reports a somewhat similar case of a girl, aged eight years, who was a healthy-looking child, but on admission to the hospital had serious symptoms pointing to the cardiac region, and represented by a tumultuous action of the heart, diffuse pulsation, increased cardiac dulness, slight cough, heightened temperature, and increased respiration. Dyspnœa and cyanosis set in, and the child died seven days after entering the hospital. A tubercle as large as a walnut was found in the internal wall of the left ventricle; a few miliary tubercles in the anterior part of the left upper lobe, and nowhere else in the lung; the bronchial glands, especially on the left side, were found in a state of cheesy degeneration, as were also the mesenteric glands; there were tubercles in the spleen and pericardium. The liver and spleen were enlarged, and the intestinal glands swollen, but not ulcerated.—*Jahrbuch für Kinderheilkunde*, vol. xviii., 1882.

Injections of Hot Water in Dysentery.—Dr. John G. Earish gives, in the *College and Clinical Record*, the history of three cases of dysentery, in all of which copious injections of hot water resulted in almost instantaneous amelioration of all the distressing symptoms, followed by a speedy cure.

Amyloid Tumors of the Conjunctiva.—In an elaborate article on the clinical significance of so-called amyloid tumors of the conjunctiva, Dr. Kubli, of Dorpat (*Knapp's Archives*, vol. xi., 1882), states that in the preliminary stages of the affection the conjunctiva is the only tissue attacked. Later on, however, other portions of the lids, or even other ocular tissues, may become involved. In twenty-seven cases (thirty-seven eyes), the whole conjunctiva was affected in thirteen, the conjunctiva fornicis in one, the scleral conjunctiva in four, the tarsal conjunctiva in one. The prevalent locality is the upper fold and neighboring portions of the tarsal conjunctiva. He divides the stages of development into four: 1, simple adenoid proliferation of the subconjunctival tissue; 2, hyaline degeneration; 3, exquisite amyloid degeneration; 4, calcification and ossification. If the neoplasm be poorly supplied with vessels, it is generally of a bright yellow color, glassy and elastic; if highly vascular, it varies from reddish yellow to reddish brown. During the first phase of development the most common symptoms are heaviness of the lids and increased sensibility of the eye to various influences. In the second the surface of the tumor becomes smooth and glistening. The greater the vascularity of the tumor, the less its consistency. Tumors in this phase are harder than those in the first, and more elastic than those in the third. In the third the consistency varies from hard to gelatinous, depending on the degree of vascularization. The tissues sometimes pit on pressure. In the fourth phase the amyloid degeneration is complicated with the presence of chalk or true bone, sometimes deeply situated in the tumor, and discoverable only by the microscope. The disturbances caused by amyloid tumors are chiefly mechanical, and include deformity, impaired mobility always of the lids, and often of the globe, ptosis, and secondary affections of the cornea, pannus, and consecutive impairment of vision. The disease has nothing in common with trachoma, but originates in a hitherto healthy conjunctiva. The simultaneous existence of trachoma and amyloid degeneration must be looked on as accidental. Relapses sometimes occur after extirpation, and the author thinks that they are frequent in proportion to the degree in which true amyloid degeneration has taken place. The treatment, when possible, should be radical extirpation at once, but, if not, then partial extirpation at intervals, in order to prevent symblepharon. The chief point in the after-treatment is to cleanse the conjunctival sac frequently and thoroughly with a two per cent. solution of boracic acid, which does not irritate.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, December 2, 1882.

THE EARLY RECOGNITION OF DISEASE OF THE KIDNEY.

THE importance of an early recognition of kidney disease and an accurate knowledge of the agents or influences which tend toward its development can be appreciated only when we consider how comparatively easy it is, in many instances, to interrupt early the course of this disorder, and, in other cases, how much may be done to avert a fatal issue, even after the disease has passed through its initial lesions and has become *chronic*. Until quite recently it has been generally taught and believed that the only trustworthy manifestations of the chronic forms of Bright's disease were such as œdema of the face and lower extremities, pallor of the skin and mucous membranes, pain in the back and loins, gastric disturbances, and increased or diminished flow of urine containing albumen and casts. More recent investigations, however, show that there are other symptoms, more or less constant, which point toward the existence of this obscure lesion.

Dr. Arthur V. Meigs, of Philadelphia, shows in a report of sixty-two cases of albuminuria that *dyspnœa* associated with great nervousness and loss of self-control, with no other sufficient cause for its existence, should excite the suspicion that there exists a lesion of the kidney. These attacks of dyspnœa frequently come on with great suddenness in persons who have not considered themselves sick, and such attacks are often quite rapidly fatal. This condition has been described as *renal asthma*, but he believes it to be much more common than is usually supposed. Another symptom considered valuable is *coryza*, of a character more severe than the ordinary cold in the head. With it there is not much nasal discharge, but the patient finds it difficult to breathe, except through the mouth. Associated with this condition there is excessive oppression—more than can be accounted for by the local disturbance. The presence of tube-casts is regarded as a proof of the existence of Bright's disease, but not a distinctive mark of any one of its varieties, for any form of tube-cast may occur in any division of the disease, and at almost any stage, or all the varieties may occur simultaneously in one case. The appearance of oil-casts and cells need not always excite great alarm, for they have been found for many weeks in the urine of patients who have recovered. Tube-casts may occur in the urine *without* or in *advance* of the presence of albumen, or, on the contrary, there may be albumen constantly, without tube-casts. It is also stated that the presence of albumen and tube-casts, even though found for so long a time as *two* years, is not a sufficient reason for giving a *fatal prognosis*. As to etiology, the existence of oxaluria or of uric acid lithiasis is a prolific source of mischief to the kidney. The presence of this gravel usually precedes the appearance of albumen and casts.

Dr. T. A. McBride, in his recent monograph on "The Early Diagnosis of Chronic Bright's Disease," in touching on the points already referred to, coincides with Dr. Meigs. He further states that increased arterial tension is a valuable sign, being present in the *acute* and chronic forms. The qualities of the pulse in high tension are described as *long*, *persistent*, *hard*, or *incompressible*. The tension is appreciated by gliding the finger along the artery forward and backward, and from side to side. In the first or highest degree the artery feels like a cord or tendon; in the second degree, like a rubber tube distended with fluid; in the third degree, like a fine rubber tube. Hypertrophy of the heart, especially of the left ventricle, is very constantly found, the following statistics showing its frequency: Bamberger discovered hypertrophy of the heart in 344 out of 807 cases of chronic Bright's disease; Traube, hypertrophy of *left ventricle* in 93 cases out of 100. Grainger Stewart records 31 cases out of 68 of chronic Bright's disease.

The analysis of two hundred and fifty cases of granular kidney, drawn from St. George's Hospital books, gives forty-eight per cent. as the proportion of cardiac enlargement. *Chronic endarteritis*, especially of the *temporal* and *radial* arteries, when it can be determined not to be the direct result of the usual causes, is a forerunner of chronic renal inflammation. The *initial* stage of chronic interstitial nephritis, contracted kidney, manifests itself in the following symptoms: persistently high specific gravity of the urine, the very frequent presence of *large* crystals of uric acid, and more occasionally of crystals of oxalate of lime; persistent presence of high arterial tension, the early detection of beginning hypertrophy of left ventricle, the occurrence of murmurs,

denoting valvular insufficiency, and the early detection of chronic endarteritis. The causative relationship between *impaired functional activity* of the *digestive organs* and the chronic inflammatory lesions of the kidney, is shown in the following manner: the nitrogenous material, imperfectly oxidized, is taken up by the blood, carried to the kidneys, exerting upon them a directly stimulating effect, maintaining in them a constant state of functional hyperæmia, and by increasing the general capillary resistance, raising the systemic blood-pressure, so as to keep up a permanent strain on the organs of circulation. This condition is *at once* marked by dyspepsia, constipation, lassitude, headache, muscular pains, coldness of extremities, tendency to pharyngeal or tracheal catarrh, resulting finally in cardiac dilatation, and hypertrophy, chronic bronchitis, dyspnœa, chronic gastric catarrh, arterio-capillary fibrosis, and *interstitial nephritis*. It is very important to note the *quantity* of urine passed in twenty-four hours. In chronic parenchymatous nephritis the amount is usually *below* the normal, it may be as low as ten or twelve ounces in twenty-four hours; or a small amount may be passed for a *few days*, then a normal quantity voided for a while. In chronic diffuse nephritis the amount may be small at first, then normal for a few days; the longer the patient lives the larger the flow. In chronic interstitial nephritis Grainger Stewart thinks that in the early stages of the small kidney the urine is not increased in quantity, while Dickinson and Saundby believe that an increased quantity of urine appears early. The intercurrent affections, most commonly found, are *emphysema*, bronchitis, pneumonia, and cerebral hemorrhage. With this new light thrown on the symptomatology of the disease in question, we are enabled to interpret correctly certain indications which before had no special significance.

THE HEALTH OF AMERICAN WOMEN.

THE "Health of American Women" is the title of a symposium which appears in the current number of the *North American Review*. This magazine shows itself courageous as well as enterprising in thus bringing a topic before the public which necessarily involves discussions and allusions that have generally been thought too delicate for the ordinary reader. The *Review* has done a good and timely act in thus presenting a subject so strikingly to the public.

The writers in the symposium are Dr. Dio Lewis, Elizabeth Cady Stanton, and Dr. James Read Chadwick. Dr. Lewis, assuming the fact of a very large amount of ill-health among American women, directs his remarks chiefly to the cause and cure. Chief among the causes he puts the corset, while for the cure of female ills he recommends removal of that delusive appendage and systematic physical education. Dr. Lewis writes from the standpoint of a partisan. Much that he says is true, yet it is not true that corsets and heavy skirts necessarily cause disease. They form only one of numerous other factors. We must have other than sidewalk observations also to prove that they uniformly reduce the size of the waist from three to fifteen inches. As for physical exercise, its usefulness and necessity are of course admitted. Dr. Lewis has done good service in forcing this point upon the attention of educators.

Mrs. Stanton touches upon nearly every phase of the woman question in her brief article. Co-education, wider scope for woman's energies, and in general her liberty and elevation to equality with man would, according to this writer, remove many of the physical evils that attach to women.

Dr. Chadwick's article contains much more to attract the attention of the thoughtful and especially of medical men. The most prevalent and potent causes of ill-health in American women, he says, relate to education, climate, and food and drink.

Dr. Chadwick refers at once to the radical views propounded by Dr. Edward H. Clark about ten years ago on the subject of the education of girls. To these views our writer is strongly opposed. He believes that the function of menstruation is essentially one of elimination. The system throws off every month materials accumulated in excess for an emergency that does not occur. It should, therefore, not necessarily involve a special demand upon the vital powers any more than does the exercise of other emunctories. It is admitted that severe disturbances do very frequently occur at the present day in American women. But these are because she has been the victim of a defective training and education, by which there has been developed "an abnormal acuteness of the sensory faculties." The remedy, therefore, is to subject the female sex, from earliest childhood to full womanhood, to a systematic course of physical and mental exercise. "Let us," says Dr. Chadwick, "store their minds with useful information; let us disclose to them the entrancing interest of nature and nature's laws; and finally let us open as an end and motive for their efforts, the same fields of labor, with the prospects of reward, as are now open for men."

Dr. Chadwick is undoubtedly right in his view that in a normally developed woman menstruation should not make any great or special demands upon the vital powers. Perhaps he puts the matter somewhat too strongly, for physiology, human and comparative, teaches us that at the menstrual period there is necessarily some nervous perturbation over and above the simple process of eliminating superfluous blood and epithelium.

It must also be shown that some of the existing menstrual demands upon the vital powers of women

are not necessary accompaniments of a high state of civilization.

As for the educational remedies offered, we believe that the medical profession will endorse the physical but not the intellectual part of Dr. Chadwick's programme. A strong, vigorous woman may be sensitive and emotional without having dysmenorrhœa. It is a serious question whether she would not be less likely to have menstrual troubles than if she were studious and intellectual.

We greatly doubt if the pointedly intellectual education of women will ever help the sex as a whole. Woman's intellectual contributions to the world's progress have so far been trivial. It is impossible that they should ever be great so long as a large share of her energies must be absorbed in the function of maturity. Woman's power and usefulness rest upon other things than her erudition. It would be unwise and impracticable to enforce upon the whole sex systematically and persistently "useful information" and exclusively "mental exercises." While these things may be made more of than is done at present, we should say that it is physical education and prudence which will do more for American women than any store of facts or study of natural law.

Perhaps, after all, we do not differ so greatly from Dr. Chadwick. All admit that ignorance is dangerous and knowledge is useful to women. It is only a question of how much and how pertinaciously facts, hard and otherwise, should be driven into them. We advocate, as a healthful education, that kind which brings out all that is latent or potential. An education which embraces the sciences rather than the arts would be more likely to strain than develop the female mind.

Regarding the influences of our climate nothing new is told us. The effects of its stimulating dryness as well as of the piercing winter cold which compels in-door life are well known.

The food and drink of American women is justly criticised. The former is abundant but of a bad quality and badly cooked. In tea, women have an enemy which, according to Dr. Chadwick, is comparable to tobacco with men.

Some interesting facts are given regarding the fertility of American women. He publishes statistics which indicate, though they are insufficient completely to show, that the period of fertility is greater in American women than in the English or Irish, being respectively 31.85, 31.35, and 29.16 years. It is inferred that the small present fertility of American women is due not to physical but to social causes.

Dr. Chadwick closes with the statement which will be generally accepted that American women are not less healthy than those of most other civilized races. Nor does he think that any of the causes of impaired health in American women are inherent in our climate, institutions or social customs.

THE ASYLUM REFORM MOVEMENT AND THE NATIONAL ASSOCIATION.

We have received a circular from the Secretary of the National Association for the Protection of the Insane and the Prevention of Insanity, announcing some new departures in the plan of the Society's work.

Many things, we are told and believe, have combined to encourage this organization and stimulate it to greater activity. The stupid self-contentment which characterized so large a part of the asylum superintendents has been at last much disturbed. Those who have most pretended to ignore the teachings of reformed psychiatry have, in a half-clandestine manner, begun to follow its suggestions.

A considerable number of superintendents are becoming rather more interested in insanity than gardening—which could not be said ten years ago. There is in fact a break in their once solid and stolid ranks. The use of mechanical restraint has vastly diminished; employment and freedom have taken its place. Many superintendents are in full harmony with the reform movement represented by the Association.

But for all this, sufficiently serious work remains to be done. We are confronted with the fact that the United States contains 100,000 lunatics who need care and watching, and that 10,000 new victims of mental disease knock at our asylum doors every year, asking for admission and right treatment. Yet we cannot point to more than half a dozen States where the asylums are conducted independently of political rings, or where they are managed as though they were medical institutions with patients whose diseases deserved scientific study. As yet, in the public opinion, insanity is more than a misfortune, and more than a disease. Asylums are looked at as prisons, and their superintendents as keepers, never quite above corruption. This sad lack of confidence in our asylum system is shown almost every week. The opinion of a county judge or a third-rate lawyer is accepted before that of the most venerable expert. The public trusts all things before it does an insane asylum.

Certainly, therefore, matters want mending. The people need instruction, our system of care for the insane needs to be such that we can ask people to have confidence in it. Besides, there is the question, how shall we lessen and prevent insanity?

The National Association proposes to work for all these objects. It has obtained active correspondents in nearly all the States, who will report upon local deficiencies, local wants, and progress. A national journal or bulletin is to be issued regularly, and is to contain reports of progress in scientific and economic reform. We observe the names of Dr. Bancroft, Dr. Walter Channing, Dr. C. K. Mills, Dr. Peter Bryce, Dr. Bannister, and others, who are to

be connected with the future work of the Association.

A meeting will be held in Philadelphia, January 25th, when further active and aggressive work will be inaugurated.

THE IMMIGRANT INSPECTION SERVICE AGAIN.

On June 1, 1882, the immigrant inspection service went into operation in the West, under the direction of the National Board of Health.

We have already referred to the reports of the Supervising Inspector, from which one concludes that nearly twenty per cent. of Western immigrants are imperfectly protected against small-pox.

The monthly reports give more fully analyzed data. Of 16,473 immigrants who were examined in October, 4,728, or nearly 30 per cent. were susceptible when they landed. Nearly 1,400 of these, however, were vaccinated by Eastern inspectors, the work being finished by Dr. Ranch's inspectors.

Under the present system it is quite plain that very few unprotected immigrants escape vaccination by the time they reach the West. It is equally clear, however, and we wish to reiterate the fact, that this system is cumbersome, expensive, and unnecessary.

It is now the custom for the ship-surgeons to examine and vaccinate the immigrants. The port health officer and Eastern inspectors examine them again and vaccinate as many as they consider necessary; finally the Western inspectors re-examine and complete the work.

Much of the time and labor thus expended might be saved if the ship-surgeon did his work properly. The tables show that in some steamers the number of imperfectly protected immigrants reaches from thirty to fifty per cent., while in other cases it sinks as low as five per cent. We are told also that some steamship companies buy cheap virus in large quantities, and keep it till it is all used up. It is but fair that these companies should be compelled to land none but protected immigrants at our ports. The vaccinations can readily be done on shipboard during the voyage, thus avoiding all the delay and expense now incurred.

PATHOLOGICAL EXPERIMENTATION AND THE ERYSIPELAS-COCCUS.

If the present enthusiasm over experimental human pathology in Germany continues, there may be needed a society for its prevention. We recently made note of the case of a German surgeon who resected part of a human lung. Although the operation was measurably successful, the patient very soon died, and the doctor was remanded to a jury. A case is now reported of a somewhat similar result, obtained in experimenting with the bacteria of erysipelas.

The view that erysipelas has a specific micrococcus has been upheld by several pathologists. The test of cultivation and inoculation, however, was first made, so far as we know, by Dr. Fehleisen. His experiments were reported not long ago at a meeting of the Würzburg Society of Physiological Medicine. Dr. Fehleisen stated that in a great number of cases of erysipelas which he had examined he always found in the diseased skin peculiar micrococci. He tried to cultivate these in the fluid from the blebs, but without success. He then used Klebs' culture-fluid, composed of flesh-infusion and gelatine pepton. In this fluid he placed small bits of erysipelatous skin containing the micrococci. These "erysipelas-cocci" grew there, and could be transferred to other previously barren fluids, where they speedily developed again.

To prove that these transferred organisms were specific, there only lacked a suitable opportunity to inoculate them. This opportunity was finally offered in the person of a woman suffering from multiple fibro-sarcomata. The inoculation was made, and with such success that the patient died. It is considered proved, therefore, that erysipelas is due to the presence and malign activity of a special bacterium. It may be that the patient who thus died to reveal a scientific truth was moribund, and would have died anyway. She may also have been quite conscious of the danger to which she risked herself voluntarily. But there are some doubts of all this, and we would at any rate suggest to pathologists to bear in mind that human life is worth rather more than a micrococcus or a surgical theory.

Dr. Fehleisen is continuing his investigations, but now employs rabbits.

An Old Physician Gone.—Probably few remember when Dr. Edward N. Bibby, who recently died at the age of ninety, practised medicine in this city. He began his professional career with Dr. Bruce in 1815. After about twenty-five years of successful work he retired, and has been known since then chiefly in social circles. He retained his faculties to the last, prescribing for himself five minutes before his death.

Death of Dr. Christopher C. Cox.—Dr. Christopher C. Cox died in Washington, November 25th. He was born in Baltimore, Md., in 1816, graduated at Yale College in 1835 and was made Doctor of Laws by Trinity College in 1867. Dr. Cox practised medicine in Washington for many years, holding at the same time a number of responsible positions. He was appointed Commissioner of Pensions in 1868, and a member of the District of Columbia Board of Health in 1871. He was for one year a Professor in one of the Philadelphia colleges. He also served as a surgeon in the army during the rebellion, and as Surgeon-General of Maryland. Before the close of the war he was elected Lieutenant-Governor of Maryland. He was also a Commissioner to the Australian Exposition. He was a man of fine literary attainments, some of his published poems having obtained a wide circulation. His professional skill was widely acknowledged, and he was among the leading practitioners of his city.

Reviews and Notices of Books.

A Guide to Therapeutics and Materia Medica. By Robert Farquharson, M.D., Edinburgh, F.R.C.P., London. Third American Edition. Enlarged and adapted to the U. S. Pharmacopœia, by Frank Woodbury, M.D. Philadelphia: Henry C. Lea's Son & Co. 1882.

The author, in this volume, institutes a comparative estimate of the absolute importance of medicines, giving, in this way, satisfactory laws for our guidance in the administration of such remedies as are best calculated to hasten recovery from morbid conditions. Some very practical remarks are made on *the proper time* for the administration of drugs, individual peculiarities, and chemical and physiological incompatibilities. The art of prescribing for children, a subject usually only incidentally touched upon, is represented in such a manner as to correct some erroneous views entertained by many therapeutists. It is stated that the organs of elimination in children are in unusual activity, therefore disposed to excrete medicinal substances with special promptitude. For this reason doses equally large with those for adults may be given, not only with impunity, but with decided advantage.

Questions on Human Anatomy. By Samuel O. L. Potter, M.A., M.D. Sixty-three Illustrations. Philadelphia: P. Blakiston, Son & Co. 1882.

This little volume is practically a digest of the larger works on human anatomy, presenting to the student a concise arrangement of questions and answers which would greatly facilitate the study of anatomy prior to graduation.

Acute Dilatation of the Heart.—Dr. Heitler, Docent in Vienna, who first called the attention of the profession particularly to acute dilatation of the heart, in a paper lately published, is preparing a much more elaborate one, in which he will go more especially into the literature of the subject. Frequently before his hearers he will demonstrate a case of acute dilatation which in a few minutes has almost entirely disappeared. According to the length of duration of the dilatation is the prognosis favorable or not. He has never seen a case follow simple fatigue or excessive exercise; it is most frequently during the fevers, such as typhoid. It happens in pneumonia, Bright's disease, chlorosis, anæmia, and also when there is chronic dilatation with valvular insufficiency and hypertrophy. The sudden dilatation may occur many times in the same individual, and sometimes it lasts for several hours with the gravest symptoms. Digitalis, which Dr. Heitler calls a heart-tonic, and rest with quick and sharp percussion over the heart he recommends in the treatment. It is to be hoped this suggestion of Dr. H.'s will be thoroughly worked up, since many symptoms may thus be explained which have puzzled even the best auscultators.—*Cor. of Maryland Medical Journal.*

The Inhabitants of Kentucky and Tennessee, says the *Louisville Medical News*, are the tallest people in the world. The men weigh from 154 to 158 pounds on the average, and the women, though weighing somewhat less, are, our contemporary proudly adds, of extraordinary beauty.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 8, 1882.

R. E. Van Gieson, M.D., President *pro tem.*

Dr. W. M. Carpenter presented, in behalf of a candidate, a specimen of

DERMOID CYST OF THE OVARY.

Dr. Willard Parker, Jr., presented, in behalf of a candidate, a specimen of

FIBRO-SARCOMA OF THE BREAST.

Dr. J. H. Ripley presented portions of membrane removed from the trachea, accompanied by the following history:

PRIMARY CROUP—TRACHEOTOMY—DIPHTHERITIC CROUP.

"Richard Mc——, six years of age, had had a cough for two weeks, which was only troublesome at night, otherwise he was in fair health. No dyspnœa had been observed by his grandmother, who had him in care, until the morning of October 16th. In the evening of that same day Dr. Leipziger was called to see him, and found the dyspnœa very distressing. He sent for his neighbor, Dr. Cushman, and both decided that the patient's only chance was in having tracheotomy done. I was asked to do the operation, and saw the child at once. The dyspnœa was then extreme, the face and extremities cold and clammy, and the intellect clouded. The pulse was full and slow, the respiration frequent, the temperature subnormal. There was no swelling of the neck or tonsils, no nasal discharge, and no membrane to be seen either in the nose or throat. Chloroform was sparingly given, and the trachea opened without delay, Drs. Leipziger and Cushman assisting. Much purulent matter escaped from the wound, but no distinct shreds of membrane. Soon after the operation the temperature became normal, the respiration easy, and the evidences of imperfect oxygenation disappeared.

October 17th, 10 A.M.—Breathing easy, and child looking well. Still no membrane to be seen and no swelling of neck or glands. 6 P.M.: Has coughed up several pieces of membrane and a piece is now heard flapping in the trachea. There is a profuse discharge of muco-purulent matter from the right nostril, and the left tonsil is red and swollen, and partly covered with a milk-white membrane.

October 18th, 10 A.M.—Neck is much swollen, face congested and perspiring, respiration somewhat embarrassed, nose still discharging, wound covered with membrane; several pieces of membrane are removed from the trachea, but breathing is not relieved. 6 P.M.: Boy has passed only four ounces of urine to-day, and it is albuminous, and contains both red and white blood-corpuscles.

October 19th.—Morphine enabled the patient to pass a comparatively comfortable night. His general condition this morning is very unfavorable. The neck is enormously swollen, two large serous blebs have formed near the edges of the wound, and both tonsils are covered with membrane; respiration and pulse have increased in frequency, and the temperature has fallen from 103° to 101° F. The urine remains scanty, and the proportion of albumen has increased. The child is rapidly failing. 6 P.M.: Died at 5 P.M. of asthenia.

Steam lime-water spray, pilocarpin, and other remedies were faithfully tried by Dr. Leipziger, who had charge of the case."

The points of special interest in the case were the following: The child at first presented all the rational symptoms of so-called membranous croup, but there was no glandular swelling, nor could membrane be seen, and yet the child was evidently dying of laryngeal stenosis. After the operation all the symptoms of constitutional poisoning developed, and were so marked there could be no doubt that it was a case of diphtheritic croup. He believed that contagion would not have necessarily followed exposure to the case when he first saw the child. Granting that there was such a thing as pseudo-membranous croup, he believed that the early symptoms, in such cases, gave no clue as to what was to follow, and no man could predict what would be the condition of the case on the next day. Hence it was necessary to remove at once all children from exposure without reference to the apparent mildness of the attack.

Dr. Van Gieson confirmed the remarks made by Dr. Ripley, by referring to cases which recently came under his observation. The attending physician, an eminent practitioner, had told the parents that there was no danger, and that the other children need not be removed. Two children died, and the third barely escaped. He believed it was eminently safe to remove the other children in a family, no matter how mild might be the attack of the first child, and also without reference to what our belief might be.

PECULIAR EXOSTOSIS OF THE FEMUR.

Dr. J. A. Wyeth presented the left femur which had been fractured. It exhibited an exostosis at its upper portion, an inch and a half long, about one-fourth of an inch in diameter, and projecting *downward*.

RECOVERY FROM A GUN-SHOT WOUND OF THE KNEE.

Dr. Wyeth also presented a specimen removed from the body of a man who received a gun-shot wound of the knee-joint, and recovered with motion. There was a wound of entrance and exit, and the missile, either a Minié or a Belgian ball, passed beneath the patella and clipped off a piece of bone from the surface of each condyle. The surface of the internal condyle had been entirely obliterated. Recovery had been so complete that what remained of the track of the bullet was non-articular. There was no anchylosis.

Dr. G. L. Peabody presented a specimen of

HEMORRHAGE INTO THE PONS VAROLII.

A. C——, aged fifty-seven, of Ireland, widow, servant, was admitted to the New York Hospital April 14, 1882. She was brought into the hospital in a moribund condition, artificial respiration having been necessary in the ambulance. An incomplete previous history was obtained from her friends. She had had a number of severe pulmonary hemorrhages within four years past. This morning she started to go to her work, complaining of headache and dizziness, and very suddenly she became unconscious. A physician was summoned, who found her suffering from œdema of the lungs, and gave her brandy hypodermically.

On admission she was emaciated and anæmic. There was no œdema. The muscular tissue was very flabby, and she presented an appearance of senility. Her skin was warm and dry; her pupils dilated and immobile. She was completely comatose; reflexes were all absent, and she did not respire. Both heart-sounds were audible, and the radial pulse could still be felt. A faradic current was applied to the phrenic nerves, and brandy, ether, and digitalin were administered hypodermically. Presently she gasped twice, and the respiration again ceased. Artificial respiration was resorted to and continued for nearly half an hour, but without avail. The radial pulse soon disappeared, and the heart ceased to beat.

At the autopsy it was noticed that the convolutions of the brain were generally somewhat flattened. The third ventricle contained a small clot of blood, and the fourth ventricle was completely distended by blood. The tissue of the pons was almost entirely disintegrated by hemorrhage.

The heart contained an enormous amount of fat, in many regions the transverse striæ having been rendered quite invisible. The left ventricle was somewhat hypertrophied.

The kidneys showed the common lesions of advanced diffuse nephritis.

Dr. Peabody also presented specimens illustrating

PIGMENT IN THE BLOOD-VESSELS OF THE BRAIN, SPINAL CORD, LIVER, AND SPLEEN.

E. H——, forty-nine years of age, United States, widower, mariner, was admitted to the New York Hospital on November 6, 1882. He was quite conscious, though greatly depressed. He was suffering from a chill, his temperature being 100° F.; pulse was 120, full and bounding; breathing was good. He soon began to suffer from general convulsion; later the convulsions were confined to the upper extremities. His temperature became quite irregular soon after admission, rising to 102° F., and then again falling to normal.

It was impossible to obtain urine, at first, for examination, because his penis exhibited the condition of hypospadias, and the meatus was too small to admit a catheter. He passed it involuntarily, in apparent abundance. About a drachm was finally obtained for examination, and found to contain albumen and granular casts. He was given croton oil, and put into a hot-air bath. The oil did not operate, but he was soon in a profuse sweat. Subsequently the administration of more croton oil was followed by free purging. Soon after this he roused himself sufficiently to talk about his condition. In the evening convulsions suddenly returned with increased intensity, respirations were accelerated and noisy; pulse became 130 to 140, and his temperature (which had been normal at 6.40 P.M.) began to rise rapidly.

At 1.30 A.M. on the following morning his temperature was 104° F., and he was completely unconscious. The hot-air bath was again resorted to with the effect of producing morbid sweating, but without causing the temperature to fall. At 2 A.M. it was 105.4° F., his pulse became weaker, œdema of the lungs developed, and soon thereafter, despite cupping and stimulation, he died.

The autopsy was held on the afternoon of the same day. The chief lesions of interest were in the gray matter of the brain, in the spleen, and in the liver. The gray matter of the brain was much darker gray than usual, while the liver and spleen were of a very dark brown hue. The changes in color were due to the presence of a large amount of granular pigment within the blood-vessels of these organs. He had found that in the brain the pigment

was not confined to the vessels of the gray matter, but also existed in those of the white matter. In the liver it was chiefly in the vessels, not altogether, and was also in the connective tissues. He had also found it in the white blood-cells.

Dr. Peabody exhibited hardened sections of brain and kidney taken by him some years ago from a similar case. They exhibited the vessels, even the small ones, of the brain almost as distinctly marked out as if they had been injected; in the kidney the vessels of the Malpighian tufts, being the first of the two sets of capillaries through which the blood has to pass, contained large quantities of pigment.

The case was instructive regarding the diagnosis of similar ones, and suggested the propriety of examining the blood in all such conditions. He believed that if the examinations were carefully conducted, pigment would always be found *during* a paroxysm of the disease.

As to the etiology of the disease, he could only say, in view of the defective history, that the man had been a sailor, and suggested that he had probably been in the tropics, where malignant forms of ague were not infrequently contracted.

PIGMENTATION OF PIA MATER OF THE CORD.

Dr. Peabody further presented a specimen that illustrated the above condition. He had seen this condition several times, both about the cord and at the base of the brain, and in none of the cases was he able to trace any symptoms to it. The pigment in cases of this kind was not free in the lumen of the vessels, but was deposited in the fixed cells of the membranes, and was permanent, having quite a different etiology and significance from that in the organ first exhibited.

Dr B. Robinson asked Dr. Peabody if he wished to affirm that that pigment could be found invariably in the blood in malarial fevers.

Dr. Peabody replied that he did not wish to be understood as making that assertion, but he thought it could be found in all cases of pernicious fever if the blood was examined during the paroxysm, and taken from parts of the body where the circulation is not very active. If the blood was examined in the common way by removing a portion from the end of a finger, probably pigment would not be found uniformly; but, if the blood was taken from the back, pigment would probably be found in all cases in abundance. He did not, however, believe that pigment would be uniformly found in the blood in ordinary attacks of intermittent fever.

Dr. Robinson remarked that in a number of cases of intermittent fever he had examined the blood soon after the occurrence of the paroxysm, and had failed to detect pigment.

ANEURISM OF THE AORTA.

Dr. B. Robinson presented a specimen with the following history: It was removed from the body of a man, aged thirty-two, single, a native of the United States, and by occupation a saddler, who entered St. Luke's Hospital one week ago. He had always been healthy until two months ago, when he took a severe cold which was attended by a severe cough and the usual symptoms of acute bronchitis. The difficulty of breathing seemed to be no greater than could be accounted for by the bronchitis, but a few days afterward it increased and persisted until he entered the hospital. At times the dyspnœa was accompanied by severe paroxysmal attacks of coughing. On admission there was considerable dyspnœa, both inspiration and expiration being prolonged and noisy. Examination of the chest revealed no cardiac symptoms. There were no râles, but there was hyper-resonance on percussion and the physical signs of vesicular emphysema. The difficulty of breathing continued. Laryngeal examination did not reveal anything abnormal.

There was not much hoarseness; certainly no aphonia. There was no history of specific disease or strain. The stridor was marked in both inspiration and expiration; but there was no cyanosis nor œdema of the extremities. The diagnosis was acute vesicular emphysema, generalized, possibly developed by the acute bronchitis in an individual who had not presented any other signs of disease. The man became comatose and died.

At the autopsy there were found general emphysema of the lungs, and in the lower portion of the lower lobe of the left lung a possible condition of consolidation. The right ventricle contained a fibrinous clot. The larynx was normal. An aneurism of the arch of the aorta, about the size of a pullet's egg, was found, most prominent upon the left side and extending in front of the trachea, and it had evidently produced a certain amount of stenosis.

As bearing upon the theory that the fine chest râles are produced in pleural plastic exudation, it was remarkable that such râles were heard distinctly upon both sides under the clavicles, but upon one side only did there exist any plastic exudation.

Dr. Ripley remarked, concerning the general emphysematous condition of the lungs, that, some time ago, he presented a specimen of aneurism of the arch of the aorta, which pressed upon the trachea and one bronchus, and directed attention to the fact that the lung which did not receive the usual quantity of air was in a state of emphysema. He had also proved that those children who died with bronchial and laryngeal obstruction did not have pneumonia but emphysema. Dr. Robinson's case sustained his theory. Every case in which he had made an autopsy after death from croup had showed the lungs to be in the same condition, and to this he had also directed attention in connection with that subject.

Dr. J. Lewis Smith thought that in nearly all cases of recent catarrhal pneumonia in children the lungs could be inflated, and the same was true with reference to atelectasis; but that the two conditions could be differentiated by the semi-solid feel of the lungs in pneumonia.

Dr. Ripley believed it was impossible to inflate those lobules which were the seat of catarrhal pneumonia, unless they were only partially filled with inflammatory products.

TUMOR (LIPOMA) OF THE AXILLA IN AN INFANT FOUR MONTHS OLD.

Dr. Briddon presented a specimen with the following history: The patient from whom it was removed was brought to his office by its parents in company with their attending physician, Dr. Stephen I. Clark, on November 3, 1882. The parents were healthy-looking people, and were not aware of any such disease as that which afflicted the child having occurred in any member of the family on either side. The mother first noticed a swelling two months ago, about the size of her thumb; it was situated one inch to the outside of, and a little above the level of the left nipple; it had steadily increased in size, and twenty-four hours before Dr. Briddon's

examination it was explored by Dr. Clark with a hypodermic syringe, with negative results.

The child was four months old, large for its age, laughing, lively, bright and healthy in appearance; certainly bearing no evidence of systemic contamination. The left axilla was filled with a tumor fully as large as the closed fist of an adult. It bulged in front and below, passing upward into the apex of the space. It was ovoid in form, and its long axis was directed obliquely from the neighborhood of the anterior border of the scapula to the middle of the clavicle. The skin was free and did not dimple on lateral pressure of the tumor. It was slightly mottled, reddish, with a few superficial veins meandering over the surface. It yielded the deceptive sense of fluctuation, that was common to some malignant growths, and such was his opinion of its nature, but to satisfy Dr. Clark he explored it with an aspirating needle, with no different results than those obtained by the doctor himself.

Dr. Briddon recommended an operation, and gave a guarded prognosis as to the probable recurrence of the disease. In view of the dangers of such an operation in so young a child advised that it should be performed in the hospital; and at a consultation held there on November 7th, the doubtful character of the tumor was recognized by the attending staff.

Operation (Presbyterian Hospital, November 7th).—The tumor had visibly increased in size since last seen. The measurements taken by the house surgeon, Dr. H. B. McCarroll, were as follows: long diameter, six and one-half inches; vertical, five and a half.

An incision was made in the direction of the long axis of the tumor, dividing the skin and subcutaneous fat. The deep fascia was then divided on a director, when it was found that the anterior border of the growth was covered by the lower border of the pectoralis major muscle. This was divided obliquely upward suffiently to permit free access of the fingers, which were then principally used in freeing the growth from surrounding structures. A large lobe grew backward under cover of the anterior border of the latissimus, which was divided to afford more space; and there was then no further difficulty in enucleating the whole. The axilla was entirely emptied of everything, exposing the muscular boundaries and the vasculo-neural sheath that passes through it. The hemorrhage was insignificant, some of such vessels as were encountered being tied before, and others promptly after division. A drainage-tube was introduced in the most dependent angle, and the edges were approximated by interrupted sutures, and covered with a pad of antiseptic cotton.

The structure of the tumor, to the naked eye, resembled that of the fresh section of a pancreas. It consisted of two lobes connected by an isthmus, and weighed five and a half ounces.

The child made an uninterrupted recovery, and was discharged from the hospital on the 14th.

Report of the Pathologist, Dr. Satterthwaite.—"The tumor removed from the axillary region by Dr. Briddon, November 7, 1882, proved on microscopic examination to be a lipoma. In gross appearance it was lobulated throughout, separated by a constriction into two unequal halves, bluish pink color, quite different from that of most fatty tumors."

In evidence of the great difficulty sometimes encountered in the diagnosis of tumors it may be stated that there was absolutely nothing in the clinical history, or in the physical condition of this tumor, that appeared to warrant even a suspicion of its true nature. In fact, the pretty general impression of its malignancy led to a rather strenuous opposition to its removal, and at the meeting of this Society not a single member ventured to express an opinion from naked eye examination. Only the microscope revealed its character.

Dr. Ferguson presented specimens illustrating varieties of

DIVERTICULUM OF THE SMALL INTESTINE.

There were six preparations, and they illustrated anomalies of fœtal development. Originally they were processes of the umbilical vesicle which communicated with the intestine; usually with the lower part of the jejunum or ileum. From the intestine they pass downward and forward a varying distance toward the umbilicus, which they sometimes joined. Their structure was the same as that of the intestine from which they proceeded.

They were of interest pathologically because they produced peritonitis and sometimes death in different ways. First, when the diverticulum was small, foreign bodies taken in with food might lodge in it and produce peritonitis and death. Secondly, the diverticulum might become adherent, by local inflammation, to the intestines or to the parietal peritoneum, etc., thus forming conditions favorable for the strangulation of part of the intestine. Thirdly, a diverticulum might have a partially developed mesentery, forming an opening through which a loop of the intestine could pass and become strangulated.

Dr. Ferguson also presented a specimen of

ANEURISM OF THE ABDOMINAL AORTA, INVOLVING THE SUPERIOR MESENTERIC ARTERY.

It was removed from the body of a man, forty years of age; United States; married; laborer; accustomed to heavy work. He gave a history of syphilis, and had been a constant drinker of ardent spirits for several years. He first noticed pulsation in the epigastrium four years ago. This was followed by constant pain in the back, and later on pain developed in the region of the pulsation. Within a time which he variously stated as ranging from one to two years, he noticed a tumor in the epigastric region; it was tender to pressure but otherwise it was not inconvenient. He gave a history of having received a blow in the epigastrium a short time previous to his admission, which was followed by symptoms of collapse. He was admitted into the New York Hospital on October 28, 1882, and died the following afternoon with symptoms of internal hemorrhage. At the autopsy, there was considerable blood in the peritoneal cavity. Only the part presented was removed from the body. It consists of a section of the abdominal aorta four inches in length, connected with which was an aneurismal sac about three inches in diameter, containing recently coagulated blood and fibrin. This sac communicated with the aorta by an opening one inch in diameter. Extending from the upper and anterior part of this sac was the superior mesenteric artery, the first four inches of which were distended into an elongated sac, the wall of which was continuous with that of the sac below it. This portion of the artery was uniform in size, and about one and a half inch in diameter, and was filled with laminated fibrin.

The Society then went into executive session.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, October 24, 1882.

T. M. Markoe, M.D., President, in the Chair.

ANEURISM BY ANASTOMOSIS.

Dr. McBurney presented a patient with the following history: A boy, eleven years of age, had a disease of the vessels which was almost entirely confined to the external ear. He had been under the charge of Dr. Grovesteen. It had been ascertained that at birth there was possibly a slight difference in color of the two ears, but it was not until the boy was two years old that the difference was noticed by others than the mother. Since that time the increase in the size of the ear had been marked. It pulsated throughout, and the pulsations could be felt at different points distinctly. It had bled at different times considerably, particularly at a point just at the entrance of the external meatus. The growth had lately steadily increased in size. The pulsation could be entirely shut off by pressure upon the common carotid artery. Over the whole surface of the growth there was a distinct bruit, which could be heard with the stethoscope. The diagnosis was aneurism by anastomosis. The growth had been injected with persulphate of iron on one occasion; hot needles had been thrust into it on two occasions, and ergotine had also been injected. All these methods of treatment had been accompanied by considerable hemorrhage, which was somewhat difficult to arrest. The enlargement of the external jugular vein was marked, and the posterior auricular artery was also decidedly enlarged.

Dr. W. T. Bull about three months ago saw precisely a similar aneurism in the upper lip of a child about one year old. The lip was fully three times the normal size. It had been in the President's service in the New York Hospital, where the four arteries leading to the growth had been ligated with only temporary effect upon the pulsation. Dr. Bull attempted to dissect the growth out, but finding that it would be impossible to do so he cut away all the tissue involved. There was considerable hemorrhage, but it was fairly controlled by ligating all the bleeding vessels. The cavity was stuffed with iodoform gauze, and the wound healed without accident.

Dr. Sabine said that Mr. Teale, of Leeds, had directed attention to the fact that in many of these cases the growth had a capsule, and that it could be dissected out with comparatively little hemorrhage.

Dr. Briddon said he had removed several with the knife without more hemorrhage than usually occurred in the removal of the same amount of tissue in any other part. His plan was to cut well to the outside of the growth.

Dr. Howe then read a paper on

PERITONEAL TRANSFUSION.

Dr. McBurney presented a specimen of

SPONTANEOUS PERFORATION OF THE BLADDER,

with the following history: It was removed from the body of a man aged thirty-four, who entered his service in Bellevue Hospital with the ordinary history of urethral stricture, and suffering from retention of urine. Otherwise he was in apparent health. A small catheter was introduced and twelve ounces of urine were withdrawn from the bladder, although he said that he had not passed water for thirty-six hours. On the second day ater his admission he got out of bed and went to the water-closet for the purpose of making water. Within half an hour afterward he had a severe chill and when Dr. McBurney saw him one hour afterward the patient was in collapse. Examination of the abdomen revealed an extensive blush over the right half of the lower part, extending into the right iliac fossa. Dr. McBurney inferred that the man was suffering from rupture of the bladder. At the autopsy there was found a perfectly round opening in the posterior wall of the bladder, and from its appearance he thought it was the termination of a long-standing ulceration. The extravasation was post-peritoneal and entirely confined to the pelvic region. The only instrument introduced while the patient was in the hospital was a small elastic catheter. With reference to what instruments had been used outside he had no knowledge whatever. The apparent good condition of the patient, the sudden occurrence of the chill and development of profound collapse, were the noticeable clinical features, and the limited extravasation of urine found at the post-mortem.

The President remarked that a distended bladder was a favorable condition for spontaneous rupture, and that the opening had the appearance of one which had been made by some instrument.

Dr. Post suggested that an instrument would not be likely to produce perforation at such a distance from the urethra.

The Society then proceeded to the transaction of miscellaneous business.

What a Blind Man Sees.—The French scientist, Plateau, who for the last forty years has been totally blind, has just published a little paper on the sensations which he experiences in his eyes. He states that he has constantly in his eyes the sensations of light; his field of vision is divided into spaces, of which some are very clear, and others sombre or almost black. These spaces are not precisely limited, but run into each other at their borders; but what is remarkable is that their general tint alternates between gray and reddish. For example, if it be gray M. Plateau perceives now, in a few hours it will be red; then, a few hours later, the gray again, and so on. The reddish tint is that obtained by mixing pale rose-color, or rather flesh color, with a certain quantity of black. The relative arrangement of these different spaces is always the same, but the intensity of their tints varies. The central space shows itself sometimes very clear, and sometimes very sombre; above and below, as far as the limits of the visual field, there is sometimes clearness, sometimes obscurity. It is the same with the space to the left; there is generally a vertical, almost black band, and the space to the right of that, as far as its limit, is almost always clear and ruddy. These appearances seem to M. Plateau to fill the whole extent of his ordinary visual field. He believes the distance at which they are is small. These same appearances follow all the movements of the eyes, as if they resulted from a modification of the retinas. It appears to M. Plateau that the two eyes do not participate in the same manner in the tints in question; but he is absolutely incapable of distinguishing what belongs to the one from what belongs to the other. He has not been able to establish any coincidence between the changes of the general tint and the work of digestion.—*Boston Journal of Chemistry*, September, 1882.

Correspondence.

MEDICAL LATIN: A REJOINDER BY CHARLES RICE, PH.D., NEW YORK.

To the Editor of The Medical Record.

Sir: In No. 21 of the current volume of The Medical Record we find a paper entitled "Medical Latin," by John A. Armstrong, Esq., of Brooklyn. While we are in perfect accord with the author as to his general statements regarding the legitimate use of Latin in medical practice, as well as the almost general lack, among physicians and pharmacists, of a thorough knowledge of this language—which lack is not to be wondered at in these days of rapid transit—yet the paper contains some incorrect and misleading statements, which, if left uncontradicted, might expose certain features of the nomenclature adopted in the new United States Pharmacopœia to false and undeserved criticism.

Our dissension from the author's remarks begins with that portion of the paper (p. 567, first column, line four from below) where he commences to discuss the gender of such modern-Latin technical terms as *Carbonas*, *Murias*, *Sulphas*. He states that the London and Edinburgh Colleges of Physicians assigned to these nouns different genders,

> "the London college rightly, according to analogy, making them feminine, and the Edinburgh college, for no apparent reason, masculine."

He seems to be also surprised at the "extraordinary mutability of gender" of these terms, since he finds them used as masculines and as neuters in Mayne's Dispensatory, and in Gray's supplement even of all three genders. Still, he realizes the fact that this seeming versatility is due, in such works of reference, to the necessity of correctly quoting the original texts from which they are compiled. But finally he says (p. 568):

> "It is in the highest degree creditable to the ability and care of the gentlemen hitherto engaged in the compilation of the United States Pharmacopœia, that their work is disfigured by no such blunders. Such words as *Carbonas*, *Sulphas*, etc., in the United States Pharmacopœia, are rightly made to follow the analogy of their class of nouns of the third declension, and are qualified by adjectives in the feminine gender."

The question of the correct gender of these modern chemical nouns formed one of the many topics which had to be carefully considered by the Sub-committee on Nomenclature of the Committee of Revision of the United States Pharmacopœia of 1880, of which subcommittee the writer had the honor to be a member; and it was conclusively proved that the action of the Revision Committee of 1860, which had changed them from masculines to feminines, was based on error. Indeed, it was shown that there is no analogy whatever in Latin for the feminine gender, in the case of these nouns; it being altogether wrong to bring them into one category with the large class of Latin feminines ending in *-tas* (as *œstas*, *pietas*, *brevitas*, etc.). We will not occupy valuable space here by reiterating the arguments already published in *New Remedies*, 1882, p. 58, where this whole question has been fully discussed, and to which we must refer the reader. It may be considered as finally settled that these terms should *only* be used as *masculines*, and they have, accordingly, been restored to this gender by the present Committee of Revision.

The author of the paper next proceeds to say:

> "We find, however, in a recent report of the American Pharmaceutical Association's Committee on the Revision of the United States Pharmacopœia, p. 119, the expression *rhus glabra* recommended to take the place of *rhus glabrum*, but no reason assigned for the proposed change. Why *rhus glabra? Rhus glabra* is very proper sometimes; but the propriety of writing *rhus glabra* or *rhus glabrum* must depend on the part of the tree which it is meant to designate. If the bark or leaves are meant, by all means let us have *rhus glabra;* if the berry or seeds, *rhus glabrum*. Now our officinal *rhus* is the berry or seed, and the noun is of the second declension. But where the name of a fruit-tree is of the second declension feminine, and ends in *us*, the name of the fruit is neuter; as *malus*, an apple-tree; *malum*, an apple; *pirus*, a pear-tree; *pirum*, a pear. *Rhus*, the fruit or berry, is exceptional in not taking the neuter termination; but Pliny and Celsus both make *rhus* neuter when they use it to express the *berry* or seed of the *Syrian sumach*. *Stet rhus glabrum*."

We regret to say that this passage betrays the incompetency of the author to discuss and criticise philological questions requiring more than a superficial knowledge of grammar. Were it not that the case in point has a bearing upon the adopted text of the new Pharmacopœia, and that the accuracy of certain expressions therein is impugned by the author's statements in these columns, we would have passed the latter by with silence. As it is, we feel in duty bound to make a reply, but we shall be as brief as possible.

The writer of these lines, who edited the Report of the Committee of Revision of the United States Pharmacopœia of the American Pharmaceutical Association, and who is responsible for the proposition to change the *Rhus glabrum* of the Pharmacopœia into *Rhus glabra*, did not assign any reason for it, simply because he thought the reason would be self-evident. As the new Pharmacopœia has adopted the alteration, it seems right and proper to state why the change is justified.

Among the rules of pharmacopœial nomenclature of crude vegetable drugs is one, recognized in this country for a long time, but more generally applied in the new Pharmacopœia, which directs that the *botanical* genus- or species-name shall denote the particular *part* of the plant which is officinal, provided only *one* such part is used.

Examples of genus-names: Capsicum (meaning the fruit); Hedeoma (meaning the leaves and tops); Spigelia (meaning the rhizome and rootlets), etc.

Examples of species-names: Belladonna, Dulcamara, Frangula, etc.

In some cases it became necessary to use *both* genus- and species-name, to distinguish the drug from an allied species which might be also officinal, or at least in common use, and might be confounded with it.

Examples: Quercus alba; Mentha piperita; Mentha viridis; Veratrum viride; Prunus virginiana; Rosa gallica; *Rhus glabra*, etc.

These terms are precisely the same as those used to denote the *plant* itself,[1] and no change of gender or termination is permitted by reason of any meta-

[1] Except in the case of *Prunus virginiana*, which term has been retained, for obvious reasons.

phorical application of these terms upon different parts of the plant, as the leaves, fruit, root, etc. If it so happens that the fruit of any particular plant has a common, generally used name, the latter may be substituted for it; for instance, *Prunum* (the prune) is the common and also pharmacopœial name for "the fruit of *Prunus domestica*." The Pharmacopœia could have called it also, in conformity with the above rule, *Prunus domestica* (the species-name being added to distinguish it from *Prunus virginiana*); and if there were no other "Prunus" in the Pharmacopœia it would have sufficed to call it *Prunus*. But it would be incorrect to draw the adjective of the *plant* to the *part of the plant*, and to say *Prunum domesticum*. We could not wish for a better example than *Rhus glabra* to show how inadmissible such a change would be. This particular species of *Rhus* was called *glabra* by botanists, because it differs from other species of *Rhus* by the fact that the stem and leaves of the *plant* are quite smooth and free from the fine hairy covering so common in other species. That is, the *plant* is *glabrous*. But if we were to write *Rhus glabrum* to designate the fruit, we would ascribe to the latter a property diametrically opposed to fact; the sumac berry being densely covered with acid crimson hairs, just like the fruits of other species of *Rhus*.

The last portion of the paragraph last cited contains a remarkable collection of mistakes and misstatements, as will be seen from the following:

First.—*Rhus* is *not* a noun of the *second* declension, as the author says. In Latin it belongs to the *third* declension, and has in the genetive [1] usually rhois. A contracted form of this is *rhus* (rhūs),[2] or even *rus* (rūs).[3] The genitive *rhi*, which would be that of the second declension, is unauthenticated by any good manuscripts.[4]

Second.—The alleged rule about neuter fruit-names in *um*, from feminine tree-names in *us* is not without exceptions; for instance, *ficus*, *caprificus*, *balanus*, etc., all of which denote both tree and fruit. The form *rhum* [5] occurs, but this is the accus. sing. of *rhus* in the third declension.

Third.—There is not a single passage in Pliny, from which it could be proved that *rhus*, as name of the fruit, must be neuter. The words *quod rhum diximus*, 29, 3, (11), 50 are explained by another passage where it is decidedly feminine, viz.: *quod Rhun Syriacam vocant*, 14, 14, (79), 129; yes, it even occurs as masculine: *rhus qui erythros appellatur, semen est hujus fruticis*, 24, 11, (55), 93.[6]

And Celsus quotes the word *rhus* only *once* (6, 11), and then decidedly as a masculine: *rhus quem Syriacum vocant* (meaning the fruit).

Hence: *Stet Rhus glabra!*

CHARLES RICE, Ph.D.

NEW YORK, November 23, 1882.

[1] The genetive occurs rarely in the older writers; but the medical authors, whose works contain many formulæ giving the ingredients in the genetive, generally use this form; f. i., *Scribonius Largus*, De compos. med., 142, etc.

[2] For instance: (*Pseudo-*) *Plinius Secundus*, *De Medic.* (ed Rose), 2, 4 (where some MSS. read rōs); *Scribonius Largus*, 111, 113, 256.

[3] *Cassius Felix*, *De Medicina*, 42, 48, 73. The similarity of the form *rus* to Latin *ros* (*roris*), the dew, afterward led to a curious confusion. Pliny, the elder, and other authors denote by *Rhus Syriacus* (or *Syriaca*) a species of sumac (probably *Rhus Coriaria* L.); later writers (as *Gargilius Martialis*, *De Medic.*, 41, page 182; Columella, 9, 13, 5, 12, 42, 3; *Palladius Martialis*, 15, 1) make the genetive of this *roris Syriaci*, after the analogy of *roris marini* (gen. of *ros marinus*). And we even find *Rhus Syriacus* used as a synonym of *ros marinus* by *Theodorus Priscianus* and *Marcellus Empiricus* (f. i., page 367, D.).

[4] In Greek, the corresponding noun ῥοῦς may take the terminations of either the second or the third declension—ῥοῦ or ῥοῦς.

[5] Also rhun.

[6] In later authors it occurs as neuter: f. i. *Cassius Felix*, 39; *Apicius*, *De Re Coquin.*, 10, 403, 477, etc.

QUININE IN SPASMODIC COLIC.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Some months ago, being in Professor Frank Hamilton's office, and saying that I had not read his paper on "Strangulated Hernia," he kindly handed me, not only that, but the one also on "Posture in Colic," both of which I have read with great interest, and the reading of which has brought to a focus a half-formed resolution to send you a few lines upon this last subject. That resolve is now three years old. It has been held in abeyance only to make assurance doubly sure, and because I am not at all inclined to "rush into print." I should still be silent if not fully convinced that the suggestion I shall make will be of benefit to some sufferer from this peculiarly distressing complaint. Never having satisfied myself as to the cause of colic, I am fully prepared to accept Dr. Hamilton's theory of its origin as very probable, and also the conclusion that sometimes posture will cure it.

Without going into its pathology at all, the affection to which I refer is on this wise: First, a sense of abdominal fulness, not amounting to uneasiness even. After some time, possibly an hour, a trace of uneasy feeling lasting for a few seconds—after an interval of quiet, longer or shorter, a dart of pain at some point in the abdomen, enough to call attention, and again an interval of quiet, succeeded in a few moments by another and severer evidence of coming trouble. This state of things, which has always seemed like an alternate spasm and relaxation, may continue for an hour, or hours, and is at last succeeded by a pain which is agonizing and continuous, just as if the intestines had been suddenly folded and gripped in the hands of a strong man, and were being wrung as a washerwoman wrings clothing. I speak of this matter from the standpoint of a life-long experience. From boyhood until three years ago I have had abundant opportunities of studying this trouble in all its phases. That and a constantly recurring severe headache have always been accustomed, but very unwelcome visitors—so much so as to interfere very materially with my business. It would be without good to enumerate the remedies tried for the colic during this long period; ranging through the list of cathartics, antispasmodics, emetics, aromatics, stimulants, injections, alkalies, mechanical applications, anodynes, sedatives, and finally chloroform, for none of them were at all reliable, except possibly morphine; but this was exceedingly objectionable, leaving always behind a nausea which lasted for days, and was about as distressing as the original difficulty.

About three years ago, having endured a severe headache for some days, I concluded to try a dose of quinine, with the hope that it might bring relief, as it had done occasionally before, but before reaching my office from a lengthy visit, decided symptoms of colic were developed. Immediately on arriving I took ten grains of quinine, hoping thus to give the headache its *coup-de-grace*, and so be allowed a free and uninterrupted contest with the colic. A patient coming in, claimed my attention for perhaps half an hour, and when allowed again to think of myself, I was surprised to find that the pain had not increased.

This was such an unusual thing, and so contrary to years of experience, that I could hardly believe in it. I, desiring to know what would follow, sat down quietly to wait and watch. Soon there began to come a sense of languor and drowsiness, and a

hope, amounting after a time to a certainty, that for once I had escaped some hours or days of suffering. The question very naturally came to me, Had the quinine anything to do with this unusual ending? Believing that it had, I of course determined to try it again. In the next two attacks the quinine was taken early, and with entire success. Being now satisfied of its power to prevent an attack, if taken in the early stages, and desiring to know what it would do if left to a later period, I allowed the next attack to progress until it was well established and certain of being severe. Then the quinine was taken, and in half an hour the pain was gone, and nothing remained but a sense of ease and safety.

Since then, now three years, I have taken it myself, and given it to many patients during these attacks, with complete success.

Remembering with gratitude the kind services of my professional brethren during many occasions of this kind in early professional life, and how consoling their care and presence was in these hours of suffering and anxiety, I have always been careful to remain with these patients, sometimes at great inconvenience, until they were better. Now I send a capsule containing eight or ten grains of quinine, and pay no further attention, being quite sure that I have done for them the very best thing possible, and have thus been saved many a night of tedious and unsatisfactory service.

N. R. DERBY, M.D.

BERGEN POINT, N. J.

TRISMUS NASCENTIUM AND ADHERENT PREPUCE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Without being positive, I have been unde the impression that trismus nascentium is much more prevalent in portions of the Southern States than it is anywhere at the North.

However this may be, there is no doubt of its very great prevalence in many portions of the Southern country, and especially among the colored race, although not confined by any means to this people. My experience is that it is a fearfully fatal malady, and takes off thousands of infants within the first fifteen days of their life. About a year ago, when examining a case, I discovered that there was adhesion of the prepuce to the glans penis, accompanied with the usual priapism. I circumcised the child, after having torn up the adhesions, and then gave two grains of hydrate of chloral every two to four hours, keeping down the spasms as well as I could with this agent, and producing nearly constant sleep, and the case recovered. This was the first recovery of trismus nascentium within my experience, which has been very considerable in twenty-seven years. The result could not have been entirely due to the chloral, as I had often given this agent before, and pushed it as far as safety would allow. But this case does not stand alone, as I have just had another recovery from the same procedure of treatment. I am also informed that a case in the practice of Dr. Wiechelbaum, of this town, has recovered under the same treatment.

I think, too, that I should have had more cases to report but for the fact that experience has taught me to examine every male child carefully within the first few days of its birth, and break up the adhesions betwixt the glans and the prepuce where they occur, and split the prepuce in some instances and circumcise in others. I have been greatly surprised at the very large percentum of cases where adhesion exists, and have no doubt that this surprise will be shared by other general practitioners who will take the trouble to examine every male child born under their auspices. Further good results will follow, for there are in my experience many children made very restless and nervous, which conditions last through the first year of life, and end in the form of paralysis, for which Dr. Sayre, of New York, first pointed out the remedy of circumcision.

I am not aware that these conditions have ever been treated upon in medical books before, and are merely hints drawn from experience and which I think every thoughtful practitioner will appreciate. It is the common belief of most physicians that trismus neonatorum is due principally, if not always, to trouble in the cord. My belief is that it may be due in some instances to the navel cord, but by no means in my case. Adhesion of the prepuce produces a certain percentage in male children, and cold draughts of air is an active factor in causing the disorder in both males and females. I have the impression that it is much more common in the male child than in the female, but intend to satisfy my mind upon this point by hereafter keeping notes. The colored population, as is well known, are a very careless people, and live generally in houses badly built, which abound in air-holes. During the winter season children born in such places are very apt to have this disease. Yours truly,

J. G. THOMAS, M.D.

SAVANNAH, GA., November 16, 1882.

MEDICAL EDUCATION AND THE AMERICAN ACADEMY OF MEDICINE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In THE RECORD for November 4, 1882, is a report of the annual meeting of the Academy of Medicine. Its attempt to elevate the standing of medicine as a learned profession is worthy of praise.

Some of the conclusions of Dr. Beard, however, may not meet with general approval.

He advises that "if a student must economize in time or means, let it be in the professional and not in the academical training."

Again, praising the superiority of Germany in medical education, the Germans are spoken of as "thinkers, philosophers, men with abstract ideas, with inherited genius for theory and for language." He admits that "the defects of Germany are mainly on the side of practical application of science and philosophy to daily wants," and that "in medicine their special great defect is in the treatment of disease." The Germans, therefore, are good theorists, but fail practically. Our young men, however, are to be encouraged in following their example, and "to study and travel in Germany." Because that, "outside of a small circle of German-taught experts, the medical literature and the medical practice of England is from five to fifteen years behind Germany and America." And because "the profession as a profession has slight honor, the position of its individual members coming from individual character despite their calling." What an admission to make! Would it not be better for those doctors to whom their position comes through "individual character despite their calling" if they had chosen some other life work? Happily there are some of us who do

not feel that our "profession as a profession is without honor."

About eight per cent. of medical men in the United States are college graduates. Perhaps some of the remaining ninety-two per cent., not thus favored, may also wish for the advancement of medical reform, but without the practical being sacrificed to the theoretical teaching. So long as there are ninety teaching bodies, each possessing the power of granting not only a degree in medicine, but also a license to practise; so long as but thirteen of these ninety schools require any preliminary examinations; so long as seventy-two "regular" schools have one thousand one hundred and thirty-one instructors interested in the *successful* examinations of two thousand six hundred and seventy-three graduates in one year, will the profession as a profession deserve slight honor.

True reform will begin when the power of granting a license to practise medicine is taken out of the hands of interested teachers and placed under the control of those who seek the welfare of the profession at large; when a fixed standard in general education is compulsory before the student can proceed to the examination in medicine. This can be accomplished without shutting the doors against all but college graduates.

Then, and then only, will ignorant students cease to find entrance, through cheap institutions, into what should be an honorable profession.

The Academy of Medicine alone, with its select few, cannot work a reform in which all medical men are interested. Neither is it desirable that the teachings of one of its members, as quoted, should ever receive favor.

NEMO.

HOW SOME MEDICAL MEN ARE EDUCATED.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: In a recent issue I noticed a communication signed "Claudius," which expresses so much good sentiment that I wish to re-echo his statements in a somewhat different manner, *re* the specialist. While C. speaks of one who had ability or volubility sufficient to become the proud "pater" of a pamphlet, miserable or otherwise, my remarks will refer to a different species of the would-be-man-of-particular-talent. Details of practical experience with one or two will best illustrate what I wish to bring out.

CASE I.—Some three years ago there was in a rural school, not far from here, acting in capacity of teacher, a man; and let no one who has read thus far think that because a teacher he was devoid of ambition. One day, on going to the post-office, he found there an announcement of a so-called medical school which in those days flourished out West. A sudden idea takes hold of our hero—something beside the realization of which the occupation of teaching was nowhere. He counted the cost, discovered that, by restricting his diet to "beans," his wardrobe to its present dimensions, and by means of occasional odds and ends which he could acquire by portering, he would be enabled to take a course and graduate there. Oh, then what a field would be open before him—a field that nowhere on all its vast plain would be seen such a giant as he would prove himself to be. That was three years ago, and for nearly *two* years his card has figured in our papers as specialist in "diseases of women" and "surgery."

CASE II.—Three or four years ago a great many of the farmers of a certain county in Pennsylvania were quite familiar with a certain vender of a patent sulky horse-rake. For some months (twenty-four or more) that "ambitious rake vender" has been a full fledged M.D., and is also advertising himself as a specialist on diseases of women. Some time ago he was summoned to attend a case of "morning sickness," well marked and uncomplicated. With great gravity he told the friends that "Mrs. —— was suffering from a severe attack of malarial fever." He prescribed quinine!

My object in writing this is not to ridicule the plodding, earnest, though poor student, but to show what ignorance, combined with conceit, is capable of doing—to endeavor to awaken the intelligent portion of the profession to the fact that men such as these are lowering, and that permanently, our profession in the estimation of the laity.

Ours is a "noble profession," but I deem it *noble* only as the individual members of it render it so, both in education, precept, and practice. Of all quacks the licensed quack is the worst, and what better are specialists (or even general practitioners of the same grade) of the above type than the brazen advertiser who offers to "elevate wombs at a dollar a bottle," or the man who declares himself to be the "possessor of the jewelled medal, the gift of the American National Association of Medicine," or the reverend gentleman who practised self-abuse and could find no remedy short of the natives of some undiscovered island! Are we who endeavor to act conscientiously, and with all the possible light of modern science beaming through speculum and guiding the hands of the real gynecologist and surgeon, to calmly stand by and see the essential dignity and honor of our profession trodden under feet by such swindling knaves? Does not home, love, love of country, and all the finer feelings impel us to say we will not see a member of our race "cut and hacked" by the self-styled and unskilful surgeon, nor fair woman's finest sense shocked by every "boasting ass" who can buy a speculum—at least not as long as a "few" can become incorporated by an act of legislature for the purpose, not of advancing scientific work and aiding in the alleviation of human suffering, but only for mercenary ends? We have good schools and good men, but I will venture the assertion that out of every five doctors graduating in the whole United States four of them are not competent to intelligently practise medicine, surgery, and midwifery.

Yours very truly, S.

THE USES AND ABUSES OF THE ELECTRIC BATH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Will you allow me a little space in your valuable journal to give my explanations for Dr. Wm. F. Hutchinson's failures in the use of the electric bath, as published in THE RECORD of October 21st?

The four electrodes made stationary in the tub, two in the upper and two in the lower end of the tub, with the faradic current passing through them to the patient, would produce deleterious effects, somewhat similar (if I may use the comparison) to lifting a rheumatic patient by the nape of the neck and the feet. Anyone may satisfy themselves on this point by placing both hands in the water in the middle of the tub, and extending one toward the

head and the other toward the foot at the same time; if the current is very strong it will become almost or quite unbearable before they reach the electrodes, when it is hardly perceptible with the hands near together. He says, "the constant current used was from a permanent series of forty two-gallon Weiss elements, which produced an even and steady flow capable of minute division by selectors and a wire rheostat." This is by far too strong a galvanic current to be used for any considerable length of time without producing depressing and injurious effects. The temperature of the bath, he says, "was carefully maintained at such a height as was perfectly comfortable, usually about 80° F."

How could it be possible that a feeble rheumatic patient could remain in water fifteen minutes with the temperature nearly 20° below the normal temperature of the body, without "a sensation of chilliness, followed by a stroke of cold"?

I have prescribed and used the electro-thermal bath in my practice for twenty-one years. After I had the proper key-board or switch-board and the appropriate number of electrodes in the tub (improvements I had made from the Dr. Young patent the second year of my use of the bath), I prevented the unfavorable results which had sometimes occurred; and when my instructions to my operators were fully carried out, not one in one hundred treated ever complained of the symptoms described by Dr. Hutchinson. I never allow a patient to take my electro-thermal bath or any other electrical treatment without first being examined by me or a physician who understands my means, and the directions for the treatment are given to the operator.

I have asked my bookkeeper and cashier, who has had this position seventeen years, to give me the average number of electro-thermal baths given in my institute during that time. The average per year is over six thousand. I would be pleased to quote from my work on "The Electro-Thermal Bath," page 16, how to prepare the bath for a patient: "It is necessary to know if the patient is very sensitive to warm or cold water; the bath should be of a temperature to meet the feelings of the patient pleasurably on first going into it. As a general rule, it should be prepared at 98° F., and gradually increased till it reaches in some extreme cases 110°; the guide for increasing the temperature must be the patient's feelings, as no one set rule can be given for every case. The time in the bath ranges from eight to thirty minutes; the effects of this bath will serve as a guide to the time occupied in subsequent treatment of the case. The patient lies down in the bath, being covered at the same time with a canton-flannel sheet, the head resting on a sponge or air-pillow, which is wrapped in a napkin and placed above the insulator, the feet resting against the foot of the tub, unless the patient is too short to reach it, then they should be supported by a foot-adjuster; a small napkin wet in cold water, wrung out so as not to drip, should be placed on the forehead."

I am confident that there is to be a new era in our profession in the prescribing and using medical electricity. I think it is not far in the future when physicians will become thoroughly educated in its use, and there will be medical electrical operators as thoroughly instructed as the professional nurses. Then the physician will prescribe electricity, the instructions to be carried out by the operator, as he does drugs, the prescriptions to be filled by the druggist, and directions to be carried out by the nurse. And frequently he may prescribe for the same patient both medicine and electricity. If static electricity is prescribed, the quantity and intensity are two important factors, as well as the kind of electrodes to be used in a given case. And so it is with the faradic and galvanic currents. In the treatment of the patient in the bath, the proper temperature of the water is nearly as essential as directing the currents.

JUSTIN HAYES, M.D.

CHICAGO, ILL.

New Instruments.

A NEW MEDICAL BATTERY.

BY A. M. ROSEBRUGH, M.D.,

TORONTO, CANADA.

WITHIN the last few years decided improvements have been made in electro-therapeutic apparatus. This improvement is conspicuous in the construction of portable galvanic and portable faradic batteries, as well as in the instruments where the two are combined. The thanks of the profession are especially due to the American manufacturers and inventors for what has been accomplished in this direction. But perfection has not yet been attained; the model battery has yet to be produced. These batteries, though highly finished—even ornamental—are still too complicate and too difficult to be kept in working order, and withal too expensive, to become popular with the profession. We are not all practical electricians, and we require a battery that is simple in its construction, almost automatic in its action, and easily kept in order. As a contribution to this end, I propose to describe a modification of the portable galvano-faradic battery which I have recently adopted with advantage.

As a basis of the new battery I took one similar to that of Dr. McIntosh. In batteries of this description the horizontal plate to which the elements are attached is padded on the under side to form a hydrostat plate, one-half of which is used to cover the acid-cells when the battery is not in action, while the elements, attached to the remaining half, are suspended in a drip-cup by the side of said acid-cells. The end of each hydrostat plate is pressed down upon the cells by means of spring bolts and clamping screws. This latter arrangement is quite effective but very inconvenient, as much time is spent in clamping and unclamping the plates—not merely when the battery is taken to the bedside of the patient, but also whenever the battery is used. In the new battery the pressure upon the hydrostat plates is made automatic by simply placing bearings upon the lid of the battery case. When the lid is closed the acid-cells are firmly covered, and when the lid is open the bearings are removed and the plates may be moved without loss of time.

Again, in the McIntosh battery, when the apparatus is used each hydrostat plate (with the elements attached) is raised from the drip-cup, rotated upon its horizontal axis, and the elements immersed in the acid solution.

When the *séance* is ended, each hydrostat plate is lifted from the fluid, and, before it can be replaced in the drip-cup, must again be rotated upon its horizontal axis. This manipulation is not specially inconvenient, but unfortunately the dripping of the acid solution from the zinc and carbon elements

commences before the horizontal rotation is completed, and, unless very special care is taken, the metal parts on contiguous plates are liable to become spattered. This is obviated by the expedient illustrated in the accompanying figures.

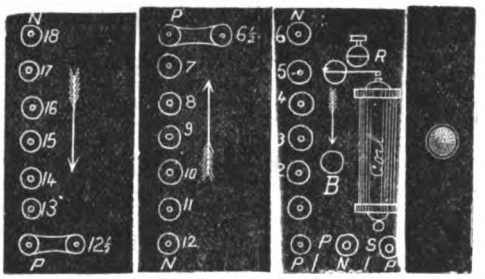


FIG. 1.—The elements at rest.

Fig. 1 represents the position of the hydrostat plates of an eighteen-cell combined galvano-faradic battery when the elements are at rest. The elements from 1 to 18 are resting in the drip-cups, six pairs being attached to each of the three hydrostat plates, and on the left hand side thereof. The overlapping part of each hydrostat plate covers the top of six acid cells, which latter are to the right of each drip cup. In the McIntosh battery the elements of any one series, as from 7 to 12, can be immersed in two ways: first, by lifting and then rotating on the horizontal axis, and second by allowing the projecting hydrostat plate to override the screw-cup, on the adjoining plate to the right (1 to 6). Both methods are objectionable, the latter obviously so, and the former for reasons already named.

In the modified apparatus the battery-case is elongated to the right, to the extent of half the width of a hydrostat plate, so as to provide a space for overlapping to that extent. When the elements of the first series (1 to 6) are immersed, space is left for the overlapping of the hydrostat plate of the second series, which, in turn, makes way for the third. When the third series of elements are immersed, the end drip-cup to the left is left uncovered. This may be covered by the narrow plate or cover removed from the right, as represented in Fig. 2.

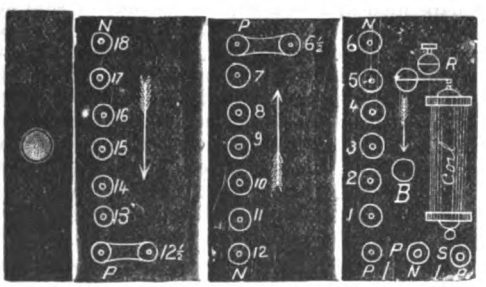

FIG. 2.—The elements immersed.

The screw-cups 6 and 6½ of the first and second series, and 12 and 12½ of the second and third series, are connected by a spring or wire, this connection being facilitated by the supplemental posts 6½ and 12½. The positive electrode is connected with No. 1, and the negative with No. 18. The cord of the negative electrode is bifurcated, so that, by a step by step arrangement, the number of elements in circuit may be increased or diminished gradually without breaking the circuit.

Some batteries are provided with an extra acid-cell and an extra pair of elements for the faradic coil—the extra cell being placed to the right of the coil. When this is the case, a space for the overlapping of the hydrostat plate is afforded by simply uncovering this extra acid-cell.

By these modifications the battery is ready for use as soon as the lid is open. The elements may be displaced to the right and back again to the left without loss of time and without being rotated; and, moreover, in the original battery, any one of the zinc or carbon plates may be easily removed, repaired, or replaced without the help of an electrician.

To sum up, the advantages claimed are as follows: 1, cleanliness; 2, economy of time; 3, simplicity in management; 4, simplicity of construction.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from November 18, 1882, *to November* 25, 1882.

ALDEN, CHARLES H., Major and Surgeon at expiration of present leave to report to the Commanding General, Department of Dakota, for assignment to duty. S. O. 273, par. 10, A. G. O., November 23, 1882.

BARNETT, RICHARDS, Captain and Assistant Surgeon, the leave of absence granted November 1, 1882, is extended five months. S. O. 273, par. 11, A. G. O., November 23, 1882.

BILL, JOSEPH H., Major and Surgeon, at expiration of present leave to report to the Commanding General, Department of the Platte for assignment to duty. S. O. 273, par. 10, A. G. O., November 23, 1882.

BROWN, PAUL R., Assistant Surgeon, the leave of absence granted May 25, 1882, is extended six months on Surgeon's certificate of disability. S. O. 273, par. 7, A. G. O., November 23, 1882.

CLEARY, PETER J. A., Captain and Assistant-Surgeon, now awaiting orders, will report to the Commanding General, Department of Dakota, for assignment to duty. S. O. 273, par. 10, A. G. O., November 23, 1882.

CORSON, JOSEPH K., Assistant-Surgeon, is assigned to duty at Jefferson Barracks, Mo. S. O. 273, par. 8, A. G. O., November 23, 1882.

MCKEE, JAMES C., Major and Surgeon, now awaiting orders, is assigned to duty in the Department of California. S. O. 273, par. 10, A. G. O., November 23, 1882.

MUNDAY, BENJAMIN, First Lieutenant, Assistant-Surgeon, will be relieved from duty at Willetts Point, N. Y., and assigned to duty in the Department of the Columbia. S. O. 273, par. 10, A. G. O., November 23, 1882.

SMITH, ANDREW K., Major and Surgeon, at the expiration of his present sick leave will be assigned to duty at Willetts Point, N. Y. S. O. 273, par. 10, A. G. O., November 23, 1882.

WHOOPING-COUGH IN A PATIENT OVER EIGHTY.—A rare case of this nature is reported by Dr. W. Hale White in the *British Medical Journal*. There were no signs of bronchitis in the lungs. The patient could not remember whether she had had the disease when she was young.

The Typhoid Fever Epidemic in Paris has continued to decrease in violence. This decrease has taken place, we are told, despite any precautions taken in the matter of drinking water or of household disinfection. The epidemic is thought to have been due to the bad state of the tenement houses and other crowded dwellings. The French theory of typhoid fever admits that the disease may be developed spontaneously by infection or specifically by contagion; but the great majority of French authors do not accept the unity of the typhoigenetic poison.

A Bradshaw Lectureship has been established by the will of the late Mr. Bradshaw. The annual lecture this year is to be given by Sir James Paget.

A New Disease.—It has been observed that the manufacture of bichromate of potash has a singular effect upon the nose, manifesting itself in a curious manner. A little hole is formed in the septum of the nose, and increases gradually until the partition entirely disappears, with the exception of its lower part, so that to a superficial observer there is nothing except a little outward depression. It is noticed that as soon as the partition is destroyed, the process appears to stop there, neither the lungs, air-tubes, nor throat being in the least degree affected. Some workmen at the chrome factory in Russia, where the disease has been chiefly watched, have been employed for ten years and remained unaffected, while with others the hole in the nose begins to be formed after one month's work. But that the disease is something more than an individual peculiarity, is evident from the fact that an inspection of all the hands proved that more than fifty per cent. of the men had diseased noses. The early symptoms are a slight tickling of the part affected, followed by bleeding, but with no uncomfortable feelings; and, in fact, the destructive process is painless.

Professor Pettenkofer has been raised to the rank of nobility by the King of Bavaria, on account of his services to medical science and hygiene.

A College Professor on Trial.—Prof. Frothingham, of the medical department of the Michigan University, has had a hearing before the faculty on charges preferred by Mr. Morgan that in his lectures he had made sneering remarks against Christianity and had said that all ministers were liars. A large number of witnesses were examined, most of whom denied that such language as that attributed to Prof. Frothingham had been used.

The Source of Nourishment of the Cornea.—Until quite recently it has been generally believed that the cornea draws its nourishment from the aqueous humor. Ulrich and Denissenko, but more especially the latter, gave very strong reasons for believing that the anterior chamber is only the outlet for the fluids which nourish the cornea, and which pass into it from the surrounding conjunctival and scleral vessels. Their surmises have been shown to be correct in an interesting experimental manner by both Ehring and Pflüger.

A Bacillus or a Fat-Crystal.—At a meeting of the Pathological Society at the Charity Hospital, New Orleans, November 21st, an important microscopic demonstration was made by Dr. H. D. Schmidt, President of the Society. Dr. Schmidt stated that beyond doubt the bacilli were fat-crystals. Dr. Schmidt succeeded in finding crystals, which were similar in appearance to bacilli discovered by Koch, and apparently the same. To determine their nature, Dr. Schmidt subjected the crystals to the action of boiling ether, when they disappeared, proving, as he claims, that they were not germs or organisms.

The Late Dr. Wm. H. Allen.—At a special meeting of the Board of Trustees of the New York College of Dentistry, the following preamble and resolutions were adopted:

Whereas, This Board has been called together to express by resolution and record their deep sorrow at the death of their late President, Dr. William H. Allen; and

Whereas, Dr. William H. Allen was one of the incorporators of the New York College of Dentistry, an active worker in its interests since its organization, and for the last seven years the President of the Board of Trustees, we, the members of this Board, express our appreciation of him as a co-worker and a man; therefore

Resolved, That the College deplores the loss of an honored President and an earnest promoter of her interests.

Resolved, That the Trustees are deprived of one who was a wise counsellor, a tried friend, and a true gentleman.

Resolved, That the profession which he honored has been robbed of one of her brightest ornaments, and that the community has lost a man of integrity, fidelity, and manliness.

Resolved, That we tender to his widow our sincere sympathy in her bereavement, and direct that a copy of these resolutions be sent to her; that they be spread upon the minutes of the Board, and that they be published in the *Dental Cosmos* and the New York Medical Record.

Committee of the Board of Trustees

The Treatment of Strychnia-Poisoning. — Dr. W. J. Byrne, of Russelville, Ky., sends us the following: "I was called on the night of October 9th, at 10 P.M., to see Mr. W. E. C——, aged twenty-two, student of theology at Bethel College, in this place, who had taken strychniæ sulph. with suicidal intent. On arriving I learned that he had eaten but little supper; was supposed to have swallowed the drug about 9 P.M.; was found in a tetanic convulsion by one of his fellow boarders at 9.30. His condidition, when I saw him, was such as is produced by the action of the poison, the paroxysm being an-

nounced by a shudder passing through the entire frame, jerking and twitching of the head and extremities, and then suddenly a general tonic convulsion occurring. The paroxysms were then recurring every five minutes with a tendency to shorten the interval of relaxation. Drs. Alderson and Harper who had reached the boarding house before myself, had given the patient forty grains of pulv. ipecac a few moments previous to my arrival. We immediately began the inhalation of chloroform, which, while not warding off the convulsions, appeared to lessen their intensity. Finding it impossible to introduce any medicine by the mouth, we resorted to the use of hypodermic injections of the hydrate of chloral and bromide of potassium, fifteen grains of the former with thirty grains of the latter in aqueous solution. This, in connection with the inhalation of chloroform was continued till 12.30 at various intervals, during which time there was administered one hundred and fifty grains of chloral with three hundred grains of the bromide. During the same period of time he had hypodermically one grain of morph. sul. Under this course of treatment the paroxysms were apparently weakened, but the frequency was about the same. We then administered four drops of the fluid extract of physostigma, the inhalation of chloroform being continued, and for the first time he rested forty-five minutes before a recurrence. The convulsions not being so violent as before, we awaited the expiration of an hour before repeating the calibar bean ex., and this was succeeded by a rest of one hour, when the convulsions reappeared and the calibar ex. was again given. From this time on there was but little evidence of the action of the poison—some twitching of the facial muscles and jerking of the lower extremities. Having sufficiently recovered by 6 A.M. to swallow freely, we then gave the solution of chloral and bromide of potassium internally, at intervals of four hours, in the same doses as had been hypodermically administered. During the day he progressed well, and at the termination of thirty-six hours was well. I have thought the case of sufficient interest to give a synopsis, inasmuch as by weight he had taken ten grains of the ordinary commercial strychnia and yet was enabled to live by the antagonistic action, as I believe, of the chloral hydrate. The case also illustrates, in a beautiful manner, the paralyzing action of the physostigma."

TOTAL EXTIRPATION OF UTERUS FOR CARCINOMA.—Dr. W. C. Burke, Jr., of South Norwalk, Conn., on November 11th extirpated the entire uterus, by the vaginal method, for epithelioma involving entire cervix to internal os, but confined to uterine tissue. Up to the fourteenth day she has progressed favorably, and now has a very fair prospect of recovery, pulse and temperature being normal. Only once during entire case did the temperature reach 101⅗°, on the night of the fourth day, but remained there only for an hour.

HYDATID CYST OF THE LIVER.—Considering the rarity of ecchinococcus disease in the United States, the following note by Dr. W. S. Cheesman, of Auburn, N. Y., is of interest: "On admission to hospital, March 3, 1880, the patient, a woman, about forty years of age, stated that she had been quite well up to two weeks before, when she was seized with a sharp pain in the right side while at work. This pain radiated to the right shoulder, and was relieved by pressure. She vomited a greenish matter, and two or three days later she became jaundiced. Tenderness developed in the right side, the fæces became clay-colored, and the urine very dark. At the date of admission she was jaundiced and evidently in great pain; she suffered from nausea, and occasionally vomited. Marked tenderness was noted over the hepatic region, and at one point an unnatural fulness was detected, which was supposed to be the distended gall-bladder, though a little to the right of the normal position of that viscus. These phenomena were referred to impaction of a gall-stone. On the fifth day after admission peritonitis developed, and on the seventh the patient died. The autopsy revealed as the cause of death general peritonitis. Bile was found in the peritoneal cavity, and oozed through an ulceration in the bile-duct when the gall-bladder was squeezed. No gall-stone was found; perhaps it had escaped into the peritoneal cavity, and so eluded observation. The special interest of the case centred in a rounded tumor, about three inches in diameter, located in the liver just to the right of the gall-bladder. When opened it proved to be a hydatid cyst containing daughter and grand-daughter vesicles. Its fluid, turbid with pus, was shown by the microscope to contain great numbers of the hooklets of the echinococcus and the parasites themselves."

NEW ANÆSTHETICS.—Dr. V. Mering, at the recent meeting of German Naturalists and Physicians, reported his experiments with two new anæsthetics: diethylacetat and dimethylacetat. The former has a burning pungent taste, the latter a disagreeable taste and smell. Both produce narcosis very rapidly in frogs and rabbits. There is slowing of the heart-beat, and finally weakening of respiration. In inhalation they act much like chloroform. Mering gave the diethylacetat to some criminals and found that it acted very well, producing narcosis with no bad after-effects.

PRESCRIBING PROPRIETARY MEDICINES.—Dr. C. A. Lindsley argues in the *Therapeutic Gazette* against the prescription of proprietary medicines: "It is demoralizing to the profession because it is ruinous to scientific nomenclature, and renders a classification of medicines utterly impossible. What will the next generation of medical men know about Lactopeptine? Maltine? Vitalized-Phosphites? Celerina? Bromidia? Iodia? Petroleum Syrup? Soluble Phenole? Malto-coca? Hydroleine? Listerine? Caulocorea? Viburnum Compound, and a more innumerable host of mixtures? These are all of ephemeral existence, having no vitality other than what they derive from the advertising pages of medical journals and the newspapers. They are for the most part the inventions of tradesmen, and in no sense represent the growth and progress of medical science."

SIR THOMAS WATSON is reported to be losing strength.

THE THIRD CORPUSCLE OF THE BLOOD.—Mrs. Ernest Hart, in the *London Medical Record*, publishes a criticism upon Dr. Norris's work on the physiology of the blood. She claims that the "invisible corpuscle" described by him is really only a red corpuscle decolorized.

THE TARIFF COMMISSION'S REPORT ON QUININE.—A semi-official Associated Press dispatch announces that the commission in their report, which will be printed and indexed for the use of the Committee of Ways and Means, have outlined their action in the following words: "The reimposition of the duty on quinine will not be advised."

Original Communications.

A CASE OF MYXODÉMA,

With a Consideration of the Neurotic Origin of the Disease.[1]

By ALLAN McLANE HAMILTON, M.D.,

NEW YORK.

In the year 1873 Sir William Gull called attention to several curious medical cases, the histories of which he presented to the London Clinical Society. Two were reported in full, and five others were briefly analyzed, but all of them, however, were alike. Some of these identical cases have since been seen by various English writers, among them Ord.

The peculiar features of the disease, which Gull called "a cretinoid state supervening in adult life in women," consisted of more or less diffused swelling of the whole body, but marked in the face, and especially prominent in the lips, eyelids, and tongue.

This swelling had a doughy feel, and rarely pitted under pressure, and was not due to ordinary nephritic disease, because of the absence of albumen in the urine and other signs. In these cases the speech was slow, the hearing dull or lost, and the mental condition depressed or greatly changed. The bodily temperature was lowered, and peculiar trophic changes indicated the probable involvement of the sympathetic nervous system. The thyroid gland had disappeared entirely. The hair became changed in thickness, and the finger-ends were flat or clubbed. From the alteration in facial expression, the swelling, the mental obtuseness and thyroidal atrophy, Gull was inclined to consider the disorder as one closely allied to a form of imbecility long recognized as an endemic disease confined to Southern Europe, and known as cretinism.

Fagge, however, presented several cases of cretinism of English origin—well marked sporadic examples, in many respects resembling the adult cases presented by Ord.

In 1878 Dr. Ord brought forward five more cases, two of which he detailed, and also a carefully made autopsy, with clinical and microscopical examination. Interest having been excited in the curious malady, many investigators, in England chiefly, have since presented examples, so that nearly fifty cases have been brought forward, all of which, however, I do not believe to be examples of the disease described originally by Gull. Among the English observers are Inglis, Lunn, Cafavy, Mahomed, Heron, Lloyd, Hadden, Hopkins, and Gowan. In France, Morvan first described the disease as *cretinoid œdema*, and Charcot, Ballet, and Thaon, of Nice, as *cachexie pachydermique*. Olive, Bourneville, Blaise, Ridel-Saillard, Ollier, Merkelen, and Fiesinger presented cases in 1880-1881, and lately Sepelli has turned his attention to the disease in Italy.

In this country, so far as I know, but three cases have been reported—one by Dr. Hammond, one by Dr. Cushier, and another by Dr. Holland, of Louisville. This last case, sent to me by Dr. Preston Scott, of Louisville, was that reported by Dr. Holland, and must form the basis of the present paper. I have also under observation an incipient case, and I hear Dr. Ball has recently reported another to the New York Medical and Surgical Society.

It is probable that there are many others that have hitherto been looked upon as old cases of chronic nephritis, or as examples of cutaneous disease. I can remember several such that have puzzled me, and I do not believe my experience is unique.

The first of the two cases I have recently seen is a woman fifty-five years old. She is married, and has had seven children, and one miscarriage. Besides an attack of dysentery in 1852, she has never had any serious illness. Several members of her family have died of cardiac disease, and her father for a long time presented a swollen appearance, which probably resembled hers. Her menopause is over, and she menstruated for the last time one year ago. For some years, and notably when unwell, she has suffered from violent attacks of hemicrania.

About eighteen months ago her husband's attention was directed to a change in her general health. She became pale and her face appeared swollen. Her speech was affected and she expressed herself in a clumsy manner, and in words containing linguals her difficulty seemed greatest. She was indisposed to take exercise, and found it difficult to use her fingers in buttoning her dress or sewing. She had pains in her arms and legs, and suffered from gastric disorders. Her food was tasteless, and nauseated her. At times she had a profuse discharge of saliva from her mouth. She suffered from the cold, and found it necessary to wear thick clothes even in the warmest weather. She rarely perspired, and at the suggestion of her physician took a series of Turkish baths. Upon several occasions, when dressing after these baths, she noticed her body dotted with myriads of minute sudamina, which, when pressed, discharged a clear liquid, and were unattended by any inflammation or irritation, disappearing in a few hours.

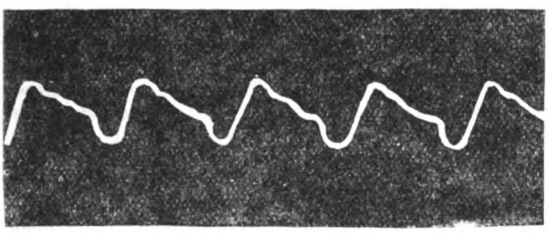
The pallor and swelling of the face attracted the attention of her friends and family, her nose becoming broad and flat, her lips thick and pale, and her eyelids decidedly full and puffed. Her legs and body were also enlarged, but there seemed to be no increase of swelling in the lower extremities toward the end of the day. Her hearing was impaired, and her temper easily ruffled. She was morose and depressed and disposed to seek solitude. Memory, too, became defective, especially in relation to recent events, and she has been unable to concentrate her attention. When shopping she has often forgotten her errand, and on one occasion has paid twice for the same article.

I first saw the patient on September 27, 1882. She was apparently an anæmic, badly nourished woman, and I was immediately struck by her extraordinary appearance and peculiar voice. The swelling just described was observable in the face. The cheeks, lips, loose tissue about the eyes, nose, and forehead were swollen and gave a doughy, tough feel to the finger. The tongue even was large, but not indented at its edges. The swelling, I found afterward, extended all, but not equally, over the body, and the ankles were enlarged. Very firm and prolonged pressure over the tibiæ produced moderate pitting, but with quick return to the general elevation, and there was nothing at all like the pitting in renal disease. Her fingers were broad at the ends, or clubbed, the right, perhaps, being more deformed than the left. Her color was like that of old white wax, and in places where the swelling

[1] Read before the New York Academy of Medicine, December 7, 1882.

was not so great it was crackly and rough, but withal shiny, like the surface of morocco. Local stimulation produced little reaction and no reddening. Her hair is thin and dark, and there is no staining of the skin, so often met with in trophic disorders. The thyroid gland has almost completely disappeared, her temperature is decidedly lowered, and this is unilateral. In the mouth it is 97.2°, in the left axilla 97°, while in a corresponding part on the other side of the body it is but 96°. Trials also made by Dr. Holland showed unilateral lowering. She has subjective areas of coolness over the arms, back, and thighs, and her feet are usually cold.

The pulse has been small, and averages about sixty. The sphygmographic tracings I took indicated, upon several occasions, a condition of increased arterial tension; but no heart-lesions ex-



isted, so far as I could judge. She has suffered from flushes and palpitation.

The numbness spoken of is more persistent in the hands than feet, and is very decided in the two outer fingers of each hand; and in addition to this there has, for some months, been formication in both hands. One of the peculiar features of her case is the disturbance in the sense of taste. She perceives very often disagreeable metallic tastes, and by actual tests I found decided impairment. Her hearing is diminished upon the right side, and she can only hear the watch at six inches. Her vision is impaired likewise, and the right eye suffers more than the left. The disorders of motility in the patient's case are conspicuous. Dr. Holland was unable, some months ago, to find ataxia, and so far as diminished co-ordinating power of the upper extremities is concerned, I agree with him. The patient, however, cannot stand steadily with her eyes closed, and when she walks her gait is something like that of the general paretic. She is very clumsy at times, but the awkwardness seems to wear off to some degree as she moves about.

The tendon-reflex is decidedly exaggerated on both sides. Electro-muscular contractility is diminished, especially on the left side. Galvanic reaction is better on the right side than the left.

Her speech is slow, thick, and hesitating, and there is the occasional elision of a syllable. There are no material ocular changes, and the pupils contract normally.

There is a certain slowness in expressing her ideas, and in the past there have been the indications of mental failure already spoken of.

Examination of the urine upon several occasions failed to show the presence of albumen. The specific gravity of this fluid was 1022, and it contained earthy phosphates and an appreciable amount of sugar. No casts were found. She passes from one to two pints in twenty-four hours. No treatment has helped her in the least.

In this patient's case, the degree of œdema was not everywhere constant, although certain regions were always more or less swollen. At these times, however, no urinary change was found. Certain parts, such as the face, always remained enlarged.

The constancy of individual symptoms dignifies the disease as well established; and I do not think we should regard it, with Mahomed, as simply an irregular form of Bright's disease—although, in many cases, albuminuria occurs at a late date, and in several of the cases this has been the apparent mode of death. We should, I think, draw the line sharply between the examples with albuminous urine, and those without. Many so-called cases of myxodema are clearly not examples at all, and these we shall leave entirely out of the question. In all the true cases there has been more or less constant swelling of the face, even when no mention has been made of enlargement of the legs—a fact inconsistent with the anasarca of renal disease. The lips seem to be involved nearly always, and so is the tongue. In one of Gull's cases, the swelling was so great that the patient could not wear false teeth. The urine in this disease has, as a rule, been of low specific gravity, averaging about 1016. No albumen has been found in the early stages. In one of Lunn's cases, however, a trace of albumen has been found from time to time, but this is unusual. In the fatal cases, and, in fact, in the later stages of the twenty-seven cases collected by Mahomed, albumen has been discovered; but this is rather a result than an evidence of original renal trouble.

The proportion of urea is always diminished, and this fact was first pointed out by Ord. In one of Lunn's cases, the patient passed from 34 to 38 ounces of urine daily, averaging 5.72 grains of urea per ounce, which is equal to 194.48 grains in twenty-four hours. In Hadden's case 196 grains were passed in twenty-four hours. This was a notable diminution when we know that the normal quantity is from 450 to 500 grains per diem. No sugar has been found except in one of my cases.

The temperature in myxodema is notably lowered and there is great subjective suffering from cold, although changes in temperature do not affect the patient as disagreeably as it might be supposed they would. In Morvan's fifteen cases, however, the patients felt worse in winter. The deep temperature may be reduced from two to three degrees.

In one of Inglis' cases the axillary temperature was only 95°, while in many others it rarely exceeded 96° at any time. A peculiarity of the temperature change is its unilateral character. In nearly all of the true cases there is this difference of at least one degree between the two sides of the body, usually, however, in favor of the right side. In one of Duckworth's cases the right axillary temperature was 99.4°, the left, 97.2°.

The surface temperature is also lowered. In Ord's fatal case the temperature below the right mamma was 94.9°, and below the left, 95°.

No repeated records of temperature have been been made, so far as I am aware, except in Hadden's cases. In one of these cases seventy-one observations were taken. The temperature reached the normal point only sixteen times. It was never above 98.6°; upon nineteen occasions it fell below 97°.

In one of his patients it fell to 94° a day or so before death, and remained at that point until the patient died.

In Ord's fatal case the temperature fell frequently to 95°, and never exceeded 97.6°. It reached 99° just before death. In my own cases the same unilateral difference existed, but in the second patient there

was chronic mania, and the unilateral change was elevation, the left axillary temperature always exceeding the right.

The circulation undergoes changes, the arterial tension being, as a rule, increased. There is usually some difficulty in obtaining sphygmographic tracings, owing to the toughness of the skin. The tracings taken in my first case were extremely interesting, and showed in every instance a short first stroke and a wavy, long diastolic line, with tremulous valvular indentations. In Hopkins' case there was slight roughness with the first sound at the base, and reduplication of the first sound at the apex. As a rule, however, there are no heart-lesions. The pulse is usually feeble and slow, though slight muscular exercise causes an immediate increase. The patients are always anæmic, and the red-corpuscles are decreased in size and number. Seguin, who made some measurements, found only a slight reduction in the number, but a great reduction in the size of the corpuscles.

There is great difference of opinion in regard to the mental condition of patients with myxodema. All observers admit that there is dulness and stupidity; and some have described a much more pronounced condition of affairs.

The peculiar mental state of the cretin is a sluggish action of the mind and a slowness in expressing ideas, which are tardily formed. This may vary greatly from hesitation to utter stupidity. With this there are very conspicuous physical defects closely allied to the appearance presented in the adult cases I have referred to, though usually more marked. This resemblance led Gull to apply the word cretinoid to the disease. There is, I have noticed, a great lack of concentration, a forgetfulness of small duties, and a dulness of perception. The mental trouble usually precedes the swelling and other symptoms, though it is sometimes masked and unrecognized.

In some of the cases, Cafavy's among the number, melancholia preceded the actual manifestations of other kinds. In Morvan's and Duckworth's cases hallucinations are referred to, and a variety of minor changes varying from irritability of temper to actual mania are present. Bad dreams, and disturbed sleep are mentioned by several writers. Hallucinations seem to be very common, and indicate not only an erethism of the perceptive centres, but a state of excitement of the organs of special sense.

The trophic changes consist of alteration in the texture and color of the skin, bronzing, acquired moles, changes in perspiration, loss of hair, and thyroidal atrophy. The latter symptom is very common, and in Ord's cases especially was it apparent. In most of the cases deposits of fat were found to have taken the place of the atrophied thyroid. In these cases as well as the infantile cretins of Fagge a supra-clavicular deposit of fat was found to have taken place. This I noticed in my first patient. In Duckworth's second case the thyroid was apparently unaffected.

Various other interesting changes in the texture of the skin and its appendage have been found. Hadden observed brittleness of the nails, and other investigators have noticed changes in their thickness and configuration. In one of Duckworth's cases the face, shoulder, and scalp presented acquired moles, and he had seen the same thing in eight or nine other cases. In Gowan's case there were numerous brown, warty growths. The thinness of the hair has attracted the notice of several observers who have reported examples. In both my patients this was the result of the disease, and in Charcot's case not only the hair but the teeth fell out. Lunn has noticed falling out of the hair not only from the head, but from the pubis and axilla, and in Gowan's case the hair disappeared in great part from the head and axillæ. Inglis has found warty growths upon the hands. These and other like defects seem to have been present in the majority of reported cases.

There has been observed in most of the cases a peculiar clubbing of the ends of the fingers. In the cases of Gull, Ord, Duckworth, Inglis, and the French writers, as well as one of my own, the finger-tips were conspicuously broad and patulous. To this appearance Ord and others have applied the term "spade-like."

Myxodema is attended by a real loss of muscular power, and not by a feebleness which results from the bodily enlargement, as has been held. It is true that in Thaon's case and others the circumference of the thighs and legs was immense, and the patient could only move slowly, advancing sideways, and with difficulty placing one foot before the other; but such a deformity is unusual. There is always motor enfeeblement, which is general and grave, and is shown in both upper and lower extremities. Inglis has found in one of his cases that the hand-grasp was very weak; and in many cases the women were unable to use their needles, button their clothes, write, or execute delicate movements. In all that have been tested by electricity there has been diminished peripheral excitability and the galvanic reaction has been normal.

Ballet's patient could not take twenty steps without resting, and one of my own was obliged to ride whenever possible. This feebleness seems to be of a peculiar nature. Charcot and Morvan's cases could make great efforts with ease, lift heavy weights, and walk long distances, but in minor acts they were powerless. One of Morvan's cases could lift a heavy weight, but actually had not enough strength in her fingers to crush a flea when told to do so. This would indicate something closely allied to incoordination, or perhaps volitional enfeeblement. The gait is always peculiar, and has been compared to the waddling of a duck.

The voice of the myxodematous patient has been spoken of as nasal, guttural, hesitating, muffled, or thick. Sepelli says, "The movements of the tongue are slow, and the words succeed each other sleepily; the tone of voice is monotonous, harsh, and has a nasal timbre"—the latter he believes to be due to the infiltration of the pharynx. I do not agree with this explanation entirely, and think the slowness is psychical and the embarrassment of the tongue ataxic. I have heard the same phonation in other diseases, notably in Parkinson's disease and general paresis. In an advanced case reported by Ord the difficulty of speaking was curious. "In speaking she commenced by closing her lips and swallowing; her voice was nasal, with defective intonation; and while articulating she often made a partial act of swallowing and ejected air by the nose."

Morvan found paresis and relaxation of the vocal cords, but no infiltration or œdema.

So far as ocular symptoms are concerned, nothing distinctive has been found. In a few of the cases there is some failure of accommodation, but nothing else. No retinal hemorrhages were found, which are so common in certain varieties of renal disease. In Morvan's cases amblyopia and hemiopia is reported, and in Hammond's double optic neuritis.

One of the striking features of the disease is the

deafness which comes on usually at an early period. It is sometimes, in fact frequently, unilateral, and the right ear is more often affected. There seems to be not only a dulness of auditory perception, but there is an actual local loss of function of the apparatus of hearing, the watch test and tuning-fork showing this to be the case. In the late stage respiration is often embarrassed, and probably by pulmonary œdema, as well as central causes.

Smell and taste are often lost or greatly interfered with. In Hopkins' case the sense of smell was so far gone that the patient could not even detect the odor of a wallflower.

In several cases, notably those of Ballet, Hopkins, Gowan, and one of my own, there was a free and abundant secretion of saliva, and it escaped from the mouth in large quantities. This is sometimes associated with hemicrania or with facial anæsthesia. In six of Morvan's cases there was at times a copious discharge of a watery secretion from the nose.

The disease, so far as I know, has, with very few exceptions, been confined to adult women who have passed the menopause. The male instances are rare, and the number of young female patients is very small. Two of Hadden's cases were women under forty. The ages of the majority of subjects range from fifty to seventy, and in every instance there is a history of great fecundity. Few of them have borne less than five children, and most of them eight or ten, and a number of miscarriages in addition are usually spoken of. Ballet's patient was a woman of fifty-seven, who had had seven children. One of Cafavy's cases had six children and four miscarriages, the other five in eleven years. One of Duckworth's patients had had nine children. Semon's patient had had frequent pregnancies and seven miscarriages. Taylor's patient, a woman of thirty-nine, had had eight children. One of my patients has had seven children and one miscarriage. This feature of the etiology is of great interest, and suggests that a constant tax upon the sympathetic nervous system may have had much to do with the development of the disease. In fact Mercer noticed this in Ord's cases. As I have said, the male cases are few. One of Inglis' patients, who presented a clear picture of myxodema, was a man, but Heron's case is exceedingly doubtful.

Several cases among young people have been presented, but it is very questionable whether these cases were not examples of pure cretinism, as were those of Fagge. Rösch reports the case of a boy seventeen years old, while Bourneville and Ollier have presented two cases in young men twenty and twenty-one years old. Morvan says he has seen the disease in a boy ten years old. Charpentier reports the case of a child four years old who was born apparently healthy. There was remote insane family history, but the children's parents were both healthy. At the age of five months the myxodematous symptoms appeared and she has gradually become swollen and stupid, and has manifested all the symptoms of myxodema. There was everything to militate against the diagnosis of cretinism, her head and ears being well-shaped, and there was no goitrous trouble in the family. In this case convulsions complicated the disease.

As to the other etiological factors not much is to be said. In some cases melancholia is said to have preceded the myxodema, but whether this is a symptom of the developing disease or an actual predisposing condition it is difficult to state. In several cases a neurotic hereditary taint is referred to, while in one I am not sure that the disease had not affected the father of the patient.

In some cases a history of antecedent chronic gastric disturbance is given. Morvan, who claims to have been the first to recognize the disease, believes that prolonged lactation has much to do with its origin. Menorrhagia and uterine disease is mentioned by others, while by many observers reverses of fortune and mental worry are mentioned as causes. In Thaon's case the disease is supposed to have been caused by climatic changes.

A consideration of the pathology of myxodema opens up to us a most attractive field of study, and furnishes interesting facts that must have a bearing upon our present imperfect knowledge of many puzzling trophic maladies.

Gull looked upon the disease as a form of adult cretinism, and there can be no doubt that in many respects these two diseases resemble each other, though Charcot is not disposed to consider them as identical.

Ord believed in the peripheral origin of the affection, considering the central symptoms as secondary. He found in one of his cases in which there had been a post-mortem examination a deposit of mucin in the skin itself, and therefore thought that the central nervous troubles were simply of an asthenic order and due to a diminution of the reflex tonus of the skin, the nerve termini being insulated by the encroachment of myxœis. The peripheral involvement of the cutaneous nerves and the presence of mucin is supposed by several observers to account for the anæsthesia which often exists, the tactile blunting that is frequently found, and the various defects of taste, and subjective coldness. Ord refers to Becquerel's classical experiments, in which he coated animals with varnish, to show the disturbance of the nervous system that follows an abolition of function of a large part of the cutaneous surface. Thaon, of Nice, in discussing Ord's views, very properly shows that in anæsthetic leprosy and other disorders there is necessarily no cerebral disorder, such as might be inferred.

The conspicuous symptoms of myxodema lead us to the conclusion, I think, that the nervous system is primarily at fault. Not only do we reach this conclusion by a realization of the existence of trophic changes of a pronounced sort, and by bulbar symptoms, but by the recognition of the unilateral expression of neural symptoms, which are so common. Savage, Hammond, and Hadden believe in the central origin of the disease, and Cushier, in a recent paper, has found appearances in the spinal cord which lead her to class the disease with such affections as pseudo-hypertrophic paralysis and progressive muscular atrophy. Other observers hold different theories, and Henrot thinks that the essential lesion is in the pineal gland.

The most acceptable theory of the origin of myxodema is that of Hadden, who holds that there is a condition of angio-spasm in this disease in contradistinction to the vaso-motor paresis which exists in exophthalmic goitre; that the deposit of mucin depends upon lymphatic obstruction; that the mental symptoms were due to the condition of the brain itself, and are subsequent to the lesion of the sympathetic system, which is primary and *peripheral*.

The existence of a continued angio-spasm is, I think, opposed to all advanced physiological laws, and, to some extent, destroys the value of his otherwise reasonable theory. Dr. Cushier has found cell-degeneration in the giant-cells of the anterior horns

as well as of the gray matter of the posterior columns. No examination has yet been made of the sympathetic ganglia, and none, so far as I am aware, of the brain, medulla, or cervical cord—at least, no microscopical examination. I believe, however, that when such an investigation is made, there will be found lesions of importance. The early appearance of bulbar symptoms and mental disturbances are, in my mind, suggestive indications that the seat of the disease *originates* in the higher centre, and not in the cord.

The existence of a principal medullary vaso-motor centre has been determined by a variety of observers. Dittmar has found it to be situated in the lateral columnar tract of the formatio reticularis, between the copora quadrigemina and calamus scriptorius. This point when irritated results in contraction of the vessels and lowering of the general temperature. Whatever offices the lower centre in the cord may have, it cannot be denied from the experiments of Goltz and others that they are all controlled by this superior medullary centre. The reduction of temperature in the cases of myxodema, which is usually unilateral, and is very constant, points very strongly to a lesion above the pyramids for its production. Then, too, if we consider for a moment, it will be found that there are various well-defined disturbances which may be referred to deep lesions in nerves that take their origin very near this part of the bulb. The copious escape of saliva with defective sense of taste, the facial anæsthesia, sometimes found, and the escape of nasal fluids, are undoubtedly due to a disturbance of function of the trigeminus. It may be reasonably inferred that the nuclei of the trigeminus and hypoglossus are involved in typical cases, and as one result we find in the tongne the motor defects which are manifested in the peculiar ataxic articulation. The loss of hearing, which is also frequently unilateral, has as well pathological significance. The experiments of Claude Bernard, which proved that irritation of certain parts of the floor of the fourth ventricle produces glycosuria, also suggest a local origin, for in my case, besides bulbar symptoms, there was sugar in the urine.

An irritation of the medulla, which would cause profuse salivation has been found by Gruetzner to produce as well irritation of the sympathetic, manifested by other than local expressions. I mention this fact because I believe a tissue change may exist and be limited to the medulla, and still produce a general disorder of the trophic centres. The symptoms of general paresis (many of which depend upon irritation of the sympathetic system), and resemble those found in myxodema, are probably due at first to local trouble at the floor of the fourth ventricle as described by Magnan. Much of the mental disturbance in paresis arises from varying vascular alterations in the beginning, rather than coarse organic changes, though there can be no doubt as to the condition of the brain in the established disease. In myxodema the mental symptoms are varying, and of vascular causation.

I am inclined to believe that the cutaneous trophic changes are due, in the main, to subsequent disturbance in the lateral and posterior columns of the spinal cord. In cases of mixed postero-lateral myelitis the tendon-reflex is usually increased, as it was in my case, and when the numerous pathological contributions of Charcot are investigated, we must adopt the theory which has been accepted by Schiff and others, that the sensory nerves are those in which trophic fibres go to the skin. In myxodema it is not unusual to find cutaneous anæsthesia, and deep pains are occasionally mentioned.

The significant experiments lately made by Raynaud and Arthaud show that in certain cases of posterior spinal sclerosis, attended by trophic cutaneous defects, there is degeneration of the spinal sympathetic ganglia, with disappearance of Remak's fibres, and destruction of the nerve-cells.

However, so far as we know, the production of cutaneous change is very obscure. There is a close connection between pigment alteration, thyroidal enlargement or atrophy, and mental disturbance. It has been proved, I think, not only by Gull and Curling, but by many others, that this disease bears some relation to exophthalmic goitre, being a sort of antithesis, there being atrophy of the thyroid instead of enlargement.

I have pointed out the coexistence of mental impairment with thyroidal and various cutaneous changes in a paper upon the hairy growths of the insane. Goitre is often attended by trophic derangements of the skin and its appendages, and I have repeatedly found in association various curious phases of mental disturbance, notably melancholia, hypochondriasis, and sometimes mania.

In all the carefully reported cases of myxodema there are striking nutritive changes indicative of a pathological upheaval of the sympathetic nervous system—alteration of color and texture of the hair or falling out, brittleness of the nails or deposits of pigment. Duckworth has noticed the coexistence of molluscum fibrosum with mental disease, and other writers, especially Charcot and Weir Mitchell, have repeatedly in their writings dwelt upon the significance of moles, clubbed fingers, and hair changes.

Geneau de Mussy found increased pigment deposit, and cutaneous changes with medullary irritation of the vagus nuclei, and Mobius has pointed out lesions of the medulla in connection with exophthalmic goitre.

The occasional existence of amblyopia, of double optic neuritus (Hammond's case), the lost sense of taste and smell, vertigo, impaired sense of localization, and other special neurotic defects denote a limited localization.

Whatever the peripheral process is that leads to the formation of mucin in the tissues it is difficult to say. Ord has satisfactorily proved the nature of the deposit, and Hadden is disposed to believe the initial process to be a lymphatic obstruction, the accumulated products being afterward converted into mucin. It is very probable that this peripheral alteration which is always a feature, and connected with diminished or absent perspiration, is the cause of the albuminuria, which is so often found in the *late* stage of the malady—the excretory function of the skin being suspended and the kidneys being obliged to perform double duty.

The diminished excretion of urea is probably due to the apathetic condition of the patient, who rarely uses his muscles, except when he is obliged to. In this respect the condition has been compared to that of a cold-blooded animal.

I removed a piece of skin from the leg of my patient. Under a low power (×200) a specimen stained with hæmatoxylon showed great increase in fibrous tissue, and general evidence of a low inflammatory process. Groups of nuclei were found here and there—more toward the superficial layers, and the rete mucosum was at its lower border

fringed by a row of deeply stained cells. The vessels were all thickened and enlarged, and evidences of infiltration were shown. Though several sweat-glands were seen, there was not one with a duct which extended unbroken to the surface. The gland itself was surrounded by a space which had evidently been filled with some clear substance.

FIG. 1.—Open space which probably contained mucin.

At several points large gaps were filled, the edges of which were dotted with the same small round cells.

Under a higher power (× 500), the cut ends of the vessels were found to be greatly thickened, and when a group of these arterial openings were found it was easy to trace the course of thickened bundles of

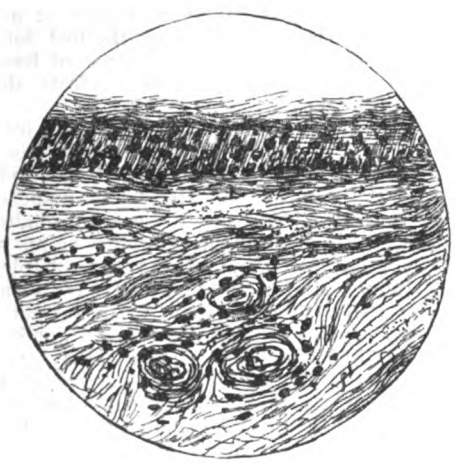


FIG. 2.—Vessels with thickened walls, and surrounded by exudation products.

connective-tissue which passed about them. Groups of exudation corpuscles were found about the vessels. No apparent nervous degeneration was to be discovered.

Mercer has examined specimens of the uvula and tongue from one of Ord's patients, and the same nuclear proliferation and vessel-thickening was found.

Post-mortem examinations have not been numerous, and carefully recorded ones are very rare.

Ord's autopsy was the first, but no microscopical examination of the nervous-tissues was made. The vessels of the brain were found to be generally atheromatous, *especially at the base*, the kidneys were found to have undergone vascular alteration, and were "minutely granular," the lungs were emphysematous, and the heart was affected. One case is reported in the *St. Thomas's Hospital Reports*. On autopsy, the kidneys were found to be sublobulated, elongated, and abnormally firm. The brain was anæmic, but healthy. The thyroid body had disappeared, and its place was occupied by two little fatty masses.

Of Morvan's fifteen patients, several of whom died, there is no record of a carefully made autopsy. In fact, with the exception of Dr. Cushier, no one has made any special examination, so far, of the nervous system.

It is hardly possible to confound myxodema with any other condition—scleredema or icthyosis. In the former there is a hardness and limited invasion, and a toughness that does not belong to myxodema. The latter disease cannot possibly be mistaken. In neither of these skin diseases are there mental or speech defects.

As to the possible confusion with renal disease, there is much to be said if we are disposed to bring a number of irregular cases of nephritis under this head. True myxodema should include only cases with tough or doughy swelling, mental degeneration, speech defects, thyroidal atrophy, deafness, and constant lowered temperature. In the latter respect unilateral lowering is of great diagnostic significance, as has been already shown.

The prognosis of myxodema is usually bad, and but one case, so far as I know, has been cured, that of Ballet. The probable origin of the disease in itself is sufficient to place it in the long list of progressive degenerative and fatal disorders of the nervous system. Its course is a comparatively long one. Morvan's longest case had lasted twenty-seven years, and he reports others of long standing. Thaon's patient had suffered for eight years. In one of Duckworth's cases the disease had lasted four years. In my own cases the disease had lasted a comparatively short time.

The *treatment* of myxodema has been attended by very unsatisfactory results. Ballet reports a case, also observed by Charcot, in which the milk treatment was followed by decided amelioration in the symptoms, the skin becoming more supple, the swelling subsiding, and this was in a patient who had suffered for many years and had well-developed symptoms. Thaon refers to the improvement of his patient as the result of a residence at Nice and Aix, but when she went to a cold climate all the symptoms were increased.

In a discussion before the Clinical Society, Cafavy recommended sulphur baths, which had been used by Thaon. Dr. Bennet had seen good results follow the use of iodide of potassium, but it would appear that Bennet's patient had had syphilis, and was probably a questionable case. Taylor treated one of his patients with jaborandi, but without success.

A form of treatment, which so far has done good, consists in the use of either nitrite of amyl, as suggested by Hadden, or nitro-glycerine. The latter drug has been used in several cases with much benefit. In one of my cases it was administered in

doses of one-fiftieth of a drop and has really done some good.

To recapitulate: 1. Myxodema is a disease of adult life, chiefly in women. It is allied to cretinism and is slowly progressive; it is attended by the gradual and uneven deposit of mucin in the skin itself, by various trophic skin changes, by unilateral lowering of temperature, mental impairment, increased arterial tension, deafness, and ataxic speech defects. 2. It bears a significant relation to frequent pregnancies and the menopause. 3. It probably depends upon a lesion primarily of the bulb, with secondary extension to the postero-lateral columns of the spinal cord and the spinal sympathetic ganglia. 4. Cases with muscular atrophy and deep tissue-changes are rare, and when so found probably indicate degeneration of the multipolar cells in the anterior horns. 5. Renal disease is not the cause of the malady, but the result.

POPULUS is the last new and perfect substitute for quinine. It is also claimed to be a powerful antiseptic.

LOCOMOTOR ATAXIA COMPLICATED BY ACUTE CARDIAC DISEASE.[1]

BY LEONARD WEBER, M.D.

NEW YORK.

IN a paper published in the *Montpellier Médical*, for June, 1880, Dr. Grasset records certain facts tending to establish a causal relationship between typical locomotor ataxia and certain cardiac lesions. He relates two cases of disease of the aortic valves developing in the course of locomotor ataxia, and fifteen other instances, collected from various sources, in which locomotor ataxia and valvular lesions were found to be associated.

In the *Berliner klin. Woch.*, for July 7, 1879, Drs. Berger and Rosenbach, of Breslau, have reported seven cases of tabes, coupled with incompetency of the valves of the aorta. Four of these occurred in females, and three in males. The patients were from thirty-five to fifty-five years of age. It is to be regretted, however, that they were unable to determine, in any of their cases, which of the two diseases was first developed

In the works of standard authors on neuro-pathology, I have not found any observations bearing on the subject in question. With regard to the circulatory apparatus in locomotor ataxia, it may be mentioned that Eulenburg has taken sphygmographic tracings in a number of cases, and has found diminished tension of the pulse. Charcot states that, in the great majority of cases of tabes, the frequency of the pulse is increased to 90 or 100, or even more beats per minute.

I will now give the history of the case that has come under my observation:

H. F——, aged forty-five; German; married; merchant. First consulted me in February, 1879. He is a tall but thin man, of pale yet not cachectic appearance, and of a very nervous temperament. Family history good; no neurotic taint. He acknowledges having had sexual intercourse freely in his early manhood. He does not at present complain of any weakness as regards his sexual powers; but he feels rather exhausted and has pain at the back of the head on the day after coition. He also perspires freely soon after the act, and is altogether given to much freer perspiration after muscular exertion or mental excitement than formerly. Has had neither syphilis, inflammatory rheumatism, nor other severe illness. His children appear to be strong and healthy.

He finds it difficult, of late, to properly attend to his business, which is laborious in so far, that for many years he has been in the habit of buying and shipping large quantities of goods. This circumstance compels him to be on his feet, more or less, all day long, in order to make the necessary selections. For the past two years he has been troubled by fulgurating pains, more severe in the lower than the upper extremities, and associated with articular dolors. But they never have been severe enough to confine him to his bed for any length of time.

His sleep has been bad for some time, and he has of late been much more irritable and excitable than formerly. Appetite good, bowels fairly regular. No paræsthesia, nor paresis of rectum, bladder, or urethra. No vesical catarrh. Recently, in taking his meals, he has noticed that, the morsels of food

[1] Read before the Section on Practice, New York Academy of Medicine, November 21, 1882.

will not glide down the œsophagus as readily as formerly, and that he has to make a decided effort to get them down. This symptom of dysphagia I have noticed, in common with other observers, pretty regularly among the earlier signs of locomotor ataxia. In the physical examination of the patient, I found no evidence of visceral disease, but noticed a pulse of ninety beats per minute. Complete absence of left patellar tendon-reflex, and great diminution of right were also noticeable. When his eyes are closed, the patient cannot stand without swaying to and fro. Nor can he stand or hop about on one leg, although he does it a little better with the right than with the left leg. His gait is not ataxic, and he has no numbness of his feet. There is, however, a good deal of paræsthesia of the lower extremities. The coarse muscular power is fairly good; but all continued muscular efforts soon tire him. Writing also. There is well-marked myosis, no reaction of pupils to light. An ophthalmological examination, made by Dr. Knapp, corroborated the fact of the presence of the Robertson pupil, but failed to disclose any retinal changes. *Diagnosis:* Disease of the posterior columns of the cord, slowly ascending. *Treatment:* Extract. physostigmat., one-tenth grain, four times daily; evening dose of brom. sod. with pepsin and hydrobromic acid; half-bath of about 80° and of two minutes' duration, to be taken in the morning, three times in the week. Galvanic current to spine, also three times a week. Restriction as to sexual intercourse and general regime. The application of electricity was found not to agree with the patient. It irritated and excited him, and was consequently discontinued. The half-baths taken as described above were introduced and systematically used in locomotor ataxia by the late Dr. Runge, Physician-in-Chief of the Hydropathic Institute at Nassau, Germany. In his treatise on hydrotherapeutics, he recommends them very highly in the treatment of this disease. I may be permitted to say in this connection, that, in the present case, as well as in several similar ones, and likewise in a number of instances of spinal neurasthenia, I have been much pleased with their beneficial effects.

The above treatment was continued until May 15th, with little interruption, when small doses of ergot and belladonna were substituted for the physostigma, in order to reduce the hyperidrosis, which was a source of great annoyance to Mr. F——. Later on, the patient went into the country, continuing there the baths in the shape of a daily sponge-bath, but taking no medicine. I saw no more of him until December, when he reported himself worse again, in consequence of overwork. The right patellar tendon-reflex had now also disappeared. In other respects the patient was *in statu quo*. He was again put on the physostigma powders and half-baths. This treatment was kept up for three months. His sleep had meantime become sufficiently good to dispense with the bromides. In the summer of 1880 he went with his family to the White Mountains, where he was taken, in the night of August 1st, with acute and severe symptoms concerning the heart and lungs, which confined him to his bed for two weeks. He next went to Saratoga, where he had another attack of orthopnœa, occurring at night. I saw him again in the city in the night of September 5th. He was then suffering from an attack of severe orthopnœa, coughing violently, and expectorating a good deal of frothy mucus of a pinkish color. Râles could be heard all over the chest, as if he were going to have acute œdema of the lungs. His heart beat very fast and pericardial *frémissement* and friction-sound were unmistakably present. The systolic sound was somewhat muffled at the apex. I was informed that this paroxysm had come on immediately after sexual intercourse, and that the previous ones at the White Mountains and Saratoga had occurred in much the same manner and had apparently been brought about by the same cause. I gave him a few drops of veratrum and stayed with him an hour, when he ceased coughing and fell asleep.

A careful examination, made on the following day, confirmed the diagnosis of pericarditis, and probable endocarditis. But I failed to discover in the etiology anything except the probable influence of the sexual act, which he had been again indulging in more freely while in the country. The patient was kept quiet, and a blister applied over the heart. On September 19th he had another attack of orthopnœa, less severe, again following sexual intercourse. September 24th, I noticed that the fifth intercostal space retroceded at the heart's systole. A friction-sound was no longer audible. October 2d, I heard for the first time a systolic mitral murmur, associated with accentuation of the second sound of the pulmonary artery. This made it pretty certain that endocarditis as well as pericarditis had attacked the patient at the same time. The indulgence of sexual intercourse probably furnished the immediate cause of the development of the cardiac disease, while for the remote cause we would have to look to the spinal affection and its weakening influence upon the circulatory system, as explained by Charcot and Eulenburg, and particularly marked in this case. He was ordered tonics and small doses of digitalis, which he continued more or less during the winter of 1880–81. Sexual intercourse he was forbidden. The murmur remained the same, but the ataxia did not progress. He was able to attend to business in a moderate way, and had no further attack of orthopnœa until February 20, 1881. This attack occurred again at night, but the immediate cause was not known—perhaps not acknowledged.

In March, 1881, he had a pretty severe attack of lumbar neuralgia, requiring morphine injections.

He now prepared to go to Europe. Before sailing he consulted Dr. Alonzo Clarke, who also pronounced his cardiac trouble to be mitral. The summer of 1881 he spent at Nauheim, in Germany, an indifferent thermal bath and popular summer resort for ataxic patients. The following winter he spent at the Mediterranean, and the past summer he spent again at Nauheim. During his sojourn abroad his cardiac affection did not give him much trouble. In the course of eighteen months he had but three moderately severe attacks. He returned about a month ago.

His general condition is now not quite as good as it was when he went abroad; but in the main the disease of the cord has not made any marked progress. There is to be noted the same retrocession of the fifth intercostal space as before observed. No friction sound, but a systolic apex murmur, although somewhat softer than previously, is at present audible. Pulse fast, but rhythmical. No marked hypertrophy or dilatation of right ventricle; less accentuation of second sound of pulmonary artery than before. Again, the systolic murmur is barely heard at the lower angle of the left scapula. When a systolic murmur is due to well-marked mitral re-

gurgitation, it is distinctly audible in the above region, as well as at the apex. In nearly every case of mitral incompetency under my observation, I have heard the systolic murmur just as loud at the lower angle of the left scapula as in front. From this and other physical signs already mentioned, I am inclined to believe that the endocarditis in Mr. F——'s case has not led to as much retraction of the mitral valves, as it was feared it would in the commencement of his cardiac trouble.

136 West Thirty-Fourth Street.

THE LOCAL TREATMENT OF BURNS.

By ROBERT T. MORRIS, M.D.,

New York.

For some peculiar reason several of the common principles which are applied in the treatment of wounds of the soft parts in general, and which may be used to the greatest advantage in managing burns and scalds of the second and third degree of Dupuytren's classification, have been shamefully neglected.

In quite a large number of burns which I have treated during the last summer and autumn, when these principles have been brought to bear the patients have been almost entirely free from pain during the whole time when the dressings were applied, and the long suppuration and ugly cicatrices which so often follow burns of the third degree have been reduced to matters of small importance, to say nothing of the avoidance of such secondary effects as are apt to follow intense local pain.

In describing the treatment it will perhaps be well to take as an example a hand and arm which were burned by an explosion of gunpowder. The possessor of the limb in question was a stout Irishman who came into the Dispensary of Chambers Street Hospital one day in July last, and the burned area included all of the surface from the tips of the fingers to a point just below the elbow. The larger part of the skin was burned to the second degree, and the cuticle with transuded serum beneath stood out in great blebs, or lay torn and wrinkled over the surface, looking like sheets of wet parchment.

About the wrist and on the back of the hand and between the fingers the burns were of the third degree, while at the upper portion of the forearm there was simply hyperæmia of the skin.

In the first stage of the management of the case all of the blebs were opened and every part of loosened cuticle carefully pulled away and trimmed off as closely as possible to the edge of the healthy skin, so that the inflamed surface was entirely exposed and dressings might be directly applied. Another point was also gained, by having this dead cuticle all out of the way, so that it could not form recesses for storing up the discharges, which would decompose and irritate the sensitive skin beneath.

Iodoform was next sprinkled thickly over the denuded surface and two more points gained—the iodoform acting as an ideal antiseptic and being analgesic to such a degree that complete relief from pain followed very rapidly on its application. Suppuration also was limited very decidedly by this agent by virtue of its action in restraining exuberant granulation.

Strips of cheese-cloth were then spread thickly with vaseline and the surface sprinkled generously with more iodoform, the strips next being wound closely about the arm and hand, care being taken to leave no wrinkles. Small pieces of the cheese-cloth prepared in the same way were then wound about the fingers. Sheet lint wrung out in carbolized water (1 to 40) was placed over this and the whole enveloped in gutta-percha tissue, the latter dressing serving to keep everything beneath warm and moist and thus fulfilling two extremely important indications, besides preventing the soiling of the cloths and bandages by the vaseline and discharges. An ordinary roller bandage was finally applied to keep the dressings in position, and everything was complete.

As it is a matter of considerable importance that the wounds be disturbed as little as possible in these cases, the man was told to return every third day. On his next appearance at the dispensary the patient was found to have had no pain whatever; and he did not suffer during the whole length of time required in the healing process except while the dressings were being changed and the surface was exposed.

In a few days the portion of skin which had been burned to the second degree was covered by a very delicate and beautiful bluish film of new epithelium, while the part burned to the third degree presented the most exquisite little granulations of the ambitious and well-regulated variety which so delight the eyes of the surgeon. With the formation of these granulations there was, of course, a production of a certain amount of pus, but not nearly in such quantities as we are accustomed to see it in burns treated in the ordinary ways, when the granulations have to wage war with the dressings at fearful odds, and become weak and worn out before they have half gotten to work at their legitimate occupation. In a very short time epithelium was shooting out over those parts which had been burned to the third degree, and the process went on rapidly and completely without any signs of lagging on the last half inch; the skin which eventually covered the wounds being natural in appearance, except in a few patches where the hair-follicles had been entirely destroyed, and in these places it remained smooth and somewhat glazed.

At one time, while the healing process was going on rapidly, the dressings accidentally slipped away between two of the fingers, and, when I next saw the man, these fingers were quite firmly united nearly to the last phalanx, making it necessary to pull them apart again.

The patient, whose burns have been described, was delighted with the process and results of the treatment. He had seen a good many similar cases, and had anticipated a painful and very tedious experience.

There were only two classes of cases among my patients where any pain was complained of after the first dressings had been applied. When very small vesicles existed in the thick skin of the palm or side of the foot, there was considerable pain until every vesicle had been carefully hunted out and opened, so that iodoform could be placed in the skin underneath; and, when the burns had involved the integument over a large joint, as the elbow or the knee, a subacute synovitis sometimes appeared, which was accompanied by a great deal of discomfort. In the cases which I have seen this synovitis has been controlled and the pain relieved by fixing the joint in an immovable position and bandaging quite firmly about it; but it is a question whether such treatment would prove sufficient in severe cases.

It is not customary with most physicians to open

all blebs and vesicles and trim away the dead cuticle; but, by way of experiment, I have sometimes allowed one or two blebs to remain, while others in the vicinity were opened and the dressings applied; and by the time that the surface under the latter was covered by epithelium, that of the others was hardly in the beginning of the healing stage.

HUMANIZED VACCINE VIRUS *VS.* BOVINE VIRUS.

By FRED. W. COOVER, M.D.,

VISITING PHYSICIAN HARRISBURG HOSPITAL, PA.

Having had during the current year what has been to me a very interesting series of vaccinations, giving the opportunity, as it did, of comparing side by side humanized and bovine virus in a fair and unbiassed manner, I have thought it might be profitable to the readers of The Medical Record to have a few of the cases reported in full, allowing them in this way to draw their own conclusions. I have been using bovine virus quite extensively for a number of years with what I suppose would be called the average success. I have preferred it for a number of reasons, the only trouble that would occasionally be annoying being the extensive inflammation it would produce, followed by a large slough with from four to eight weeks of suppuration, ending in a few cases with an abscess in the axilla; but what is still more deplorable, the prejudice this occasioned against vaccination, the parents declaring that in the future it would be omitted, they preferring to take their chances of getting small-pox rather than have their children thus tortured. Parents for this reason are allowing their children to go unvaccinated, and the amount of mischief done by an indignant and gossiping parent by prejudicing persons against vaccination, to say the least, is incalculable.

Sunday, May 14, 1882, before breakfast, I was asked to call immediately at the house of Mr. S——. Without making any inquiry as to the nature of the case, but from its urgency supposing it to be obstetrical, I hurriedly dressed, and upon reaching the house, much to my surprise, was told the following story: The evening before the father had been informed of the illness of his son Harry, aged twenty, who was working in a neighboring town, nine miles away, and that during the night he had brought him home in a wagon, and also, from the eruption that was appearing on his face, he feared he was getting small-pox. After making inquiry as to his symptoms, and examining the eruption, I had no hesitation in making a diagnosis of small-pox, and advised his immediate removal to the small-pox hospital. Giving strict directions that there should be no intercourse between himself and the other children, the parents having had small-pox; the mother agreeing to act as nurse, I left for the purpose of securing vaccine matter and disinfectants, which having obtained, I returned and vaccinated all members of the family, including the parents, using a whole quill on each person of what I had been assured was fresh bovine virus from a vaccine firm in an adjoining county. The abrading of the skin and applying the virus was carefully performed, as I recognized the gravity of the situation. There were four children: Will aged eighteen, Anna fifteen, Emma eleven, and Elmer seven. The two oldest had faint marks of a former vaccination, the two youngest none at all. Harry was removed to the hospital where, under my care, he successfully passed through a severe attack of confluent small-pox. The bed-clothing was taken with him in the wagon, the house was thoroughly disinfected, and the room he occupied closed. May 24th, just ten days from the time of the eruption making its appearance on Harry, Will, the next oldest, went to bed with the characteristic prodromata of small-pox, which terminated in about a dozen papules. Four days later, Anna passed through a similar mild attack. The vaccinations having failed to take in all, I was anxious to revaccinate the two youngest; the parents, however, refusing to give permission, they were allowed to take their chances. Twelve days later Emma was attacked with confluent small-pox, from which she recovered, the parents keeping her as well as the two former ones at home. There now remained but one more, Elmer, who, ten days later, was stricken with the confluent form, from which he died on July 25th, being the thirteenth day of his sickness. This family resided in the first of a row of three frame houses; the family living in the middle house sent their children away, while the occupants of the third remained, and were allowed by the family physician to go unvaccinated. August 1st, I was asked to see this family, numbering six persons, the physician in attendance being in doubt as to the meaning of the symptoms of which the mother and son, aged seven, were complaining. The mother developed the worst case of confluent small-pox that I have ever met with, the son's being semi-confluent; both, however, fortunately recovering. The same day I vaccinated the remainder of the family with what I considered reliable humanized virus. The father and oldest daughter had been vaccinated a number of years before, while the two youngest, aged seventeen and fifteen had never been. Both cases of small-pox were treated in the house, and the whole family were necessarily exposed to the contagion. But how different and gratifying the result of my vaccinations in this instance compared with those before narrated. They all, with the exception of the oldest daughter, got very sore arms, the father in particular complaining a great deal of his, though in constant attendance upon his wife, and what was so very satisfactory, the complete arrest of further spreading of the contagion, as I had no more cases to treat in that family.

I offer no comments, but my plan of vaccinating since this experience has undergone a change. I now, when called to a family where small-pox has developed, use bovine virus on one arm and humanized on the other, feeling satisfied that only in this way can I discharge my whole duty and give them every possible advantage of avoiding the disease; and I may add that, in every instance when this plan has been carried out, I have been able to prevent any new cases from developing.

The First Successful Ovariotomy in Bellevue Hospital.—Dr. W. Gill Wylie, of this city, writes: "In a recent issue a mistake was made in saying that I had performed the first successful ovariotomy in Bellevue. Dr. Wm. T. Lusk did ovariotomy successfully in a wing of the old building at Bellevue in 1878, and the case was reported. Until very recently there has been no suitable place at Bellevue available to the gynecologists for doing ovariotomy."

Reports of Hospitals.

RANDALL'S ISLAND HOSPITAL.

Strangulated Ventral Hernia.

(Reported by Willard P. Beach, M.D., House Surgeon to Randall's Island Hospital.)

The patient, a female, aged twenty, was admitted to this hospital, October 1, 1882, suffering from a large ventral hernia about the size of a cocoanut, situated in the left inguinal region in close proximity to Poupart's ligament, and resulting from a stab-wound received some two years previously, through which, according to the history, the intestine protruded down to the knees. At that time she was taken to Chambers' Street Hospital, and, after proper treatment, recovered. No unpleasant sequelæ followed, until six months ago, when a tumor began to show itself in this region and rapidly assumed considerable proportions. She again applied at Chambers Street, but refused to allow the necessary operation which was advised.

When admitted to this hospital, a deep ulceration one and a half inches in diameter was present over the surface of the tumor. The hernia was easily reduced, but the impulse on coughing required considerable strength to overcome. On the succeeding afternoon the patient was seized with vomiting, depression, etc., from which it was believed that strangulation had taken place. The hernia was instantly returned under ether, but the symptoms persisted throughout the night, with commencing discoloration and turgidity of the part; immediate operation (under Lister) was therefore decided upon. The hernial opening through the abdominal wall was found to measure three inches in circumference, the sac consisting merely of integument and with no adhesions present, although the gut was much inflamed and quite dark. The sac was afterward laid completely open, the superabundant skin cut away, and, after freely paring the edges of the deep opening, the parts were united by silver sutures passed through the entire thickness of the abdominal wall.

The patient soon rallied and made an excellent recovery, with no bad symptoms, the wound showing very little suppuration, and with complete reduction of the hernia. The subsequent general treatment consisted merely of the usual measures, and locally of an iodoform dressing, over which was placed a firm compress and bandage. No signs of general peritonitis supervened. One week after operation a natural alvine evacuation took place, and the bowels have since acted normally.

The case is rather a remarkable one in itself, but more so from the evident occurrence of strangulation, which rarely complicates this form of hernia.

New York to have a Crematory.—A report comes from Washington, Pa., that New York is to have a Crematory. It will be near the city and will have many improvements on the Lemoyne furnace, doing the work in much less time. It will be so constructed that the ashes can be removed before the retort cools, allowing friends to carry the remains home with them in their pockets.

Cremation of a Physician.—The body of the late Dr. L. Ehrhart, of Alleghany, Pa., was cremated at Washington, Pa., on November 26th.

Progress of Medical Science.

Diagnosis of Spurious Heart Murmurs.—Dr. Rosenbach (*Transactions of the German Medical Congress*, 1882) recommends the following simple procedure to determine the pneumocardial nature of any murmur: Firm pressure is made with the tip of the finger in an intercostal space at the point of maximum intensity of the murmur. In this way the portion of lung in which the murmur is produced is pushed away from the heart, and the heart itself is also pressed back, and is prevented from transmitting its pulsations to the lung with force sufficient to give rise to a murmur. The spurious, extra-cardiac murmurs are thus greatly weakened or entirely suppressed, while no effect is produced upon the true cardiac murmurs.

An Explanation of the Uræmic Seizure.—Dr. Rühle (*Transactions of the German Medical Congress*, 1882) states that in every case of death from uræmic convulsions œdema of the brain is found to exist. But simple œdema of the brain does not cause convulsions, and some toxic agent must be added to the serous exudation to produce this condition. That chemical changes accompany the uræmic attacks is shown by the fact that the gastric secretions become alkaline and that the breath turns moistened litmus-paper blue. So soon, therefore, as œdema of the brain comes on in the course of these, as yet undefined blood changes, it acts as a poison and gives rise to convulsions.

Placental Origin of Congenital Heart Disease.—Dr. Von Hoffmann records a case of congenital closure of the semilunar valve. The child suffered at birth from cyanosis, atelectasis, and great irregularity of the heart's action, and died from suffocation on the third day. The placenta had been previously examined and was found to be the seat of numerous recent and old extravasations. From these hemorrhagic foci pathological products had been introduced through villous absorption into the fœtal circulation, and had thus given rise to endocarditis. The placental extravasations had been caused by violent fits of coughing, from which the mother had suffered about the sixth month of pregnancy, which date also corresponded to the beginning of the fœtal endocarditis. Von Hoffmann advises the careful examination of the placenta in every case of childbirth, and believes that much light might thereby be thrown upon the etiology of diseases of the new-born.—*Transactions of the German Medical Congress*, 1882.

The Subcutaneous Injection of Various Salts of Silver.—Dr. Eulenburg presented a paper at the German Medical Congress, held in Wiesbaden (*Transactions*, 1882), in which he related some experiments undertaken by him to determine the utility of the hypodermic injection of silver. The uncertain results following the administration of nitrate of silver per orem he thought were due partly to a reduction of the salt in the process of compounding, and partly to chemical changes which it undergoes in the stomach. The first experiments were made with chloride of silver. Immediately after the injection no discomfort is experienced, but later some inconsiderable pain is felt for several hours. This is probably due to the deposition of metallic silver in the tissues. Some injections of the phosphate were made in rabbits without exciting

any local irritation. As this salt is soluble only in a strongly acidulated menstruum, trials were made of the pyrophosphate, which requires much less acid for its solution. No irritation followed the injections. Finally an albuminate was used with the same negative result. Previous trials of the nitrate had demonstrated that no evil effects followed its injection other than some pain, and, very rarely, slight inflammation. The author stated that a part of the injected salt is precipitated at the point of insertion, and a part passes in a soluble form into the blood and is excreted by the kidneys. From the experiments thus far made Eulenburg concluded that solutions of the silver salts in suitable form might be administered subcutaneously with advantage, and that the results obtained are much more certain than when the metal is given by the mouth. As regards the particular salt most suitable for hypodermic use, the author was as yet undecided.

THE VARIETIES OF CIRRHOSIS OF THE LIVER.—Professor E. Lancereaux distinguishes three varieties of cirrhosis of the liver—the syphilitic, the malarial, and the alcoholic. In cirrhosis of syphilitic origin the liver is deeply lobulated, furrowed, and adherent to the neighboring organs. The cellular hyperplasia seems to centre around the ramifications of the lymphatic and arterial systems. There is little or no ascites, no enlargement of the superficial abdominal veins, and no icterus unless from compression of the bile-ducts by the newly formed connective tissue. The course of this affection is slow, and the prognosis is favorable. In the malarial variety the liver is greatly increased in size, of firm consistence, and presents a smooth or slightly granular surface. The principal signs of malarial cirrhosis are hypertrophy of the liver and of the spleen, long-continued jaundice and slow progress. Alcoholic cirrhosis presents two forms. In one the liver is contracted, hard, fibrous, nodulated, and not adherent to the neighboring viscera. In the second form the organ is increased in size, of smooth or granular surface, presenting a connective-tissue hyperplasia with constant granular or fatty degeneration of the gland-cells. The diagnosis of the first form rests upon the emaciation of the patient, the dryness of the skin, excessive and steady increasing ascites, and dilatation of the superficial abdominal veins. Death usually results from mechanical obstruction to respiration. In the second form the hypertrophied liver and the absence of ascites resemble the signs of malarial cirrhosis, but the two varieties differ in the character of the icterus. In cirrhosis of malarial origin, jaundice is always present, but in the alcoholic form it appears late in the course of the disease, and is then of very grave prognosis. The patients usually present symptoms of great depression and die comatose. —*Revue de Médecine*, July and October, 1882.

OOPHORECTOMY IN ENGLAND.—The *Medical Press and Circular* laments the unfortunate frequency with which Battey's operation is at present being performed in England. It comments in the following way upon this topic:

"It is perfectly safe to assert that on no organ of the body are more doubtful operations performed than on the uterus and its appendages, and that in no department of medicine is the intellectual crippling of specialism more signally demonstrated than in that of obstetrics. Greed and the predilection engendered by special and limited study are apt to compel men to unravel all forms of disease, from the standpoint of the particular department of which they may happen to have taken parental charge. This is daily illustrated in the experience of every practitioner who chooses to have his eyes and his mind open to conviction. Quite recently, at the Obstetrical Society in London, Dr. Braithwaite, of Leeds, read a paper 'On Two Cases of Unilateral Oophorectomy,' the first of which was performed for a *cardiac affection*, associated with dyspnœa! and the other for pain in the left ovarian region. We thoroughly indorse the remarks of the President, Dr. Matthews Duncan, on these cases, that 'to remove one ovary as a treatment of cardiac dyspnœa he regarded as a wild proceeding; nor could he imagine that it ever could come within the range of rational medicine.' Surely the unfortunate women thus operated on do not properly apprehend the nature of the operation to which they are subjected. It is not so long ago since obloquy and contumely were showered on an unquestionably able surgeon—the late Mr. Baker Brown—for the operation of clitoridectomy; we seem to have made rapid strides since then; yet we have no hesitation in saying that in the cases indicated by Baker Brown clitoridectomy was an infinitely more justifiable operation than oophorectomy. We hope to hear less of this barbarous operation in future. At the same time we would protest against the indiscriminate examination of women at public institutions before crowds of students as demoralizing to all concerned. At a certain clinique for women, in Scotland, we understand that the vast majority of women who present themselves are examined with the speculum in the presence of the students, and the os daubed with 'iodized thymol' for all conceivable diseases. This disgusting and degrading practice should be circumscribed, not less in public than in private."

ARTIFICIAL CARLSBAD SALT.—Dr. Harnack, of Strasburg, who assigns no therapeutic value to any constituent except the chloride, sulphate, and bicarbonate, has found the salt to have the following composition: Sodium bicarbonate, 36.19 parts; sodium chloride, 17.28 parts; sodium sulphate, 46.09 parts. He therefore recommends to prepare the artificial salt as follows: Sodium sulphate, 100 parts; sodium bicarbonate, 80 parts; sodium chloride, 40 parts.

THE TREATMENT OF ERYSIPELAS.—In the *Wiener med. Presse*, June 18, 1882, Dr. Hastreiter recommends the treatment of erysipelas by painting with oil of turpentine, on the following grounds: 1. It can be employed on the most sensitive patients, does not require any skill, and can be applied by the patient himself as often as may be necessary, and the irritation produced by excessive friction is avoided. During its application the eyes should be protected by a pad. 2. When employed frequently enough this method is perfectly safe, and tends to produce a rapid cure. 3. Oil of turpentine can be procured everywhere. 4. All other dressings are unnecessary. 5. Internal antipyretic treatment is only rarely necessary; usually all that is necessary is to bathe the body with cold water, and to make use of cold applications to the head. 6. The inhalation of the vapor of turpentine can, perhaps, act as a preventive of the extension of the disease to the air-passages. 7. When employed at the outset of the disease it may abort the morbid process. 8. The oil of turpentine may also be employed in phlegmonous inflammation other than erysipelas.

In the *British Medical Journal*, August, 1882, Dr.

C. S. Hutchinson records a case of a large, robust man, who was thought to be *in extremis* from a violent attack of idiopathic erysipelas of the head and face. Iron and the usual internal remedies had been tried; but no external application had been used. Iodine was now painted on the scalp. This had a magical effect, the patient being out of danger two days afterward, the amendment beginning with the first application of the iodine. Dr. Hutchinson has never before seen so desperate a case recover so quickly. It should be remembered, however, that the occasional value of iodine in erysipelas has been known for many years.

The Fundamental Nervous Plexus of the Uterus.—M. Rein, of St. Petersburg (*Bulletin de la Société de Biologie*), states that he has specially studied the fundamental plexus of the uterus, because, both physiologically and clinically, an exact knowledge of this network is of great importance. His description of the plexus is as follows: 1. The general features of the fundamental plexus of the uterus do not differ from those of other organs composed of non-striated muscles. 2. It is extra-uterine, and is situated principally in the cellular tissue which surrounds the vagina, just where the hypogastric plexus anastomoses with the branches of the sacral nerve. 3. This plexus presents a large number of ganglion-cells. In the plexus of the guinea-pig, these cells constitute more than a hundred ganglia of different dimensions. 4. The ganglia are generally situated on the track of the principal efferent and afferent nerve-bundles of the plexus. There are a certain number of small ganglia also scattered about in the network of the plexus. 5. The hypogastric, sacral, uterine, and vesical ganglia, and also those of the fundamental plexus, can be recognized according to the position they occupy. 6. The uterine ganglionic cells of the guinea-pig and the rabbit are limited above by the horns of the uterus. Inferiorly, the fundamental uterine plexus mixes with the vaginal plexus. None of the fibres, either of the pneumogastric or of the sacral nerves, pass into the uterus until they have mixed with those of the fundamental plexus.

The Frequency of Disease of the Sexual Organs in Insane Women.—Dr. Danillo examined 200 insane women, and found that 162, or eighty per cent., were suffering from various diseases of the sexual organs. Out of 140 menstruating women, between fifteen and forty-two years of age, only 20 were without some uterine anomaly. Out of 60 women who had ceased menstruating, between forty-two and seventy-five years of age, 18 were the subjects of some affection of the genital organs. Acute and chronic endometritis and metritis were most frequently observed; less frequently, displacement of the uterus, dysmenorrhœa, acute and chronic ovaritis, and other diseases. The above results show that the complication of psychosis with uterine disease is a frequent occurrence, and of the greatest clinical interest.

Nineteen Months' Retention of Fœtal Bones in the Uterus.—Dr. Schramm describes the case of a woman, aged thirty-two, married twelve years, who had had eight labors, the first four of which had been normal; the last four had come at full term, but the children were born dead. The last labor was very difficult and lasted nearly four days. No post-partum hemorrhage followed, but the placenta, as well as all the cranial and some of the vertebral bones of the macerated fœtus, remained in the uterine cavity. Some weeks afterward there was an offensive discharge from the vagina, and, four months later, urine. During the last six or seven months the patient occasionally found small pieces of bone in her vaginal discharge. Having been called to see the patient nineteen months after her last labor, the author found her health deteriorated; there were fever, abdominal pains, constipation, and highly fetid discharge; the uterus was low down, and the os open, easily admitting a finger. The latter immediately came into contact with several friable bones of various sizes. The removal of them was accomplished without any difficulties, hemorrhage being slight. A vesico-uterine fistula existed. The general state of the patient soon began to improve, and the discharge of urine through the vagina considerably lessened.—*London Medical Record*, October 15, 1882.

The Treatment of Urethritis in the Female.—Dr. Fissiaux relates fifteen cases, in which Dr. Leblond treated blennorrhagic urethritis in the St. Lazare Hospital in the following way: A short stilette is wrapped round with cotton-wool, covered with coal-tar soap; this is passed into the urethra and retained there. It is renewed every other day. During micturition the patient prevents it from falling out by pressing it with her finger. The *rationale* of the treatment is that the tampon separates the folds of the urethra from each other, and thus keeps the whole surface of the mucous membrane at rest and in contact with the medicament.

Cascara as a Laxative.—Dr. Carter, of Liverpool, in an article on new therapeutic agents, writes to the following effect concerning cascara (*rhamnus purshiana*): The fluid extract prepared from the bark of this shrub, or small tree, is an excellent remedy in chronic constipation. I have used it now for two years, and have no doubt of its value. The fluid extract is reddish brown in color, and extremely bitter. A very good method of prescribing it is in a mixture, with twice its quantity of glycerine, or one of the flavored syrups. Of this a fluidrachm should be given three times a day, and the dose be diminished as soon as its aperient action is developed. It is what may be termed a tonic aperient, and seems to produce an effect somewhat like that caused by belladonna and nux vomica united with an ordinary aperient. It evacuates the whole canal. The motion is not watery, but usually semi-solid, truly feculent in character, and voided without difficulty, and so far from causing subsequent constipation, the bowels will often act regularly after its use has been entirely discontinued. I have used it so extensively, and the testimony to its value is so unmistakable, that it would be difficult to select particular cases to prove this.

A New Remedy for Chronic Dysentery.—Koroniko, from *veronica parviflora*, is reported by Dr. J. Jardine ("Chinese Customs Rep.") as a potent remedy in cases of chronic dysentery, varying in duration from six weeks to four years, and in which from twenty to thirty motions containing blood and mucus were voided daily. Fifteen doses of tincture of koroniko reduced them to one-half, another fifteen doses reduced them to three or four daily, and a third like quantity effected a complete cure. Koroniko seems to be the vulgar name adopted in New Zealand for the plant.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, December 9, 1882.

GENERAL MEDICINE AND MEDICAL SPECIALTIES.

We have frequently had occasion to point out the just claims to recognition of the general practitioner. In an era of brilliant achievements in all the special branches relating to medical science, the humbler calling and more modest pretensions of the physician in general practice are apt to be regarded in a spirit akin to superciliousness, not unmixed, perhaps, with pity. In view of such a condition of affairs, we can well afford to have the high, not to say surpassing importance of general medicine once more clearly and forcibly defined.

This was recently done at the first meeting of the Congress of German Physicians.[1] The speaker was a man of no mean reputation. Indeed, Frerichs may be said to stand in the very front rank of living clinicians. And certainly his fame in Germany is second to that of no contemporary, either as a popular teacher or as a learned author. His salutatory address, delivered in the capacity of president of the Congress, is pregnant with practical good sense. It appeals to the intelligence of the entire profession by the convincing force of its strict logic and temperate philosophy. Frerichs aptly compares the present epoch, which is characterized by so manifest a tendency toward specialism in medicine, to the time when the Alexandrian school of physicians began to flourish, and also to the period when Galen was the dominant spirit at Rome. Then, as now, the special sciences threatened to drift away from the common mother who gave them birth, and maintain a separate existence.

To-day there seems, indeed, ample justification for such a course. For no one can now hope to master all the branches of our vast science, in such a way as to be pre-eminent in each. And surely we should not attempt to belittle the great benefits which accrue to medicine, from a legitimate division of labor. May we not point with just pride to the astonishing advances made in the various specialties, and the flood of new light which has thus been shed on many a dark territory of the healing art? At the same time, however, we should not lose sight of the danger that lurks in the widening gaps that are appearing between the individual branches of medicine. The fundamental idea of singleness in the human organism is gradually fading away. We are too prone to disregard the broad general principles that govern all vital action in the body. There is no lack of precise knowledge concerning the different parts, but we may fail to grasp the thought that there exists a bond of harmony which makes them all a unit.

It is the important function of general medicine to supply the needed cement that must bind the various parts together. From the main stream of this science, side-currents may issue, but they must still be fed by the common supply, or else they will dry up and cease to exist. Barrenness and not fertility would thus result from too much separation.

The times are past when systems or dogmas could dominate independent thought, and prescribe our mode of action. Facts can no longer be controlled, or distorted by ruling ideas borrowed from philosophy or other foreign sciences. The healing art has outgrown its swaddling-clothes. It is able to stand on its own feet.

Our work begins with the study and knowledge of normal action in the healthy body. All departures from this standard properly come within our sphere of action. But the great source of all our practical knowledge has been, and always will be, the direct observation of the sick. The numerous questions and problems which confront us in our path, must finally be resolved by a last appeal to this, the highest tribunal which we recognize. To be sure, modern observation of the sick is not the simple thing of years ago. It is the exercise of all our faculties, assisted and rendered more acute by the various physical and mechanical devices that inventive genius has given us.

We hail with pleasure the great strides in advance which are daily taken by experimental pathology and physiology, by chemistry, and by the other accessory sciences. Certainly we must duly recognize the material aid, which we receive through their progressive exertions. Nevertheless we remain masters in our own house. We require no guardianship. Our own experience, our personal insight must be the standards by which we gauge true work and permanent acquisition. To separate the bran from the chaff we must rely upon ourselves solely. General medicine has only too well known the disastrous consequences of tutelage, or foreign inter-

[1] Verhandlungen des Congresses für Innere Medizin. Erster Congress gehalten zu Wiesbaden, April, 1882. Wiesbaden: J. F. Bergmann. 1882.

ference, be this from what special science it may. Neither philosophy, nor chemistry, nor pathology, nor yet experimental physiology, can do our work for us. The labor must be all our own. Then, indeed, the edifice being our own construction, will be sure to stand securely.

What has been said concerning the more remote sciences may be applied also to therapeutics. Doubtless we owe a great debt to modern experimental pharmacology, which frequently supplies us with the strictly scientific explanation of curative action constantly observed. But even experimental pharmacology cannot supplant direct clinical experience, than which we have no better index of rational interference in disease. Along the path thus mapped out, aided by an intelligent empiricism, the permanent achievements of the healing art must ever come. And who shall say that the future is not bright with the promise of great results, greater than any that the past has yet bestowed.

THE INSTRUCTION OF DELEGATES.

From time to time, since last February, we have observed that some of our County societies have instructed their delegates to the approaching session of the Medical Society of the State, as to how they should vote on the question of the repeal of the new Code. It has been easy to understand how this has been done in some counties, when meetings of the Medical Society occur only once a year, and where very little interest is, as a rule, taken, except by a minority of the small number constituting the Society. It is not a difficult matter in such a body for a man with a little facility in what is called personal or machine politics to secure the instruction of delegates. If a set of resolutions be ready—and they have usually been supplied this year from a prolific, although ephemeral pen—it is not a difficult thing to pass them, even if a few timid and whispered scruples find utterance from one of the corners of the room. This done, the delegates recite a few cases, elect the man whose turn has come to represent them in Albany, and adjourn. Well, as we understood how all this was done in some of the sparsely settled counties, where the medical society may easily become a pocket borough, we were, we must confess, surprised to find that our neighboring large and influential society of the County of Kings had placed itself in the attitude of a set of machine politicians, who have "fixed" the primaries, and have instructed the delegates. The feat of "fixing" matters was not as easily accomplished in Brooklyn, however, as it is in the interior, where the time for discussion is remorselessly cut off by the departure of the afternoon train. The wordy preamble and resolutions, ending with the instructions which convert the delegates into puppets, ready to dance when the wires are pulled by the showman, were only passed by a small majority in a total number of about ninety-one votes. Without regard to the question at issue in the resolutions passed by the Medical Society of the County of Kings, we believe that the sober judgment of the profession is entirely against any such forestalling of public opinion as is shown by specific instructions on questions that must undergo discussion in order to be settled.

At first glance, it may appear to be a very proper thing to instruct delegates, yet to believe this is to assert that in a question which admits of debate, nothing new can be added by the members from other bodies when the subject comes up for general discussion and final decision. Besides, if, in the opinion of the society that instructs, the right view of the subject is perfectly plain, and if the voice of that body is unanimous or nearly so on that side, where is the necessity for instructions? Their delegates being men of like manner with themselves have gone over this question from every possible point of view, and will certainly act with their constituents. But, it is because these things are not so, that instructions are resorted to by mere managers to carry out their own personal ideas and plans. They do not have a serene confidence in the truth and equity of their own views. Therefore they wish to avoid the conflict in the large arena of free and frank discussion, and choose, by dexterous scheming, to wage a petty contest in a small field, where there are few and perhaps insignificant opponents.

We do not believe that the medical profession is about to adopt the methods of "machine" politicians, just as even these men are forced to abandon them. A delegate is an ambassador, a representative possessing discretionary powers. He is not a registering machine or an orderly. The scant majority of the Kings County Society will yet regret that they have been led by their over-zealous leader, into an action which makes phonographic apparatuses of their delegates. These twelve gentlemen need hear nothing of the discussion on Codes of Ethics which is sure to occur at our next meeting. They may stay quietly in their hotel, and at the proper moment be summoned to take part in the call of the yeas and nays. If present, they may consume their time with newspapers or the advertisements of instrument makers, if at the proper moment they vote solidly as has been agreed upon by the junto that has created them.

Let Kings County pass whatever resolutions the majority see fit, let them select the men they may choose, but as they value the preservation of free thought, fair discussion, in the medical profession, let them not instruct their delegates as to how they shall vote on broad questions, which the whole profession of the State meet to discuss, and after discussion to decide. If we do not wish the proceedings of our State Society to resemble those of ward primaries, let us not in other bodies imitate the

action of the small majority of the Kings County Society. If this action is to be taken in other counties, we may well be thankful that we have in our body a set of permanent members whose judgment will remain untrammelled by instructions and unawed by vulgar clamor. We do not envy the feelings of the Brooklyn delegates when they sit down among their fellows in Albany with the thought that whatever may be said they have no alternative but to vote as they have been directed to. But we shall be much disappointed if twelve men can be found in the ranks of the profession in our sister city, who will consent to take their voting orders in their pocket without discretion or room for variation.

The last meeting of the American Medical Association was no model for the Medical Society of the State of New York. There was no serious discussion on the subject of the action of the State of New York upon the code. Whether that action be right or wrong, it deserved the careful and respectful consideration of the delegates from other States. Instead of this, without a hearing, a prearranged plan was carried out by a set of managers, who must have obtained their notions of the proper way of determining vital questions of principle from a typical political convention.

The members of our society have been accustomed to decide the questions that have arisen among them, after hearing what has been said by those who differ as to the proper course. They have not hitherto come to their annual gathering with collars about their necks engraven with their master's stamp. In spite of the unwise action of a few counties, we have no reason to believe that our ancient and honorable body will take a step backward and become a machine to register the orders of any clique, or, still less, of any would-be manager. Indeed, it may be doubted if any instructions to delegates on questions that are in their nature only to be determined by argument and discussion are valid. It would not be surprising if they were declared illegal. Certain it is, that if they had been secured by the tyranny of a scant majority or by the acts of petty political managers, they are subversive of all the principles that should regulate legislative bodies.

THE NEW PENAL CODE.

THE new Penal Code, which went into effect on December 1st, contains a number of clauses which are of interest to the medical profession. The Code in question is, for the most part, only a re-statement of older laws. These are, however, presented in a much more compact and intelligible form than ever before.

In Section 8 the subject of responsibility is dealt with, and it is stated that every person is assumed to be responsible for his acts except as otherwise specified. A child under seven years of age is not capable of committing a crime, while between the ages of seven and twelve responsibility is presumed to exist, but may be removed by proof. Regarding insanity the old test is retained. The Code says: "A person is not excused from criminal liability as an idiot, imbecile, lunatic, or insane person, except upon proof that at the time of committing the alleged criminal act he was laboring under such a defect of reason as either not to know the nature and quality of the act he was doing, or not to know that the act was wrong. A morbid propensity to commit prohibited acts existing in the mind of a person who is not shown to have been incapable of knowing the wrongfulness of such acts, forms no defence to the prosecution therefor."

Suicide is an act which the law has always wished to prevent, and has always considered a grave public wrong. Attempts at suicide are, in the present Code, severely punished as felonies. Any person who assists or abets another in committing suicide is made guilty of manslaughter.

Despite the number of homicides which it is customary, with grim pleasantry, to attribute to the medical profession, there is very little in the Code that specially touches upon us. A physician who, in a state of intoxication, gives by mistake a poisonous drug to a patient which kills the patient, is guilty of manslaughter in the second degree.

Regarding the disposition of the body or of any part removed by a surgical operation, the following law is provided: "A person has the right to direct the manner in which his body shall be disposed of after his death, and also to direct the manner in which any part of his body which becomes separated therefrom during his lifetime shall be disposed of."

The stealing of a dead body from a grave or vault to sell or dissect, or from wantonness, is a crime to be punished by not more than five years' imprisonment and a heavy fine. It is made a crime also to attach a dead body for debt or to obstruct or detain a funeral.

Much public attention has been called to that part of the Code which revives the Sunday laws. These are very rigid if literally interpreted. All servile labor, excepting works of necessity and charity, are prohibited, and so also are all public sports, exercises, and pastimes. An attempt to carry out such provisions strictly would be impossible in a cosmopolitan city. In discussing their merits, however, one should bear in mind that there is especial need at the present day of preaching the gospel of rest. The State might well, for sanitary and moral reasons, insist upon some restrictions as to servile labor and public amusements upon the Sabbath. The physician should plead for a sanitary Sunday as the clergy do for a religious day. Rest and such recreations only as give rest ought to be provided for.

AN IMPORTANT CHANGE IN THE STRENGTH OF OPIUM AND ITS PREPARATIONS.

In the November issue of Dr. Squibb's *Ephemeris*, attention is called to an important change in the strength of opium preparations made by the United States Pharmacopœia for 1880.

By the older process, opium, when dried at 212° F. until it ceases to lose weight, yields at least ten cent. of morphia by the officinal process. Tinctures made from such powder have a strength of four grains (gr. iv.) of morphia, equivalent to 5.33 grains of crystallized sulphate of morphia to the fluid ounce. This gave, as a full anodyne dose of the tincture of opium, by the process of 1870, twenty-four minims, or about thirty-eight drops.

But the Pharmacopœia of 1880 says that its powdered opium should contain not less than twelve nor more than sixteen per cent. of morphine when assayed by the process given under opium. Dr. Squibb states that a better process of assay will give account of from thirteen to seventeen per cent of morphia, the average being fifteen per cent.

The officinal powdered opium, therefore, of the new Pharmacopœia contains fifteen per cent. of morphia against ten per cent. in the powder of 1870. This powder will give an average proportion of six grains of morphia, equivalent to 7.5 grains of sulphate of morphia, to the fluid ounce of tincture. This makes sixteen minims (℥ xvi. = gtt. xxv.) the full anodyne dose of the new tincture, this dose being equivalent to one-fourth of a grain of morphia, and being just one-half stronger than the tincture of 1870. A proportionate increase is, of course, made in all the other preparations which are manufactured from the powder.

The changes thus described are most important, and should at once be known to the profession. They ought especially to be understood and adopted by all druggists, because they secure a more constant strength to the opium preparations and lessen the bulk of the medicines prescribed.

It will, however, be some time before the new processes are uniformly followed. Meanwhile, the physician should in his prescriptions indicate to the druggist, by the figures "1870" or "1880," which preparation he wishes used. And he should give his pharmacist the liberty of using either preparation, substituting the equivalent amounts. Thus, if he writes for twenty-four minims of tincture of opium, "1870," the druggist may use sixteen minims of "1880."

It is a serious thing to change the dosage of a frequently used and poisonous drug. It will cause for a time much annoyance to doctor and druggist, and may not be without danger, especially in prescribing for the young.

We are not quite so confident as Dr. Squibb is that the change was seriously needed, and it seems like an inexcusable oversight in the Pharmacopœia Committee not calling attention forcibly to the matter. The increase has been made, however, and must be accepted. The strength of opium preparations will be more constant, and doubtless, after a few years, the improvement will be generally admitted.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN PRACTICE.

ANDREW H. SMITH, M.D., IN THE CHAIR.

DR. L. WEBER read a paper (see page 651) in which he reported a case illustrating

A CAUSAL RELATIONSHIP BETWEEN LOCOMOTOR ATAXIA AND CARDIAC DISEASE.

DR. PUTZEL thought the reports of the French observers with regard to valvular disease of the heart should be taken only with some allowance. As a rule, it was found that they had an enormous number of cases of valvular murmurs, and it seemed to be an impression that they called hæmic murmurs valvular murmurs.

The peculiarity of the German cases was that they were females, and he thought it was a rare thing to see so many cases among women. With reference to the co-existence of the two diseases, he thought it was difficult to say which developed first. It was well established that evidence of valvular disease of the heart might not be discovered until several years after the occurrence of an attack of acute rheumatism. For example, a case came under his observation in which there was a distinct mitral regurgitant murmur, and yet on close inquiry no evidence could be obtained that, during an interval of fifteen years between an attack of acute rheumatism and the development of the symptoms for which the patient sought relief, there had been any symptoms directing attention to the heart.

He was unable to understand how locomotor ataxia could produce cardiac disease, unless by acting through the pneumogastric nerve; but if it was believed that it was produced in that way, he thought the patient would not live long enough after invasion of the pneumogastric to allow the development of organic cardiac disease. He asked Dr. Weber with reference to the manner in which he believed the heart disease was produced by the locomotor ataxia.

DR. WEBER said that he was not prepared to state how it was produced, nor to say absolutely that the cardiac disease had its origin in some way with locomotor ataxia. The clinical facts were that, in a case of true locomotor ataxia, slowly progressing, there was no evidence of cardiac disease up to a certain date, and that then, without the occurrence of rheumatism at any period of life or the known existence of any of the recognized causes, endocarditis and pericarditis developed. No arthropathies had appeared during the course of the ataxia. He believed that if the locomotor ataxia had not been present the sexual intercourse would not have been followed by endocarditis and pericarditis.

Dr. Leale said that he had seen a number of cases in which pericarditis had been produced by violent horseback exercise in patients who were anæmic. He regarded it as important to avoid excessive exercise, without regard to form, in all cases of anæmia.

Dr. B. Robinson thought that the French observers were fairly qualified physical diagnosticians. He also directed attention to the fact that a certain number of very good observers had attributed what were commonly known as hæmic murmurs to dilatation of the valvular orifices; that is, that an endocardial murmur might be due to dilatation of these orifices, and not always indicate the existence of endocarditis.

The Chairman thought that in cases in which two diseases had existed for considerable time, the chances of their co-existence were very great.

The Chairman then reported cases illustrating

THE ACTION OF CONVALLARIA MAIALIS UPON THE HEART.

The first was a case of typhoid fever, in which the pulse was rapid, feeble, finally imperceptible at the wrist, the first sound of the heart scarcely audible, when convallaria was administered hypodermically, with the result of restoring the power of the heart's action so that both sounds were distinctly audible and the pulse fairly full, and although the case terminated fatally the heart-sounds remained distinct to the last minute.

The second was a consultation case, in which the patient, suffering from peritonitis and under the opium treatment, suddenly went into a condition of collapse. The opium was administered in pill form. The urine contained abundance of albumen. The patient was about thirty-five years of age. Caffein and atropia had been given and the galvanic battery had been applied. The man was apparently dead. The battery was continued. Convallaria was used hypodermically.

After the lapse of nearly half an hour the heart's action began to increase in strength and exceedingly shallow infrequent respiration returned. Ultimately the patient was restored.

The preparation used was the fluid extract made by Parke, Davis & Co., of which the dose is from five to ten minims, given hypodermically and repeated in half an hour if no effect is produced by the first dose. He could readily see that such a remedy might be potent for evil as well as good.

Dr. B. Robinson had used this drug during the last two months in cases of cardiac and renal dropsy when there was deficient heart power, and with favorable results. He related a case in which caffein and digitalis had been administered and failed to give tone to the heart sufficient to afford any relief for the dropsy in a case of cardiac disease. Convallaria was substituted and with beneficial results. What the precise conditions were which indicated its use he had not been able as yet to determine.

Dr. John C. Peters referred to the *tincture of cainca* in drachm doses as a very serviceable diuretic in cardiac and renal dropsy.

Dr. Leale asked what the diagnosis was in the second case reported by the Chairman, and from that point a general discussion occurred on

THE OPIUM TREATMENT OF PERITONITIS.

The following items of clinical experience were brought forward: That fatal opium narcosis may be developed without either gradual reduction or marked change in the number of respirations per minute, hence reduction of the number of respirations is not an absolutely safe guide in the administration of opium in the treatment of peritonitis. That the use of opium in pills was liable to be followed by alarming if not fatal narcosis, especially with diseased kidneys. That in some cases the urinary secretion is so diminished in quantity as to necessitate partial suspension of the opium treatment. That it was not always safe to estimate the quantity of opium to be administered by the pain suffered by the patient.

The Section then adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, November 27, 1882.

David Webster, M.D., President, in the Chair.

MALARIA IN CHILDREN.

Dr. L. Emmett Holt read a paper on the above subject, in which he said that the peculiar manifestations of malaria in children was a field of observation which had been much neglected, especially in this country, where the opportunities for its study were so much more extensive than had been enjoyed by either English, French, or German observers. Most of our foreign text-books did not allude to malaria in children. Most American authors had contented themselves with a brief description of the remittent and intermittent varieties, dividing the disease into stages seen in the classical cases in adults. The organism of the child was especially susceptible to all acute infectious diseases, and malaria formed no exception to the rule. The poison acted not only more rapidly, but more generally and profoundly in children than in adults. Again, the susceptibility of the nervous, the digestive, and the respiratory systems produced such variations in the form and type of the disease as to mislead, at times, even the most careful, in diagnosis.

The author of the paper confined himself to symptomatology and diagnosis, as the etiology, pathology, and treatment did not differ materially from the same in adults. Dr. Holt then proceeded to give the results of his observation in 184 recorded cases. Nearly all were dispensary patients, belonging in an acknowledged malarial district, between Eighteenth and Fifty-fifth Streets, and west of Ninth Avenue, in New York.

With reference to *invasion*, it was gradual much more frequently in children than in adults. In 117 cases the invasion was abrupt in 45, and gradual in 72. Of 106 cases, the time of the invasion was in the forenoon in 35, and in the afternoon or evening in 71. He believed that division into stages might advantageously be dropped when studying the disease as it occurs in children.

With reference to *chill*, it was present in 19 out of 150 cases, and in only about one-half of these was it at all pronounced, and in every instance where it was well marked the patient was over eight years of age.

Fever was one of the most important and constant of all the symptoms. Very few cases occurred in which it was not present to a greater or less degree. He divided the cases with reference to fever into *three* groups: (1) those in which the temperature rose quite high at the outset and remained so for from twenty-four to seventy-two hours, and afterward assumed a

distinct remittent type; (2) those in which the fever was at first slight at some particular part of the day, but gradually increased in intensity and lost its periodic character; (3) those in which the fever assumed a distinct type from the outset, remittent or intermittent, and recurred regularly until controlled by quinine. The last was the rarest variety.

Sweating was noted in a little more than one-half of the cases.

Central symptoms, in some form or other, could be said to be the rule. Pain in the head was the most frequent. The next in frequency was drowsiness, or apathy; in some cases it might amount to stupor. Convulsions occurred in four cases out of one hundred and eighty-four. Vertigo seldom occurred in children. Pains in other parts of the body were usually complained of by children who were old enough to make their symptoms known. *The most characteristic was pain at the epigastrium.* His attention was first directed to this symptom by Dr. John H. Ripley. Dr. Holt believed it to be neuralgic, depending, perhaps, upon congestion of the stomach, which was found as one of the lesions in most of the fatal cases. Pains in the splenic and hepatic regions were complained of occasionally, but much less frequently than at the epigastrium.

The condition of the *spleen* was recorded in 79 cases; in 64 it was found enlarged; and in 38 very markedly; in 11 no increase in size was found. With reference to the size of the spleen his observation sustained Dr. Janeway's statement that unless the spleen is enlarged it does not come in front of the middle axillary line.

Disturbances of the digestive system were almost uniformly present, and usually pronounced. Vomiting was present in 78 of 112 cases. In almost all cases complete anorexia existed. The condition of the tongue could be placed among the diagnostic symptoms. The typical tongue was normal or slightly reddened at the edges and tip, while the centre is heavily furred with a brownish yellow coat, which shades off into a dirty white. A clean tongue had been noted in only 9 cases.

In 140 cases in which examination was made with reference to the *condition of the bowels*, they were reported as regular in 58, and constipated in 55. Looseness or diarrhœa was present in 27 cases.

As regards *thoracic symptoms*, there were none in simple malaria beyond slight cough from bronchial catarrh, which was exceedingly common. So far as he had been able to ascertain, *symptoms referable to the genito-urinary apparatus* had not been mentioned by authors. He had noted their presence in 17 cases, incontinence in 6, retention in 3, and in 6 frequent and painful micturition. Examination of urine negative.

COMPLICATIONS.

Of these the author of the paper made three groups: (1) the respiratory; (2) the gastro-intestinal; and (3) the nervous.

He had not met with any well-marked cases in which *laryngeal symptoms* of malarial origin were present. Such cases, however, had been mentioned by some writers. *Bronchitis* was, perhaps, the most frequent of all the complications, being present in about one-fifth of all the summer cases, and in fully one-half of the autumn and winter cases. *Pulmonary congestion* with symptoms quite uniform and characteristic. The invasion had always been acute; the temperature high, 104° to 106° F.; respiration rapid, resembling the panting of lobar, rather than the labored breathing of lobular pneumonia; face often cyanotic; pulse rapid; slight increase of fremitus; dulness on percussion usually slight; respiration always high-pitched, sometimes broncho-vesicular; resonance of the cry exaggerated; sonorous râles; occasionally coarse and fine mucous râles high-pitched.

That pneumonia, either lobar or lobular, occasionally complicated malarial fever, there was no doubt. *True spasmodic asthma* was recorded in 6 cases, based upon the occurrence of repeated attacks in the marked enlargement of the spleen, and the prompt relief by the exhibition of anti-periodics.

Of the *gastro-intestinal complications*, periodical vomiting and diarrhœa were mentioned especially. Of the *nervous complications*, mention was made of neuralgias, which did occur, but not so frequently as in adults. Motor disturbances were less frequent than sensory. Various spasmodic disorders had been recorded. Chorea had complicated two cases.

Several other complications were mentioned, as *vaginitis* in 3 cases, *hemorrhage from the gums* in 2 cases, *epistaxis* in 1 case, and *nephritis* occurred in 2 cases, in one slight, and in the other the patient died comatose on the sixteenth day of his sickness, after having been circumcised by another physician for retention. *Urticaria* occurred in two cases. *Jaundice* had not been met with, nor had Bohn observed it in any of the four hundred and thirty-five cases he had recorded. *Herpes* about the mouth was not uncommon. *Tonsillitis* associated with malarial fever had been observed in a few cases. The author of the paper then passed to the questions of diagnosis and relapses, after which he gave the following conclusions:

First.—That malaria in early life presents symptoms as distinctive as any other disease of children.

Second.—That the classification of the cases as intermittent or remittent and the division into hot, cold, and sweating stages, as in adults, leads to misapprehension regarding the course of the disease and to confusion in diagnosis.

Third.—That in any acute febrile disease presenting an unusual course the spleen should always be examined, especially in malarial districts.

Fourth.—That in obstinate cases of diarrhœa or bronchitis not affected by ordinary remedies, especially if those symptoms show a tendency to periodicity, malarial fever should always be investigated as a possible cause.

Fifth.—That spells of drowsiness and frequent attacks of epigastric pain should always excite suspicion.

Sixth.—That in children it is even more necessary than in adults to interrogate every organ before making a diagnosis when the symptoms are at all obscure.

DR. J. LEWIS SMITH said that he had been familiar to a considerable extent with the disease as it had manifested itself in the region mentioned by Dr. Holt. The term malaria he regarded as a rather comprehensive one, and he thought the author of the paper included in it two forms of fever: 1, that due to marsh miasm; and 2, that due to emanations from polluted soil and sewer-gas. The majority of the cases which he had seen that pursued a course extended to much length had been cases of typhoid fever, and he had regarded these so for the following reasons. There had been a degree of contagiousness in them. There is not that degree of intestinal catarrh in these young children which is present in adults, but in a large proportion of the cases he

had seen there had been diarrhœa. The lesions of typhoid fever had been found at autopsy in some cases. Quinine did not shorten the duration of the affection. It might moderate the fever but the disease would continue for a certain length of time, whereas if it was due to marsh miasm quinine would shorten the duration if not cut the disease short.

The symptoms he had observed were similar to those detailed by Dr. Holt, and he had especially noticed that hyperæsthesia was present in almost all cases, particularly on the inner aspect of the thighs and associated with tenderness. The duration of the disease, so far as he had observed, was very variable, and the milder cases would run on despite treatment. He had preferred to designate most of these cases as remittent rather than malarial, regarding infantile remittent as typhoid fever.

Dr. John C. Peters thought it important that the ages of the patients should be given in Dr. Holt's cases. Practically, there was no great difficulty in making a diagnosis when the patient was over five years of age; prior to that age the difficulty was very great.

He also was of the opinion that it was sometimes exceedingly difficult to differentiate the cases referred to by Dr. Smith from fever due to sewer-gas, which was very frequently distinctly periodic in character. That fever and ague might occur in children soon after birth seemed well established, but the mother was suffering from the disease at the same time. Convulsions were of frequent occurrence. He referred to a case in which the thermometer alone decided the character. The chill was absent. There was daily febrile movement. The convulsion occurred and then the child remained unconscious. Five grains of quinine were given three times a day for several days, and the child finally recovered entirely.

Dr. Fruitnight spoke of the convulsions in children as the analogue of the chill in the adult. He had observed the occurrence of epigastric pain frequently and regarded it as a valuable symptom. In nearly all the cases he had seen general hyperæsthesia had been present, and in some cases might have easily misled in diagnosis, suggesting the presence of cerebro-spinal meningitis rather than malarial fever. He corroborated Dr. Holt's statement that the stages as described in the affection occurring in adults were not well marked in children. In closing the discussion Dr. Holt said that the majority of his cases occurred between the ages of two and six years.

The Society then adjourned.

Pessary on the Brain.—In a speech at the recent meeting of the British Medical Association, Professor Playfair speaks of the "overmuch and injudicious local treatment" of the uterus. He alludes to a case in which "the patient may fairly be said to be suffering from pessary on the brain—so incessantly is she thinking of one or other of the *seventy-nine* different instruments which she has had inserted in the last few years in America and in this country."

No Complaint.—A man, in passing a country churchyard, saw the sexton digging a grave, and inquired: "Who's dead?" Sexton—"Old Squire Bumble." Man—"What complaint?" Sexton (without looking up)—"No complaint; everybody's satisfied."

NEW YORK SURGICAL SOCIETY.

Stated Meeting, November 14, 1882.

T. M. Markoe, M.D., President, in the Chair.

Dr. McBurney presented a patient upon whom he had operated for the cure of a long urethral fistula situated at the peno-scrotal junction. The patient was sent to Dr. McBurney by Dr. Geo. A. Peters, and gave the following history: As a result of gonorrhœa and stricture, an abscess appeared in January, 1881, at the peno-scrotal junction. This abscess was opened, and the opening afterward refused to close. Four attempts had been made by other surgeons to effect a closure without success. The patient was first seen by Dr. McBurney in March, 1882. At that time there existed a fistulous opening, one inch and a quarter in length, and embracing the entire width of the urethra just anterior to the scrotum. An opening also existed in the perineum, through which most of the urine passed. The first operation was done by Dr. McBurney on March 6th, in this manner: The opening in the perineum was first made perfectly free. A large, oblong flap of skin with its attached base at the left edge of the fistula was then cut and dissected up. This flap was inverted over the fistula, the edges of the cutaneous surface of this flap having been made perfectly raw, and raw surfaces having been made above, below, and to the right of the fistula. The flap was firmly stitched in place with fine carbolized silk. To cover this flap as well as the surface from which it was dissected, a long, oblong flap was dissected up from the scrotum immediately behind the fistula. This flap was easily drawn forward, pulling the scrotum with it, and was securely fastened with fine silk sutures. From this time on the urine was regularly drawn with the catheter introduced through the perineal opening. Union took place throughout, with the exception of about three-fourths of an inch at the right edge. To close this opening it was necessary on April 11th to freshen the adjacent edges and to draw one edge under the other. Complete union then took place rapidly.

The perineal opening, which had been kept open for many months before Dr. McBurney saw the case, was closed by one operation after he had made unsuccessful attempts with the cautery.

The operation done on the perineum was that recommended by Szymanowski. The urethra of this patient now admits a No. 29 F. sound with ease; he has normal erections without curvature of any kind, has no discharge, and no dribbling after urination. The original condition of the fistula was shown in a water-color drawing made by Gaertner from nature.

Dr. Keyes then read a paper on "Pneumo-Urea."

ALARMING CHLOROFORM NARCOSIS.

Dr. E. L. Keyes narrated a case as follows: A female child, five years of age, and apparently perfectly healthy, so far as the heart and lungs were concerned, came for diagnosis with reference to vesical calculus. Chloroform was administered, not more than one drachm being consumed, and the examination had been completed, when suddenly the child's face turned a livid grayish color, it gasped for breath, and the heart ceased to beat. He injected ether into the leg, held the child upside down, made intermittent pressure upon the walls of the chest, held the lower jaw forward, a slight gasp

occurred, followed by very feeble pulse, and in half a minute or so the child began to breathe in a gasping disagreeable way. There was a marked improvement at the end of four or five minutes in the respiration and the condition of the pulse, but the child was entirely unconscious and exceedingly feeble. The breathing and the pulse remained very feeble for three-quarters of an hour, and for an entire hour was the child held absolutely upside down. Twice during the hour an attempt was made to place the patient upon her back in bed, but on both occasions the face became at once pale and the pulse flickering, so that it was necessary again to place the child in the inverted position. After two or three hours the patient was fully restored. He had heretofore regarded chloroform as a safe anæsthetic for children with healthy lungs and heart.

Dr. F. Lange presented

THE UTERUS, A FŒTUS, AND A TUMOR WEIGHING SIXTEEN POUNDS

removed from a woman, thirty-six years of age, who had been married four years, had never been pregnant, but first noticed that her belly was increasing in size in February or March, 1882. Her menses remained regular until May and then ceased. The increase in the size of the abdomen then went on rapidly, and during the last three months she had been obliged to keep the upright posture, had sufferred from loss of sleep and appetite, and mental depression, and had emaciated rapidly. Dr. Lange saw the patient for the first time about two weeks ago, when after examination and consultation, it was not decided positively whether or not she was pregnant. The tumor had crowded the uterus so far over into the left iliac fossa, that only a small segment of it could be felt through the abdominal walls. It was thought that ballottement with the child's head could be made out. The uterine probe could be introduced without the slightest resistance to the depth of four or five inches. The sounds of a fœtal heart could not be heard. There was a uterine bruit, but that was frequently heard with large pelvic tumors as well as in pregnancy. It was decided, however, to open the abdomen, ascertain the condition of the parts, and then determine whether anything could be done to relieve the woman. The operation was performed November 4, 1882. It was found that the tumor was adherent to the omentum, to the abdominal walls, especially the front part, and to the intestines, and that the adhesions were exceedingly vascular. He resolved to undertake to remove the tumor, and proceeded to apply double ligatures to the adhesions, some of which were very broad, short, and difficult to secure, especially those with the anterior wall of the abdomen. The ligatures were applied by using a device of Tiersch, of Leipzig, which consists of two spindle-shaped ebony pieces, which are perforated in the middle and connected by thread. One of them is pushed through the tissues, and both are used as handles to exert a great force in tying the ligatures. For deeper-seated tissues the spindles are bent, of metal, and carried through by means of a long forceps devised for that purpose.

Finally, it became necessary to decide whether he would endeavor to remove the tumor and leave the uterus, or remove the whole mass. He decided to remove the tumor first, but there was so little space that, in order to give a little more room, he had to puncture the uterus and let out a quantity of fluid. At last he was able to reach the pedicle, secure it, and then to remove the growth, after the last adhesions toward the back wall of the abdomen had been secured. There was then left a bleeding pregnant uterus, and the question arose as to whether or not he should sew up the puncture, and leave the organ with the stump of the pedicle upon it and a child within it. There was already some blood in the small pelvis, and no possibility to get into it in order to make a thorough cleansing of the peritoneum. He decided to perform supra-vaginal amputation of the uterus, and at once made a large incision through its walls, and removed the child, which made a few respirations and then died. An elastic ligature was then passed around the cervix of the uterus, after the peritoneum had been incised somewhat above and loosened up to a line somewhat below the intended spot for it. Adhesions and stump of uterus were cauterized with the Paquelin, the stump of the uterus powdered with iodoform, as were all the spots where the peritoneum had been torn. One adhesion with the abdominal wall, near the liver, bled very obstinately, and for several minutes here the cautery had to be applied. On the anterior abdominal wall several pedicles, from tied adhesions of considerable thickness, were secured between the edges of the large wound by means of Thiersch "lead plate and silver wire" sutures, and in this manner located outside the peritoneal cavity. The edges of the wound were closed above them. Peritoneum and muscles were sewed up separately, in layers one above the other, with catgut. The abdominal incision was about fifteen inches in length and more than fifty external sutures were necessary.

The reaction during the first three days was very slight, but then came an alarming period of intestinal obstruction, without fever or pain, but tympanitis and incessant vomiting. This ceased spontaneously, however, and the woman seemed in a fair way to recover entirely. There was no fever, the abdomen was flat, and all her functions were being normally performed. A few days after the operation, swelling of the parotid glands occurred—first the right, after a few days the left one—but that had entirely disappeared. Full antiseptic precautions were used, with salicylic spray. One ovary was removed completely, and only a very small portion of the other remained. The ligature, however was located behind it.

The sutures were removed on the eleventh and thirteenth day after the operation. At this moment —nineteen days after the operation—the patient is quite well, has had several passages without pain, but is troubled with flatulence. There seems not to be any doubt about her final recovery.

The tumor has the macroscopic and microscopic appearance of a fibromyoma.

Dr. L. A. Stimson presented

THE STOMACH, PORTION OF THE ŒSOPHAGUS, AND PORTION OF THE ANTERIOR ABDOMINAL WALL OF A PATIENT UPON WHOM HE HAD PERFORMED GASTROSTOMY.

"The patient, a man, forty-one years old, was admitted to Bellevue Hospital in the spring of 1882, suffering with chills and fever, and was soon discharged cured. He was at that time a well-nourished, hearty-looking man. In July following he noticed for the first time occasional difficulty in swallowing food. He said the food 'seemed to stick' and passed into the stomach after a moment's delay. The difficulty increased gradually, so that by the middle of August he became unable to swal-

low solid food. September 27th he was admitted again to Bellevue Hospital. He was then thin and pale, and had lost thirty pounds in weight since July 1st. His previous history is without bearing upon the case.

"Examination with the œsophageal bougie showed a slight obstruction in the œsophagus at the level of the larynx, and a second and more considerable one at the distance of 34 ctm. from the incisor teeth. The diagnosis of cancer of the œsophagus was made and the patient fed upon liquid food. The bougie was passed occasionally, the last time on October 10th. The difficulty in swallowing increased, and on October 13th the bougie failed to pass. The patient frequently regurgitated the food he tried to swallow, and on two occasions the regurgitated food was streaked with blood.

"After October 13th he was nourished exclusively by the rectum; his strength failed steadily, and he complained of weakness, hunger, and thirst.

"He came under Dr. Stimson's care October 18th, who proposed gastrostomy, but the patient refused to accept it. At that time he was able to walk abroad. Ten days afterward he asked to have the operation performed, being convinced by his rapid loss of strength that he could not long survive. During these ten days he had received from three to six times daily an enema composed of about half a pint of milk, an ounce of whiskey, some pepsin, and occasionally an egg, but the injections were very distasteful to him, and he frequently refused to have them repeated.

"His emaciation was extreme, his abdomen very much retracted. No tumor could be felt in the epigastrium; the area of hepatic dulness was small, not extending to the left of the median line, and the free border of the liver could be felt just below the ribs. He complained of constant pain in the abdomen, and during the last three days received about twenty-five minims of Magendie's solution of morphine subcutaneously during the day. He was still unable to swallow, but occasionally took a teaspoonful of water, which was regurgitated, together with some thick opaque mucus.

"The operation was done October 30th. The patient was etherized and the abdomen exposed, the limbs and chest being kept well covered. The usual antiseptic precautions, exclusive of the spray, were taken.

"An incision was begun about two inches below the xiphoid cartilage and a finger-breadth on the inner side of the left costal cartilages, and carried downward and outward for two inches parallel to the latter. The different layers were successively recognized and divided, and the peritoneum exposed. Only one bleeding point needed to be secured.

"It had been anticipated that the opening of the abdominal cavity would be followed by the immediate entry of a considerable quantity of air, in consequence of the tendency of the strongly retracted anterior abdominal wall to rise to the level of the ribs in the epigastric triangle, and this expectation had been much strengthened by the behavior of the different layers as they were in turn divided. As each was cut it drew away from the underlying one, so that when the peritoneum was reached it lay at the bottom of a cavity that was fully one and one-half inches in depth; through the peritoneum and in contact with it the stomach could be seen moving slightly up and down as the patient breathed. An incision half an inch long was made in the peritoneum, and although pressure was made with the hand between the umbilicus and the wound, air entered with a whistling sound, and the abdominal wall drew away from the stomach for a distance of about half an inch. The stomach was caught with dressing forceps and drawn forward through the incision, filling the opening in the peritoneum completely. The peritoneum was then drawn up and stitched to the skin on each side, and the stomach fastened on each side by two sutures which were passed for three-fourths of an inch through its wall between the peritoneum and mucosa and did not enter its cavity. The upper and lower portions of the abdominal incision were closed with sutures and two hare-lip pins; and finally the portion of the stomach which projected through the wound was transfixed with two long pins as a precaution, to relieve the strain on the sutures and to prevent its withdrawal into the cavity in case the sutures should tear out. The stomach was not opened.

"The wound was dressed with carbolized gauze and a thick layer of borated cotton, and the patient replaced in bed. His pulse was rapid, and his hands cold; he gradually rallied, the pulse improved in quality; the temperature rose somewhat above the normal, and he came quietly out of the ether. Six hours later he grew dull and weak, the pulse became feebler, and he died unconscious ten hours after the operation.

"The specimen shows the stomach still fastened in the abdominal wound. It has been opened along the lesser curvature, and it can be seen that the sutures do not enter the cavity of the organ. The attached portion is on the anterior surface, midway between the greater and lesser curvatures, and distant two inches from the pylorus and four inches from the cardiac orifice. The stomach was entirely empty, but not contracted, measuring when fresh nearly twelve inches around its broadest part.

"Only the lower half of the œsophagus has been removed. The neoplasm begins within an inch of the cardiac orifice, and extends upward about three inches. It has narrowed the calibre of the tube at the lower part, so that it will admit only a rod about one-eighth of an inch in diameter. At the upper part the narrowing is not so great, and the mucosa is thrown into longitudinal folds and tabs, which seem to have acted like valves to oppose the passage of instruments or food. The growth is an epithelial cancer, beginning in and involving almost exclusively the mucosa. Six small cancerous nodules were found in the liver.

"Albert, whose personal experience in the operation is far larger than that of any other surgeon (he did the operation ten times in the year 1881), says, in the 'Real Encyclopedie,' vol. v., p. 565, that it was first done by Sédillot in November, 1849, and that, including the year 1879, it had been done fifty-three times—ten times for cicatricial contraction of the œsophagus, and forty-three times for cancerous obstruction. The first twenty-eight cases were unsuccessful, every patient dying promptly; the twenty-ninth was done by Sidney Jones, and the patient lived forty days.

"A rather hasty search through the periodical literature of 1880, 1881, and 1882 has enabled me to increase the list to a total of ninety-three cases, in eighteen of which the contraction was cicatricial, the result of swallowing an acid or a caustic alkali, and in seventy-five the obstruction was cancerous, the growth occupying the tonsil in one case, the œsophagus in the others.

"Of the eighteen cicatricial cases, eight died in

consequence of the operation, and ten recovered from it.

"Of the seventy-five cancerous cases, twenty lived for periods varying from three weeks to eight months, two or three of them being still alive at the date of the last report; fifty-four died within three weeks after the operation, and the great majority within the first week.

"The causes of death were peritonitis, exhaustion, the shock of the operation, and the progress of the disease, especially in the thoracic organs.

"In several of the successful cases it is noted that the obstruction was not complete, and that the patient was nourished by the mouth previous to the operation.

"The operative methods which seem to be in most favor at present, and to be most worthy of adoption, are, first, to make the incision parallel and close to the free border of the costal cartilages on the left side; second, to secure the stomach in the wound by from four to eight silk sutures, passed between the muscular and mucous coats of the stomach and including a broad layer of the parietal peritoneum. In at least one case fatal peritonitis was caused by the escape of the contents of the stomach alongside stitches that included the entire thickness of its wall. In two or three cases suppuration has taken place in the abdominal wall beside the wound, and I think it is prudent, therefore, to provide for drainage from the divided muscular planes. This can be done by drawing out the divided edge of the parietal peritoneum and attaching to the skin all around, after having placed a drain between its outer surface and the cut walls. This stitching of the parietal peritoneum to the skin gives a broad surface of peritoneal contact with the stomach. It has been employed in some cases of inguinal colotomy, as the Society will remember.

"An additional precaution was to pass two long pins or two stout silk ligatures through the portion of stomach that projects through the wound, for the purpose (in the case of ligatures) of facilitating the subsequent incision into the stomach, and also (in the case of the pins) as a precaution against the tearing out of the stitches and the return of the stomach into the abdominal cavity. This latter accident happened in one of Sédillot's cases, and one stitch tore out in one of Bryant's cases.

"In most of the later operations the stomach has not been opened until after the lapse of several days, from three to eight; and it is perhaps worthy of mention that in one case in which it was opened on the eighth day, peritonitis developed shortly afterward and proved fatal. In my own case it was my intention to open the stomach on the day following the operation, in order to feed the patient, with the expectation that it would be possible to prevent the escape of its contents, by placing a figure-of-8 ligature about the transfixing pins. It is in these more recent cases in which the opening of the stomach has been made a second operation, to be done several days after the first, that the proportion of successes has been largest.

"In several cases it is mentioned that the portion of the stomach secured in the wound was near the pylorus, and in another case I should pass the forceps to the left instead of directly backward, so as to seize the organ nearer its centre.

"Finally, the influence of the enfeebled condition produced by starvation and cachexia upon the result is so marked that if the operation is to be done at all it should be done as early as is practicable. The almost identical operation for the removal of a foreign body from the stomach, gastrotomy, has been almost uniformly successful, and this great difference in the result must be due to the difference in the strength of the patients."

RAPID LITHOTRITY.

Dr. James L. Little presented fragments of a calculus, weighing ninety-five grains, removed by rapid lithotrity. They were obtained from the bladder of a man, fifty-five years of age, who had suffered from symptoms of stone for two and a half years. During the past year he had several attacks of retention, compelling him to use a catheter. Last June he passed several fragments of stone. Before the operation he passed his urine every half hour. It contained mucus and blood. An examination showed the presence of a calculus.

On November 10th, Dr. Little performed litholapaxy. The stone was seized without difficulty and fragments removed with evacuating catheter. Considerable trouble was, however, experienced in removing the last fragment. It could be heard clicking against the catheter, but would not pass through. Continuing the suction with the aspiratory bag, while the catheter was being removed from the bladder, the fragment was found held fast in the opening at the end of the instrument. The operation lasted about forty-five minutes. The patient was doing well. No unfavorable symptoms followed the operation.

The Society then proceeded to the transaction of miscellaneous business.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, November 7, 1882.

E. C. Spitzka, M.D., President, in the Chair.

Dr. E. C. Spitzka showed sections of Guiteau's brain, and made some remarks about "artefacts." He claimed that he had discovered and announced the true character of these artefacts about five years ago. They were produced by the action of alcohol upon brain-tissue, and were probably largely composed of leucin. They could be produced artificially in healthy brains. They had often been considered colloidal in nature and had been described as pathological lesions. This was particularly the case in certain communications by Dr. Kempster and by Dr. John P. Gray in the *American Journal of Insanity*. These bodies varied in size and shape; they might be even visible to the naked eye. They did not stain unless the tissue was overstained, when they stained deeper than the surrounding parts.

The speaker thought that great injustice had been done him by those who had examined Guiteau's brain in not recognizing his work. He had seen sections of Guiteau's brain loaned him by Dr. Morton and they all showed signs of disease.

Dr. C. L. Dana thought that he was hardly to be blamed for not being acquainted with all of Dr. Spitzka's communications, especially since none of the recent writers had noticed them. That the artefacts or vacuoles were artificial and produced by the action of alcohol was one of the first things that had been suggested to him and was a thing he thought generally known among competent microscopists.

With regard to the sections of Guiteau's brain, he had admitted chronic disease of the blood-vessels. In the sections which he had examined and

reported upon, however, there were in his opinion no morbid changes that could be considered as proving anything regarding Guiteau's mental condition. In this opinion he was sustained by a number of pathologists equally competent with Dr. Spitzka, to whom he had submitted his sections.

Dr. Spitzka thought it unjust when there was so much said about the lack of original work by Americans that his should not have been acknowledged. The specimens of Guiteau's brain which he had examined showed all the signs of disease described in the official report. He intimated that Dr. Dana's report in The Medical Record was "fixed" to make it correspond with the editorial views expressed in that journal.

Dr. Wm. A. Hammond read a paper on the

SEAT OF INSTINCT IN MAN,

claiming that its seat was in the medulla oblongata. Dr. Hammond arrived at his conclusions from a study of the history of acephalic monsters and from a series of experiments which he and others had made upon frogs and reptiles. He said that he had found very little written about this subject. In acephalic monsters the capacity for suckling and other instinctive acts was observed, provided the medulla was present. In monsters in which there was no brain or cord, no such actions took place. In frogs, the removal of the cerebral and cerebellar lobes did not interfere with instinctive acts, such as swimming, the sexual act, etc. Neither did removal of the spinal cord.

In the discussion which followed the subject turned upon the nature rather than the seat of instinct. There was a general expression of disagreement in Dr. Hammond's conclusions, however.

Malaria in Italy.—In Italy has been published the first part of a large map designed to illustrate the prevalence of malaria in that country. It is shown by this map that out of 60 Italian provinces only 6 are entirely exempt from the disease. These are Genoa, Porto Maurizio, Florence, Massa and Carrara, Pesaro, and Piacenza. Two principal causes of the scourge are the marshes produced by the excavations of the railways, leaving a want of a good outflow for the water, and the destruction of the forests. It is is said that there are in the Italian hospitals every year some 12,000 patients suffering from malaria, and that out of the 2,200 men employed on the Sicilian railway alone 1,455 have been attacked in a single year.

A Curious Monster.—M. Paul Bert describes a living monster, five years old, seen by him at Geneva. It has two heads, two thoraces, four arms, one abdomen, and one pair of limbs. The fusion begins at the umbilicus. It has two stomachs, and probably two duodenums, one anus and one set of genital organs, the sex being male.

Remarkably enough though anatomically the same below, they are physiologically independent, each having control of the leg on his own side. The monster can walk, however. M. Bert states that the two faces are much alike. They are intelligent, and speak German, French, and Italian. Their health is good, they are mentally independent; eat and sleep alternately. The food which one takes does not satisfy the hunger of the other. The need of urinating and defecation is felt simultaneously. One has had a fever without the other being ill.

Correspondence.

THE PATHOLOGY OF TUBERCLE.

To the Editor of The Medical Record.

Sir: The article of Dr. Satterthwaite, in The Record of October 28th, is a fine *résumé* of the subject, and is praiseworthy for its freedom from bias and for the thoroughness with which the literature of the subject has been abstracted. The author, however, makes no mention of the noteworthy labor performed by Dr. O. C. Robinson, in the Pathological Laboratory of the University of Pennsylvania, under the direction of Dr. H. F. Formad, and reported in the *Philadelphia Medical Times* for December 3, 1881. These experiments, one hundred and nine in all, were carefully conducted and extended over a period of two years. The conclusion arrived at was unfavorable to the specific origin of the disease. I only wish to add that in any discussion of the question of the contagiousness of phthisis we should remember that we have already a well-defined etiology for the disease. There is scarcely a case of consumption where the predisposing cause or causes cannot be made out. The removal of the cause, if possible, is, of course, the first step in the treatment, and is often followed by the improvement or recovery of the case.

It was formerly supposed that the *Torula cerevisiæ* was capable of transforming starch into alcohol, water, and carbonic acid, but it is now known that the starch must be changed to glucose before the fungus can develop. Now, is it not true that the inroad of the *Bacillus tuberculosis* (admitting its existence) is *subsequent* to pathological changes produced by the disease. It is said that Koch admits that the parasite must have a suitable soil. Does he mean that the soil must be a morbid one?

A. H. Phinney.

Howell, Mich., November 3d.

INEBRIETY, A VICE OR DISEASE.

To the Editor of The Medical Record.

Sir: Dr. Crothers, in a recent paper on this subject, takes strong grounds against the theory of vice and sin being urged as a reason for the first use of spirits in obscure and gradually developed cases, and believes that inebriety is a disease, for which the victim is in no way responsible. The doctor has no doubt made an elaborate study of the subject, but has, I think, arrived at wrong conclusions. Granted that the continued use of alcohol will produce such physical and mental changes as will eventuate in a diseased condition, I still do not believe that the individual, before taking his first glass, is controlled by a disease which renders his not taking it out of his power, if within his reach. Dr. Crothers thinks this is a pernicious doctrine, but it seems to me a reasonable one, and will bear the test of criticism. The advocate of the vice doctrine may with propriety point to the fact, manifest every day in the streets of our towns and villages, that the class of young men who are drawn into the saloons are, as a rule, those who from childhood have not been subjected to proper religious training, who have been allowed to travel the streets unchecked, and to mingle with rough associates unrestrained. They go into the saloon with these associates

and take their first drink for precisely the same reason that they take their first cigar, or their first chew of tobacco, or first say "damn it." It is the chronic loafer, the young man of loose morals, above all, the young man who has grown from childhood with the inside of the saloon as familiar to his eyes as the inside of home; with the vile oath and ribald jest of the drunken more familiar to his ears than ever was the voice of prayer from the lips of his father—it is he who has added to his other accomplishments that of inebriety. The advocates of this pernicious doctrine might also allude to the no less palpable fact that the great majority of inebriates are found in our towns and cities, where saloon influences are prominent, while the greater part of our total population is distributed through the rural districts.

Given a community in which drinking-places are unknown and inebriety will be equally unknown. Given a locality in which whiskey selling is a recognized business, and we will find that the class called regular tipplers will be a numerous one, while the number of habitual drunkards will be increased in direct proportion. I call to mind a community in my own vicinity which, until within a few years, was inhabited by a native-born population, sober, industrious, religious. This population has been gradually supplanted through emigration and immigration by German residents almost entirely. Two saloons have been established, though it is only a country cross-road, and I am certain there is scarcely a man or woman, old or young, in that vicinity, comprising a population of four or five hundred, who is not a frequenter of those saloons, drinking from a single glass to beastly drunkenness. Is it not a little singular that in this case the disease should be so much more obnoxious to one class of people than to the other? And is it possible that this whole community, from the least to the greatest, is afflicted with disease, rendering them irresponsible for their acts in this respect? The advocates of this doctrine might, further, refer to the fact that drunkards—hundreds of them—are reformed by the various temperance organizations, and that a more numerous class are saved from their first drink by the good offices of these societies. The good work of these organizations is too well known to be disputed, to say nothing of the vaster influence exerted by the church of God in its various branches. Cases of disease are not cured, to any great extent, in these agnostic days, by persuasion, by the power of will, or by religious faith; hence we must conclude that those who are saved by the means to which I have alluded were not the subjects of disease, but of an appetite (I hope Dr. C. will pardon the word) which they were undoubtedly responsible for having formed, and which they had power to overcome. Another fact to which I will refer, and which I think is pregnant with proof of the truth of our position, is this: Years ago, before the subject of temperance had been agitated to any great extent, the clergy of our churches, to say nothing of the laity, were habitual drinkers of spirits; that is to say, they kept wine and other liquors in their cellars and drank it with their friends as occasion might require. The common use of strong drinks was a habit with all classes of people in the olden days.

With the last twenty or twenty-five years of active temperance work, we have seen wine-parties banished from the tables of the clergy and from every Christian home; we have seen the practice of drinking ardent spirits, instead of being indulged in by upright and honorable people in the broad light of day, relegated in great measure to the night-time—and as if this were not enough, further closed in by screens and darkened windows. What has brought about this change? Will Dr. Crothers say that the disease is being eradicated, and will he admit that the people of the church and those who possess the higher moral nature are first cured? and will he further say that this has been accomplished by a persistent agitation of the subject of the evils of drunkenness? Allowing me to substitute the word "vice" for "disease," I think he ought, at least, to say just that. Dr. C. alludes to cases in point, in which he claims that great shocks to the nervous system, caused by grief at some great loss or affection, has eventuated in habitual inebriety, as the result of physical changes over which the victim has no control. I can readily conceive of some great grief, such as the sudden loss of family or of fortune, from which we might hope to find relief in forgetfulness, or in the substitution of a state of mind opposite to that in which our grief has left us. For this we turn, if our will is not strong, to one of the intoxicants—to tobacco, perhaps, if we are not already habituated to its use, or to the stronger but more dangerous opium or alcohol. It is true that many cases of inebriation begin in this way, and I will not deny that it is possible for injury of some sort to be productive of a diseased condition leading to this result; but such cases as are cited by Dr. Crothers are so rare as to be insignificant when compared with the vast number of those who took their first glass of spirits because such action was compatible with their surroundings, and with the influences under which they had lived. The doctor well says: "If, in ten cases of a similar disease, the physical origin can be traced in fire, it is most resonable to suppose that a similar physical causation exists in the others, although not clearly traceable;" but he ought to remember that no such proportion exists in regard to the causation of inebriety. Where Dr. C. can find one case in which he can trace the cause to physical origin, I can find fifty, or an indefinite number of cases, in which I can trace the habit to deficient moral rectitude, or lack of moral force of character. And I will add further, that the great majority of inebriates are those whose religious training has been *nil*.

J. B. Stair, M.D.

Spring Green, Wis., November 23, 1882.

Foreign Medical Men in Paris.—Foreign medical men are everywhere cordially received in Paris. All the hospitals and clinics are open to them free of charge, and on the presentation of professional cards special attention is invariably afforded. Even the histological laboratories, with their advantages, are also at their service. If a stranger wishes to work in the histological laboratory of the College of France, under Bauvier, he has only to present his card as physician, enter his name, and if all the tables are not occupied, he can begin work at once, provided he has with him his microscope. It is, however, absolutely essential to understand French. In the German and Austrian hospitals nearly every one speaks more or less English, but that is by no means the case in France. It must, however, be readily conceded that a person not understanding the language of the hospital is at a decided disadvantage. —*Cor. Chicago Medical Journal and Examiner.*

New Instruments.

A SUBSTITUTE FOR THE WRIST AND ANKLE BAND.

To the Editor of The Medical Record.

Dear Sir: My friend, Dr. T. A. Emmet, on his return from his summer vacation in Europe, brought me an apparatus which is so admirably adapted to the purpose intended, that I deem it worthy of notice in your Journal.

Mr. P. H. Schmidt, instrument-maker, No. 1311 Broadway, has made several of them, with such improvements as suggested themselves to me.

It consists of a contrivance for securing the patient in the back position for all operations on the perinæum, vagina, uterus, or rectum; also for perineal urethrotomy and stone in the bladder.

The best apparatus which we have had for this purpose, up to the present time, is the wrist and ankle band, which is both awkward and painful.

The accompanying wood-cut explains itself. It consists of a solid iron rod, sliding within a hollow one, for the purpose of rendering it longer or shorter. At each end of the rod, is a padded leather strap, which is to be buckled around the leg just below the knee, a long padded strap is then fastened to one of the buckles near the end of the connecting rod, carried around behind the patient's neck and fastened to the buckle at the other end of the rod.

I have used the apparatus several times in operations for stone, perineal section, hemorrhoids, ruptured perinæum, etc., and find it all that I could wish. It enables me to dispense with one or two assistants, as the one giving ether can also keep the patient from rolling to either side, by simply grasping the connecting bar with one hand, leaving the other free.

It also secures a thorough stretching of the perinæum, lifts the legs and feet completely out of the way, and enables you to fetch the nates well down beyond the edge of the table, which is often very desirable.

Geo. A. Peters, M.D.

New York.

Professor Nothnagel delivered his opening address, October 16th, on assuming the chair of internal medicine in Vienna. He discussed the subject of clinical instruction. He was listened to by a crowded audience.

Obituary.

JOHN P. P. WHITE, M.D.,

new york.

Dr. John Payson Phillips White died in this city on the morning of December 3d, of peritonitis and cholæmia, the result of obstruction of the common duct of the liver and rupture of the gall-bladder. Dr. White was born in Northampton, Mass., July 4, 1838, and was graduated from Williams College. He studied medicine with Dr. John J. Crane, of this city, with whom he became associated subsequently, and graduated from the College of Physicians and Surgeons. At the breaking out of the war he was an interne at Bellevue Hospital, but left to join Hawkins' Zouaves as Assistant Surgeon, and afterward rose to be Brigade Surgeon. Dr. White was stationed in New York during the famous riot of 1863, and narrowly escaped being hung by the mob. He was rescued, however, by a former patient, and secreted himself in the house of a professional friend for some time.

Dr. White was connected with Bellevue Hospital as Visiting Physician, and was a member of the County Medical Society and Academy of Medicine. He was a man of singular purity of character, whose gentleness and amiability made him popular with a great number of people, and those of his profession with whom he came in contact speedily learned to love him. His cheerful face and kindly ways gained for him a hearty welcome everywhere, and his many quiet acts of unostentatious charity called forth the thankful prayers of the sick and needy.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from November 25, 1882, *to December* 2, 1882.

Powell, J. L., Assistant Surgeon. Relieved from temporary duty as Attending Surgeon at Headquarters Department of Texas, ordered to proceed to Fort Davis, Texas, and report to the commanding officer for duty. S. O. 129, Department of Texas, November 23, 1882.

Gray, William W., First Lieutenant and Assistant Surgeon. The leave of absence granted on Surgeon's certificate of disability, October 31, 1882, Department of the South, is extended five months on Surgeon's certificate of disability. S. O. 278, par. 3, A. G. O., November 29, 1882.

Luxation of the Jaw.—The late Professor Gibson used to tell a good anecdote in regard to luxation of the jaw. "An old and quite wealthy man came into the office of a surgeon, with a luxation of the jaw, and made motions to have it reduced. The jaw was reduced, and on being asked the fee the doctor mentioned an amount which the man regarded as entirely too much, and insisted on its being reduced one-half. The surgeon said no more about the fee, but began to talk, and pretty soon told a laughable story. The man began to laugh heartily, and out went the jaw. He again made signs to have it reduced, but the doctor said, 'When you pay down my fee, I will put in your jaw.'"

The Post-Graduate Schools of this city are well satisfied with their success thus far.

Typhoid Fever and Malarial Waves and their Relation.—In a recent monthly report the Secretary of the State Board of Health of Connecticut, gives statistics showing an increase in typhoid fever, and comments upon its relation to malaria as follows:

"This return of typhoid fever to prominence, and its steady increase in frequency for the last three years, is apparently a part of an extensive and comprehensive movement. As the epidemic of malaria was ushered in by a decrease, and in places almost, if not quite, a total disappearance of typhoid, this return of typhoid fever to its former importance and relative frequency is an intimation of the decrease and disappearance of malaria. The tendency toward typhoid fever commenced several years ago, and has steadily grown stronger each year, as shown by the increased prevalence, tendency to unusual frequency and severity, and the increase each year of deaths from this cause. As the decrease in the frequency of typhoid preceded the malarial wave, so its increase precedes the entire disappearance of malaria, or at least gives us some ground for hope that such a disappearance will take place. This disappearance of epidemics of malarial fever on a large scale has often been followed by an unusual prevalence of typhoid fever or an extensive epidemic. The epidemics of malarial fever of 1807 and 1824, which are stated to have extended over all Europe, were followed by typhoid fever." The writer thinks that the spread of malarial fevers over Connecticut, Massachusetts, and Rhode Island has ceased.

A Royal Surgeon.—If only we could all treat our patients as the Prince of Wales did! Recently, when out shooting, one of the servants was slightly injured by a chance shot, and howled a little. The Prince came up and said, "My friend, I am a doctor." He gave the wounded man a drink from his flask, and slipped a hundred francs into his hand. The man got well without antiseptic precautions.

Asthma Cigarettes.—Impregnate well-nitred tobacco with an alcoholic fluid extract of grindelia; let dry and use in cigarettes. Owing to the nitre they will continue to glow and develop smoke.

The Retirement of Dr. Holmes.—Dr. Oliver Wendell Holmes delivered his farewell lecture before the students of Harvard Medical College on November 28th. The ceremony was a most interesting one. The amphitheatre was packed, there being many physicians and old students in the audience. The entrance of the doctor was marked by the rising of the students, and as their applause ceased one of them presented him in behalf of his last class with a beautiful loving-cup, inscribed with a quotation from one of his own poems.

Beginning his address, Dr. Holmes said there were three times in a man's life when he might properly consider himself the centre of attraction—at his christening, at his marriage, and at his own funeral. This, the beginning of his thirty-sixth course of lectures on anatomy, was the end of his connection with the school. For about half of this time he had also taught physiology, but with the growth of the science he had gladly given it over to form a new department. It was a good thing for a college to get rid of her old men. Their ideas were antiquated and the college had better let them go. He had held his office so long because he had taught a subject which could never become antiquated. In his lifetime it had received very few important additions. He had begun the study of law in his youth as an experiment, but for various reasons had turned his attention to medicine. While in the Law School he had engaged with some friends in publishing a paper, and for the first time saw himself in print. From the printer's type he had contracted the disease of authors—head-poisoning—which he had never quite got rid of. The doctor finished with some practical remarks on the way in which the science was tending. Dr. Holmes has been made Emeritus Professor of Anatomy in the college.

Mr. Stuart Cumberland's Experiments in Muscle-Reading. — A number of prominent medical gentlemen, clergymen, and others, assembled in a parlor of the Everett House last week to witness the performances of Mr. Stuart Chamberlain, the mind-reader. This gentleman is an Englishman, who has given exhibitions of his peculiar powers before scientific audiences in his own country. He showed last week that he had quite remarkable gifts in his particular line. The feats which he performed were those usually known as mind-reading or muscle-reading. They were first shown in this country several years ago by "Brown, the mind-reader," and subsequently by others. The physiological explanation of the tricks was first made in this country also, and altogether Mr. Chamberlain comes over to tell us things which are rather stale here. The extreme delicacy of his touch-, pressure-, and muscular-sense, however, is unique and interesting.

One example of it was the following: Mr. Chamberlain, being blindfolded, took Mr. Beecher's hand and led him at once to a small spot on the wall, previously marked, upon which he almost immediately placed his finger; he then took the distinguished clergyman to another spot, which had also been marked, and placed his finger upon it. Then taking Dr. Ball's hand he at once found a small object which that gentleman had ingeniously hidden in his shoe. The especially interesting part of Mr. Chamberlain's performances was the fineness of his perceptive powers, by which he was able to pick out small objects, even placing his hand upon a single pin selected out of a number of others, and thought of by the person experimented upon.

The Payment of Garfield's Physicians.—The following are the claims allowed by the Garfield Board of Audit: Dr. D. W. Bliss, $6,500; Dr. D. Hayes Agnew, $5,000; Dr. Frank H. Hamilton, $5,000; Dr. Robert Reyburn, $4,000; Dr. Silas A. Boynton, $4,000; Dr. Susan A. Edson, $3,000; to-

tal, $27,500. The total amount appropriated to pay claims against the Garfield estate was $57,500. The allowances for the physicians are $8,000 less than the amount appropriated. We believe it will be the universal sentiment of the medical profession that the sums appropriated for the physicians are unjustly small.

GRAVE-ROBBING.—During the past week a sensation was caused in Philadelphia by the arrest of an organized gang of grave-robbers that has for nearly twenty years been despoiling Lebanon Cemetery. The bodies were sold for dissection.

SUICIDE AND THE NEW PENAL CODE.—On Monday a poor fellow, who for a long time had been brooding over severe troubles, attempted to commit suicide. He failed, was taken to a police station, and from there into court, where he learned that under the new Penal Code attempt at suicide is a felony which may be punished to the extent of two years' imprisonment, or a fine of one thousand dollars, or both.

THE FOLLOWING DEATHS FROM APPLICATIONS OF CARBOLIC ACID are reported: A man who had his hair clipped off was painted with carbolic acid over two-thirds of the head for some disease. He complained immediately about pains and dizziness in the head, became unconscious after a few minutes, and died shortly afterward. Three girls were painted for scabies all over the body with impure carbolic acid, and they became unconscious after a few minutes. Two carpenters had used carbolic acid against scabies; one of them cried suddenly, became intoxicated, and died after a few minutes; the other became unconscious, but he recovered. A child of fourteen months fell upon a bottle filled with a strong solution of carbolic acid; the bottle broke, and the child was covered with the acid. Death followed a few minutes afterward. A midwife applied a small compress soaked with carbolic acid to a suppurating spot on a little child, which died after two hours. Experiments on animals have proved that carbolic acid brought in contact with the bowels or peritoneum will produce shock and collapse.

COMPLETE DISLOCATION OF RADIUS AND ULNA OUTWARD.—Dr. S. R. Towne, of Enfield, Mass., writes: "An article in the *Medical News*, of Philadelphia, date of September 30, 1882, on 'Complete Outward Dislocation of Radius and Ulna,' recalls to my mind a case reported by me in the number of May 8, 1880, p. 525, of THE MEDICAL RECORD. The case I know to have been a similar one, viz., complete outward dislocation of radius and ulna."

THE LATEST SPHÆRO-BACTERIUM.—The *Chicago Medical Journal and Examiner* publishes the following: Drs. Daniel R. Brower and Lester Curtis were in attendance upon a lad affected with perfectly typical tetanus, resulting from a wound in his hand inflicted by the explosion of a toy pistol. They determined to examine his blood with the microscope, and, having done this, discovered that it was swarming with organisms precisely similar to the sphæro-bacteria recognized in the ill-conditioned pus removed from an abscess communicating with a joint. The blood of a horse affected with tetanus was then placed by them under the same objectives, and in it also similar organisms were discovered. Not content with pushing their investigations to this point, they proceeded to examine the mother of the boy who was their patient, and also another of her children; and, to their surprise, found in the blood of each an abundance of the same germs. A neighboring frog-pond was finally searched, and found to furnish masses of the same bacteria. The boy recovered from his tetanus, and was taken before a body of scientific gentlemen in this city, where his blood, still swarming with bacteria, was placed on slides and examined by a dozen or more physicians and others of unquestioned discrimination and veracity. All were able to recognize the existence of the bodies to which their attention was directed.

THE WOMAN DOCTOR IN FICTION.—The woman physician seems to be considered good "material" for modern novelists. Besides Charles Reade and a German novelist whose name we do not recall, three American writers have recently dealt with this interesting creature. The latest effort is that of Miss Elizabeth Stuart Phelps. Her book strikes one as being a very clever and earnest work, yet grotesque and even silly in its particular attempts to picture an impossible scientific, homœopathic ideal.

Our contemporary the *Boston Medical and Surgical Journal* discourses very pertinently as follows: "The differences between the novelist's doctor and the doctor's doctor are usually sufficiently striking. But what shall we say of the homœopathic female novelist's female homœopathic doctor? To many of those who are reading 'Doctor Zay' in *The Atlantic*, the 'scientific' aspects of the story must be among its most entertaining features. Yorke, the hero, having 'dislocated his ankle and concussed his brain,' falls (possibly as a symptom of the latter injury) madly in love with his doctor. She, however, being already wedded to her art, and not being bigamously disposed, gives him no encouragement. But if the suitor gets only homœopathic doses of sentiment, he receives heroic ones of scientific information. The doctor's remarks always savour of the 'shop,' the character of the shop and the quality of its product being shown as follows. Speaking of his passion, the patient says, 'It is beyond the reach of any pellet in your little case; the remedy is not in your Materia Medica.' 'That may be true; but Nature has her own unerring prescriptions. A single dose of absence—even in the first attenuation—will work a recovery which will astonish yourself, sir.' Again she says, 'I cannot demonstrate to you the futility of your hope. . . . Let us both consider this a case of aphonia and aphasia, and be done with it.' 'Explain yourself to the ignorant, my learned physician,' 'Aphonia is inability to speak——' 'Oh, yes; my Greek might have stood me for that. And aphasia is inability to hear?' 'Precisely.' 'That is a scientific reply,' said Yorke, regarding her keenly."

THE LATE DR. A. L. LOWELL, OF BROOKLYN, N. Y.—At a special meeting of the Medical Board of St. Peter's Hospital, Brooklyn, held at the Hospital, Saturday, October 14, 1882, to take action on the death of Dr. A. L. Lowell, one of the Attending Surgeons of the Hospital, it was

Resolved, That in the death of Dr. A. L. Lowell the members of the Medical Board have lost an associate who commanded their confidence and esteem in both public and private relations.

Resolved, That St. Peter's Hospital has lost the services of a skilful, efficient, and benevolent surgeon; one who practised our healing art with untiring and single-minded zeal.

Resolved, That we offer to his family our sincere sympathy in their loss, and that these resolutions be communicated to them, and published in the New York MEDICAL RECORD and the *Boston Medical and Surgical Journal*.

Original Lectures.

ON THE TREATMENT OF CROUP.[1]

By PROFESSOR DUJARDIN BEAUMETZ,

MEMBER OF THE ACADEMY OF MEDICINE; PHYSICIAN TO THE HÔPITAL ST. ANTOINE, ETC., PARIS, FRANCE.

PART I.

GENTLEMEN: In my last lecture I considered the treatment of diphtheritic angina, to-day I shall speak of the localizations of diphtheria in the respiratory tract. When this disease affects the air-passages, although the primitive cause is the same, the symptomatology is different, and new therapeutic indications arise. As you will often be called upon to render assistance in these cases, which are always grave, I have deemed it advisible to devote this entire lecture to the treatment of croup. You will fortunately be able to see, in the department of our hospital set apart for children, illustrations both of the disease and the modes of treatment which I shall here recommend.

The details into which I entered when treating of diphtheritic sore throat have made it unnecessary that I should devote much time to the origin of croup. In France we are agreed that pseudo-membranous croup is the extension of diphtheria to the larynx, and we reject altogether the possibility of an inflammatory or "catarrhal" croup, a notion which has been supported in Germany.

By the side of this pseudo-membranous diphtheritic croup, exist diseases of the larynx which offer a certain symptomatic resemblance to this latter, and are often confounded with it; I allude especially to simple laryngitis and laryngismus stridulus.

Simple laryngitis, in young children, is a grave affection, which may cause death by suffocation, and which produces symptoms quite like those of croup, except, of course, the characteristic expectoration of pseudo-membranous tube-casts. In the case of infants under two years of age, owing to the extreme difficulty of examining the throat, grave forms of simple laryngitis are often confounded with croup.

The mistake is the more easily made for the reason that croup is often croup from the first; that is to say, that while in the majority of cases diphtheria attacks first the pharynx, then the larynx, it may follow an opposite course, and affect first the respiratory passages, and then invade the mucous membrane of the pharynx.

To guide you in the diagnosis of pseudo-membranous croup, and of the grave forms of simple laryngitis, you will have only two important symptoms to take into account—of course you should first settle the question, if possible, by inspection, whether there be false membranes in the throat or windpipe: 1. In simple laryngitis, paroxysms of suffocation are not so common or so noticeable as in croup, the difficulty of breathing is constant but exacerbations are not so marked. 2. The march of croup is more sly, insidious, and progressive, the symptoms of the *début* are not generally alarming. The onset of simple laryngitis is more acute, noisy, and violent, but in the milder cases we soon see improvement. The graver cases, however, of this affection, soon manifest symptoms not at all easy to discriminate from the ordinary symptoms of membranous croup; in both we have the gradual increase of pallor and prostration, the weakening and extinction of the voice, the hoarse, barking cough, and the laryngeal whistling giving place to silence, the dyspnœa becoming more and more intense till death ends the scene.

Thus we see that in very young subjects the confusion is almost inevitable between simple laryngitis and membranous croup, but this is not prejudicial to the patient, since the same line of treatment is applicable to both cases. The prognosis, however, is different, and it is easily understood that tracheotomy gives better results in the first case than in the second.

The difficulties of diagnosis between membranous croup and laryngismus stridulus are much less great, and you will hardly fail to know the latter when you see it, if you will keep in mind the classical description. The little patient is attacked suddenly in the night with a paroxysm of suffocation. The child was in perfect health the evening before, or had only a slight cold. Respiration is obstructed and occurs with convulsive struggles and crowing inspirations. There is a sonorous cough,[1] and a peculiar hoarseness of the voice. During the paroxysms the child is in the greatest distress and asphyxia seems imminent. The family, in the utmost alarm, summon the physician. Here is an opportunity for a brilliant triumph of therapeutic skill; you can very speedily subdue this false croup by the use of two remedies, chloral and bromide of potassium. When your patient is very young, under two years of age, I advise you to employ bromide of sodium in the dose of half a gramme (7½ grains). This dose may be given in a teaspoonful of syrup of chloral;[2] the whole may be administered in a cup of warm sweetened milk, to which the yolk of an egg is added. For older children you may administer in the same vehicle the bromide of potassium, in the dose of half a gramme to a gramme (7½ to 15 grains), and you may double or even quadruple the dose of syrup of chloral.

I have felt it to be my duty to emphasize the importance of correct diagnosis, for before you undertake to treat a case of croup you ought to be sure that you have a case of croup to treat. When once you shall have recognized in your patient the symptoms of membranous laryngitis,[3] symptoms which I

[1] Translated from advance sheets by Dr. E. P. Hurd, Newburyport, Mass.

[1] [The cough is denied by some authorities, as Niemeyer. It is asserted that Laryngismus Stridulus, or False Croup, is purely a neurosis of the par vagum, unaccompanied by any catarrhal inflammation, and consequently by cough and hoarseness. This is not the French view, as the very name by which the affection is designated implies—*Laryngite Striduleuse*. The kind of "false croup" alluded to in the text is clearly of a subacute catarrhal character, and ought not to be confounded with spasm of the glottis, which is an independent affection.—TR.]

[2] [The strength of the French syrup of chloral is one gramme (fifteen grains) to the tablespoonful.—TR.]

[3] Pseudo membranous laryngitis may be such from the start (*croup d'emblée*), or be consecutive to membranous angina, or, still farther, may have been preceded by diphtheria of the bronchi or of the trachea (*croup ascendant*); it presents in its march a group of symptoms which enable us to divide the disease into three periods—exudative, dyspnœic, and asphyxial.

Croup begins often as a simple cold, by malaise, chills, some amount of prostration, diminution of the appetite, and a little fever, but the child continues to go out-doors and engages in his sports. Soon he complains of a tickling in the throat and difficulty of swallowing, and headache; the fever and anorexia increase, he grows pale and coughs, his voice is hoarse, weaker than ordinarily, harsh and discordant.

If you examine the throat at this stage, you often discover nothing but redness in spots, and swelling of the tonsils; when croup is complicated with angina, you will see rapidly developed little white, milky, opaline patches, which cover little by little the tonsils, velum palati, and the entire posterior fauces, and often reach the nasal fossæ, from which a yellowish serous liquid exudes. The submaxillary glands are engorged and tender to pressure.

The disease continues and makes progress, as it were, by bounds;

need not describe to you, and for whose full exposition I refer you to your treatises on clinical medicine and practice, you have two methods of combating this dire affection, and these are—(1) medicinal, and (2) surgical.

(1.) The medicinal methods are absolutely identical with those which I have indicated for diphtheria angina, and the difference in the localization of the disease necessitates but slight modifications in the treatment.

These modifications affect especially the mode of application of the remedy. While it is an easy matter to make applications directly to the pharynx, it is extremely difficult to medicate topically the windpipe. When treating of diseases of the lungs I pointed out to you how hard it is to make medicinal substances penetrate the air-tubes, and demonstrated how little service cold pulverizations can render. Hence, swabbing of the larynx and insufflations of powders have been recommended. All these means, so difficult of accomplishment, should be abandoned, and you should rely on the steam atomizer, whose medicated vapor moistens the upper part of the larynx, and is about the only topical agency which I advise.

Another indication to fulfil is to promote expectoration of the false membranes in the air-passages. You understand the utility and the necessity of this therapeutic measure. Unhappily we have no expectorants of real utility except the emetics,[1] which only indirectly favor expectoration; at the same time the efforts of vomiting promote the expulsion of the false membranes, and it is advantageous to avail ourselves of their aid.

In these cases three medicaments are especially recommended — ipecac, sulphate of copper, and apomorphia. Ipecac is the expectorant by far the most used; as an emetic it is the safest. Unfortunately it does not always produce vomiting, and one is obliged to have recourse to the sulphate of copper in the dose of 50 centigrammes (7 grains) in mucilage. Sulphate of copper is somewhat harsh in its action, but it may render you great service in these cases.

A priori apomorphia ought to be the best of emetics, since it is capable of employment in subcutaneous injections, which is of great advantage in the case of young children affected with sore throat, who refuse often with extreme obstinacy all the medicines which you try to give them by mouth. Apomorphia in the dose of 10 milligrammes for the adult (one-sixth grain), 5 milligrammes (one-twelfth grain) for young subjects of from eight to ten years, 2 milligrammes (one-thirtieth grain) for children of a still younger age, provokes vomiting in a few minutes after its introduction under the skin. It is, however, a medicament which very readily undergoes change, and on the other hand its action seems to be feeble in cases where hæmatosis is retarded, as in asphyxia; finally it is a toxic substance which in some cases determines symptoms of extreme gravity, as Pécholier has recently shown and as I have myself pointed out.[1] These circumstances have led to the virtual abandonment of apomorphia in the treatment of membranous croup.[2]

Besides medicated inhalations, expectorants, and emetics, besides a tonic regimen, there remains but little to be done, from a medical point of view, in the treatment of croup. These are, as you see, arms of little potency to combat so formidable a malady.

At the same time, if we lack medications of great activity, there are kinds of treatment that are dangerous, such as revulsives and blood-letting. Considering diphtheritic laryngitis as a veritable inflammation, some physicians have undertaken to combat it by antiphlogistics, and they have even applied vesicatories, or (what is worse still) leeches to the larynx and chest. This practice is to be mentioned only to be condemned; it weakens the patient, and by the denudation of the epidermis favors the production of cutaneous diphtheria. You ought then to refrain from all such measures.

Struck with the importance of keeping patulous the windpipe, Bouchat thought that one might obviate the dangers which result from the presence of false membranes by tubes introduced into the glottis. I was interne of the Hôpital St. Eugenie when the first trials of catheterization of the glottis were made by Bouchat; these first attempts did not

there are intervals of relative calm between the outbursts of pain experienced by the patient.

The cough, at first infrequent and barking, becomes harsher and hoarser, more annoying and persistent, and is finally extinguished; it is followed by a laryngo-tracheal whistling, and is often accompanied with a muco-purulent expectoration, which may contain *débris* of false membranes.

The voice weakens and becomes lost, the respiration becomes more labored and is attended with whistling râles of moderate intensity, inspiration becomes longer, slower, expiration harsher and more prolonged. Soon (and the younger the child the more rapidly) the difficulty of respiration augments and the tugging for breath appears. It is toward evening that the dyspnœa becomes the most marked, it is in the night that the paroxysms of suffocation are the most frequent.

The child may be lying calmly, though breathing more noisily than before; it is restless in its sleep, tosses about, then awakes, tries to get up, makes efforts to breathe, when suddenly, without cause or after some emotion, it is taken with suffocation; its countenance is pale, anxious, then becomes of a livid purple, cold like the lips; the agitation is extreme, the efforts of inspiration are violent, the alæ nasi dilate, the veins are engorged, the child is on the point of suffocating, when there is a calm. The paroxysm lasts for an indefinite period, and is repeated several times during the day and night. Some children have no paroxysms of suffocation, but suffer simply from a slow and progressive dyspnœa. False membranes are often coughed up after these attacks; this affords a momentary relief. The tugging for breath increases, and all the muscles of forced inspiration are brought into exercise; the epigastric hollow and the hollow above the sternum are very prominent in consequence of the extraordinary action of the respiratory muscles.

The asphyxia progressing, the little patient becomes more calm, is lethargic, his countenance is purple, he is covered with perspiration, the cutaneous reflexes are abolished, his pulse is small and irregular, and he passes off in a coma or in an attack of convulsions. In the course of the disease the febrile state is quite well marked, and varies according to the period, the gravity of the disease and the complications. The temperature oscillates between 38° and 38.5° (100° and 101° F.), may go as high as 39° (102° F.), or even 39.5° (103° F.), but toward the end of the period of asphyxia it falls; the pulse is accelerated, and is often intermittent; rises often to 120, 140, 160, and even higher.

Eruptions sometimes appear on the person of the patient, and petechial extravasations. In some cases albumen appears in the urine; this is always of evil augury.

Auscultation gives few results; you may detect a laryngo-tracheal whistling and an enfeebling of the vesicular murmur more and more marked as the disease advances; auscultation of the larynx sometimes enables you to hear a *bruit de soupape* [resembling the flapping of an air-valve] indicating the presence of a false membrane floating in the air-tube.

[1] Fleischmann has studied the therapeutic value of emetics in croup. Traube pretended that in the effort of vomiting the opening of the glottis dilates, but Luttich has shown that this is an error, and that the occlusion of the glottis is a constant fact during the act of vomiting. Vomiting favors expectoration, by reflex action. The sole action of emetics, according to Fleischmann, is to unload the peripheral vessels. Employed alone, medication by emetics rarely gives good results; from 1863 to 1873, thirty-seven infants were treated by this method alone, and all died but three (Fleischmann: De l'Action thérapeutique des vomitifs dans le Croup. Rev. Méd. Chirurgical, June, 1875, p. 403).

[1] Pécholier: Empoisonnement avec l'Apomorphine (Bull. de Thér., 15 Mai, 1882). Dujardin Beaumetz: Des Dangers de l'Apomorphine (Soc. de Thér., 1874).

[2] Apomorphine is a derivative of morphine, from which it differs in having one less equivalent of water. It is obtained by heating, in tightly sealed tubes, morphia with excess of Hcl. Introduced under the skin in the dose of one-sixth of a grain in the adult, it speedily causes vomiting. Quehl has shown that vomiting is produced by an irritant effect on the pneumogastrics. Mosler has maintained that in five or six days a solution of apomorphia becomes toxic. Chouppe (Sur l'Apomorphine, Gaz. Heb., December, 1874) has indicated the accidents on the part of the heart which may follow injections of this alkaloid. Dujardin Beaumetz has pointed out the same danger. Finally, Pécholier has recently experienced in himself the most alarming respiratory syncope after a hypodermic of apomorphine.

seem very encouraging, and the method never became general. This practice has lately been revived by Von Huttenbrenner, with, however, no better success.

(2.) When, in consequence of the progress of the disease, and the failure of internal medication, you find yourself powerless to prevent the more and more frequent return of the suffocative paroxysms, and the gradual progressive asphyxia which results, it is your duty to intervene surgically, and perform tracheotomy.[1]

It was a grand and brilliant idea which led the surgeon boldly to open the trachea when the larynx was obstructed, that the patient might be enabled to breathe. If tracheotomy has been slow to obtain a place in the domain of daily practice, it is because it has been found that something is necessary besides cutting the trachea; the tracheal incision must be kept well open by special means, if the respiratory function is to be materially aided by the operation. Therefore tracheotomy, practised as it has been, infrequently from the earliest times, never took rank and title among the resources of our profession, till Bretonneau, and especially Trousseau, by their manual dexterity, instrumental apparatus, and consecutive dressings, gave method and exactness to the technics of the operation.

I am going to venture somewhat outside of my province as a teacher of therapeutics, and enter into the details of tracheotomy. This is an operation which, like that for empyema, belongs almost as much to medicine as to surgery. In fact, here in Paris we see it performed quite as often by physicians as by surgeons. Moreover, it is an operation of urgency which results from a disease that appertains to medicine, and which you are likely to be called upon to perform more than once in your lifetime; it is therefore well that you should have all the details in your mind.

Tracheotomy comprehends three steps: first, the opening of the air-tube; second, the introduction of a tracheal canula to keep patulous the opening; third, the subsequent dressings. Let us examine each one of these steps.

From the point of view of the opening to be made, the various operative procedures which are recommended may be arranged in several distinct classes. This division is based on the relative rapidity with which the operation is performed, or on the place where the opening is to be made. The question of place comprises the choice between laryngotomy, tracheotomy, and crico-tracheotomy; that of relative rapidity includes the rapid, slow, and mixed methods.

[1] The first surgeon of antiquity who is known to have practised tracheotomy was Antellus, cited by Paul of Egina. He opened the trachea by a transverse incision below the third or fourth ring, and recommended to divide not the cartilage but the connecting membrane.

In the sixteenth century (1546) Antonio Masa Branavalo, physician to the Duke of Ferrara, performed tracheotomy successfully in a case of suffocative angina.

In 1660 Casserio gave a very complete description of tracheotomy, and of the manual procedures, but down to 1765, epoch when Home gave the first description of croup, the operation had been performed for suffocative anginas, and all affections producing asphyxia, without being particularly directed against croup. Home was the first to advise it in this disease.

In 1782 John André, of London, practised it for the first time in croup. The operation was afterward resorted to only in exceptional cases, and at the first great Medical Congress in 1808, every voice but one (that of Caron) was against tracheotomy in the treatment of croup.

In 1814, Thomas Chevalier published a report of a case of croup cured by tracheotomy. Then came Bretonneau, who first pointed out the necessity, in order that favorable results from the operation might be obtained, of introducing through the tracheal wound canulas of considerable size; heretofore very small tubes had been used. Trousseau followed and popularized the method of his master, and ever since tracheotomy has been an approved method of treatment.

The rapid methods are the most seductive. To penetrate the trachea at once and in a few seconds to place a canula in the respiratory passages seems to be the method the most applicable in such cases, since it removes with extreme rapidity the obstacles which oppose respiration, and does away with that painful and difficult period of immobility demanded by the other procedure.

There are three methods of rapid tracheotomy—the one originated with my regretted master, Chassaignac, the other with Bourdillat, the third with my colleague and friend, St. Germain.

Chassaignac seized the cricoid cartilage with a tenaculum furnished with a groove, serving to guide a bistoury with which he cut at one sweep the three first rings of the trachea; then this same tenaculum, after a modification which Isambert gave it, was made to open and serve as a dilator, in order to introduce the tracheal canula.

Bourdillat makes two stages of the operation: the first comprises the incision of the tissues down to the trachea, the second the incision of this latter.

St. Germain proceeds in a somewhat different manner, and his method has been described by my former interne, Dubar,[1] who has put it into practice in my service: The trachea is opened as you would open an abscess, the left hand grasping the neck makes the trachea prominent, and with a single thrust of the bistoury the air-passages are entered. A bistoury specially constructed enables you to limit the depth of the incision on the one part, and on the other enables you to hear the whiz of the air which escapes from the trachea at the moment of the incision; then, the incision being made, with a dilator you place the canula in the trachea.

I do not know what future is reserved for these rapid methods, which, indeed, have always seemed to me of the most simple kind. At the same time, used to the slow processes, I prefer them, while still recognizing the advantages of the quicker methods. Nevertheless, these advantages are at a discount when the operator fails, as he often will, speedily to introduce the canula; and this, because he attempts to do it through a wound which includes in the same extent the skin, subjacent tissues, and trachea.

SUPPOSED DEATH FROM THE ADMINISTRATION OF MALE FERN.—Dr. Coghill, of Ceylon, administered male fern according to a prescription recommended and containing the following ingredients:

Æthereal tincture of male fern...	ʒ iss.
Pomegranate	ʒ ij.
Kousso.....	ʒ iij.
Kamela	ʒ ij.

This was taken in two doses, an interval of four hours elapsing between, so that six drachms of the extract was the amount in each draught. The effects following the two doses were excessive purging and severe vomiting, with acute cramping pains, which it was deemed necessary to relieve by subcutaneous injection of morphia, one-fourth grain. The patient, however, died, in the opinion of the medical attendant, from choleraic diarrhœa, which was then epidemic in the neighborhood; but, according to the friends of the deceased, from the effects brought about by the unusual dose of male fern administered. A suit for malpractice was brought, but Dr. Coghill was exonerated.

A CASE OF FOREIGN BODY IN THE EXTERNAL AUDITORY CANAL.

Removal by Displacement Forward of the Auricle and Cartilaginous Meatus.

By ALBERT H. BUCK, M.D.,

NEW YORK.

On August 3, 1882, I was asked by my friend, Dr. Francis Delafield, to assist him in removing a locust bean from the ear of a boy, nine years old. The story told by the mother, was as follows: On the day previous one of the boy's playmates had thrown or pushed the bean into his right ear. No pain followed, but yet the mother was anxious to have the foreign body removed, and accordingly she consulted a physician in the village in which she was spending the summer with her children. His efforts to extract the bean caused pain, and failed to accomplish the object desired. The mother then decided to bring her son, on the following day, to New York. On examination, with the speculum and reflected light, Dr. Delafield found that a hard and very slippery brown body was firmly impacted between the bony walls of the external auditory canal, in the immediate neighborhood of the drum-membrane. It did not rest against the latter membrane, however, nor against the soft parts immediately above it, for it was ascertained later that quite firm pressure against the bean produced little or no pain. At one or more points the cutaneous lining of the canal was found to be torn, and a bloody secretion bathed all these parts. The boy was then entirely free from pain, and there was no soreness of the parts around the ear. Sulphuric ether was administered, and while the boy was in an unconscious state, repeated efforts were made, both by Dr. Delafield and by myself, to dislodge the bean from its remarkably firm anchorage between the anterior and posterior walls of the canal. These efforts were made entirely with steel hooks, which were passed flatwise between the bean and the wall of the meatus, and then turned through an arc of about ninety degrees, so as to bring the short arm of the rectangular hook directly behind the foreign body, between it and the drum-membrane. No force that we could bring to bear—although applied directly *a tergo* and therefore in the most advantageous manner—was sufficient to dislodge the bean. The boy was allowed to regain consciousness, and the mother was informed that it would be necessary to partially separate the outer ear from the underlying skull, in order to gain more complete access to the foreign body. She was also told that in our efforts at removing the bean we should be very likely to seriously injure the drum-membrane and ossicles, and might even destroy the hearing of that ear entirely. Her consent to the operation was readily obtained, but as it was necessary for her to make preparations for a prolonged stay in the city, the mother begged to have the operation postponed for a few days. In the meantime Dr. Delafield transferred the entire charge of the case to me.

From experiments made with different specimens of the locust bean,[1] which the boy's mother had given to me, I ascertained during the following days a few facts that threw light upon the difficulties of the problem of removing such a foreign body from the ear. In the first place, the outer surface or shell of the bean is essentially as hard as ivory. In attempting to drill through this outer shell I found that unless I held my drilling instrument (a new and very sharp dental drill) exactly at right angles to the surface of the bean, which in turn was held firmly by the fingers of my left hand, it quickly glided off from the point attacked. I repeated this experiment upon the impacted bean, taking, of course, every precaution to prevent the point of the drill from injuring the neighboring soft parts, but soon found that the procedure was not practicable. Soaking the beans in water, at a temperature of about 80° F. for even four days consecutively, failed to soften them in apparently the slightest degree. After boring a minute hole through the outer shell of the bean and then placing it in a glass of water, I found that at the expiration of twenty-four hours the physical characteristics of the bean had undergone a complete change. It had more than doubled in size, the outer shell had become so soft that it could easily be penetrated with a pointed or cutting instrument, and something strongly resembling a bud seemed to be sprouting from that part of the shell in which I had made the opening. I also tested one of the beans with strong nitric acid by placing a small drop of the acid upon the bean and allowing it to remain there until every trace of the fluid had disappeared. I then applied the sharp point of a knife to the spot thus treated, but was unable to discover any evidence of softening.

On August 8th the boy was brought back to the city by his parents. During the interval he had experienced paroxysms of pain in the ear, though not of a severe character, and there had been a constant watery discharge, tinged with blood. Frequent douching of the auditory canal with warm water had been the only treatment. On examination I found that the bean had not changed its position, nor had it undergone the slightest degree of softening. The cutaneous wall of the canal, however, was in such a swollen condition that the bean as a whole could no longer be seen.

On the following day, the patient having been anæsthetized, I proceeded, with the assistance of Dr. William S. Halsted and Dr. Huntington Richards, to perform the operation of separating the auricle from the bony parts constituting the orifice of the osseous meatus auditorius externus. As a first step the hair above and behind the ear was cut away for a short distance from the latter, and then a semicircular incision about three inches in length was made through the skin and underlying soft parts, above and behind the auricle. This incision began at a point situated in front of and a little above the upper and anterior margin of the auricle, and terminated at the tip of the mastoid process. The soft parts constituting this flap were then dissected from the underlying periosteum until the membranous part of the external auditory canal was exposed to view. The point of the knife was then passed, from without, through the membrane, as near as possible to the bony margin of the meatus, and the incision was continued both upward and forward and downward and forward until the calibre of the canal was fully exposed to view. Up to this point in the operation it had been found necessary to place ligatures around six or seven small blood-

[1] These beans are all of about the same shape and size. They are shaped like a hen's egg that has been flattened longitudinally, and they measure 10 mm. in length, 7 mm. in breadth, and 5 mm. in thickness.

vessels, the hemorrhage from which, though not considerable, was sufficient to prevent us from obtaining a distinct view of what we were doing. When the calibre of the auditory canal, however, was exposed to view, the constant welling up of blood from the deeper parts proved very annoying, and some time elapsed before it finally ceased. I was then able to see the bean lying transversely across the long axis of the canal, but its distance from the outer orifice was still so great that in my manipulations with the steel hook I was not conscious that I was operating at a materially greater advantage than when the auricle and cartilaginous meatus occupied their natural positions. After numerous efforts, and when I had almost reached the conclusion that I should fail to dislodge the tightly impacted foreign body, it suddenly yielded to a traction force greater than any I had previously dared to exert.

No attempt was made at this time to ascertain the exact condition of the drum-membrane. The raw surfaces were thoroughly washed with a strong solution of carbolic acid, and interrupted silk sutures were used in bringing the edges of the skin together throughout the upper portion of the wound, while the lower portion was left open for purposes of drainage. The ligatures, which had been applied to the bleeding vessels, had been cut off short, and they were left to take care of themselves. Powdered iodoform was blown liberally over all the raw surfaces, into the external auditory canal, and upon those outside dressings which came in immediate contact with the wound. Over these was then placed a large pad of absorbent cotton, and finally a gauze roller bandage was passed around the head and neck for the purpose of keeping the dressings firmly in position. Dr. Halsted thought that, even with this imperfect form of Lister's dressing, the wound might advantageously be left undisturbed for five or six days.

On the following day I found that the patient had passed a comfortable night, and had enjoyed his breakfast. The act of eating produced a certain amount of pain in the ear, but otherwise he was quite free from pain. Temperature, 100.5° Fahr.

On August 14th the dressings were removed. The motions of the jaw no longer caused pain, the temperature had fallen to 99° Fahr., and the only complaint made by the patient was, that the region about the ear itched intolerably. When the dressings were removed I found that primary union had not taken place at any point along the edges of the wound. There was no redness or swelling, no evidence of anything like a process of granulation, and only a trace of pus was visible at the lower part of the wound and in the external auditory canal. When the stitches were cut, however, it was found that primary union had taken place in the deeper parts throughout an area sufficiently great to keep the flap very nearly in its proper position. To favor union by granulation with the minimum degree of visible scar, I brought the edges of the upper part of the wound in close coaptation, and then applied rubber plaster in such a manner as to crowd the auricle and skin of the cheek upward and backward. The only other dressings employed were sheet lint and vaseline; a roller bandage being used simply for mechanical support.

From this time onward to August 19th I removed the dressings every day, cleansed the parts thoroughly, applied caustic (nitrate of silver) to the granulations in the lower part of the wound, whenever they appeared to be too exuberant and flabby, and then dressed the parts in such a manner as to keep the opposite edges of the wound as near together as possible. The ligatures came away on the 17th and 18th. An examination of the external auditory canal at this time showed it to be in a granulating condition throughout its inner half. There were no polypoid excrescences nor noticeable irregularities of the surface, and the discharge was quite scanty. The drum-membrane presented a smooth but reddened and swollen condition like that of the adjacent membranous part of the canal. None of the distinguishing landmarks were recognizable, nor was there any visible evidence of a perforation or laceration of the drum-membrane. The douche, with a lukewarm solution of boracic acid, had been used regularly since the fourteenth, and no other remedial measures were employed, at least so far as the meatus was concerned. With the left ear firmly closed the patient was easily able to hear ordinary conversation. The ticking of my watch was heard by him at a distance of six inches, and from this circumstance I drew the inference that the middle ear must have been involved only to a very slight degree in the inflammation that had been set up in the neighboring meatus.

On August 19th the patient was taken to his home in Buffalo and placed under the care of Dr. Frank W. Abbott, who has kindly furnished me with the following facts: The external wound healed finally on September 1st. The discharge from the meatus did not cease until about two weeks later. The perforation in the drum-membrane, which the doctor had discovered by observing that in syringing the ear the water found its way into the nasopharynx, healed at about the same time. It was not, however, until October 3d that Dr. Abbott was able to make out distinctly the well-known landmarks, and to locate the spot at which the opening in the membrane had existed; the presence of a small cicatrix in the anterior inferior quadrant showing it to have occupied that locality. It is more than probable that this perforation was the result of violence and not of an ulcerative process. The hearing had not materially improved; it was about the same as it was when the patient left New York. The congestion and swelling of the upper part of the membrana tympani not having entirely disappeared Dr. Abbott thought it was reasonable to expect that, with the subsidence of the slight remaining inflammation, a further improvement in the hearing would take place.

Remarks.—The present case is the first one in which I have known a smooth and symmetrically shaped foreign body to become tightly impacted in the external auditory canal. In fact, it is a rare thing, I believe, for even an irregularly shaped body to become so impacted in the ear that it may not be moved to a certain degree in one direction or another. The only cases in which I have found it necessary to employ an appreciable degree of force, in order to extract the foreign body from the ear, have been those in which I found the body in question (an irregularly shaped pebble) lodged in the tympanic cavity, into which it had been forced by previous unskilful attempts to remove it from the ear. Two such cases have come under my observation, but in both of them the force which I was obliged to employ was slight in comparison with that required in the present instance. Moreover, I am confident that a part of even that small force was rendered necessary only by reason of my inability

to apply it in the most advantageous manner, and not because the body was so tightly wedged in between immovable surfaces as to require this degree of force to dislodge it. In the present instance, however, the force was applied in the most advantageous manner, and yet the foreign body remained absolutely immovable until the amount of the force exerted was really considerable.

It must be admitted, it appears to me, that no ordinary force, such as that which a boy would use in pushing a locust bean into his companion's ear, would be adequate to lodge it in the peculiar position in which it was found when the ear was examined here in New York. In the absence, therefore, of other evidence, it is difficult to resist the belief that the physician who first saw the boy, must have changed the position of the bean by his instrumental manipulations, from one in which an expert might easily have extracted it to one in which repeated efforts, greatly imperilling the hearing of that ear, almost failed to accomplish the object desired. It is also a fair inference to draw from this case that it is decidedly better for the general practitioner, when called upon to remove a foreign body from the ear, to restrict his efforts to the employment of the syringe with tepid water. If such a simple and, as a rule, safe procedure fails to dislodge the body, he should not allow himself to yield to the importunities of the parents, or to his own desire to accomplish what is sure to present itself to his mind as a comparatively easy task. We should abstain from all further interference, and should advise the parents to wait until they can take their child to a physician who is familiar with the instrumental manipulations necessary in removing a foreign body from the ear. The cases are, I am confident, rare in which such a foreign body may not safely be allowed to remain undisturbed in the meatus for days, if not for weeks. Indeed, under favorable circumstances, a foreign body may remain harmlessly in the auditory canal for an indefinite period. As a general proposition, however, we may say that it should not be allowed to remain in the ear for a longer period than is absolutely necessary under the circumstances; for its presence may render an intercurrent acute inflammation of the middle-ear or of the external meatus—and at any season of the year such an inflammation may develop—a very painful and perhaps even a serious disease. It is better, therefore, to have the foreign body removed at an early day.

A word or two with regard to the employment of hooks in the deeper parts of the ear. If the foreign body is small, a slender silver hook, such as can be extemporized in an instant by bending the rounded tip of a delicate probe, will be found to serve the required purpose admirably. If the auditory canal is adequately illuminated, we can dislodge the foreign body more easily with such an instrument than with any other contrivance known to me. On the other hand, if the body occupies a large part of the calibre of the canal, a hook, in one form or another, is *almost indispensable* for its removal. The accompanying cut gives a good representation of the kind of hook which I have been in the habit of using during the past twelve years. It is made of malleable steel, and measures just five inches in length. However tightly a foreign body may seem to fit the auditory canal, it will always be found possible to push this hook onward between the skin and the foreign body, until the short arm of the instrument occupies a position in which we can rotate it through the desired arc of a circle, and thus bring it in contact with the farther or distal surface of the body. When the hook has once reached this position, we have it in our power to exert traction upon the foreign body, and thenceforward we are masters of the situation. Sometimes the hook slips, and we are then obliged to readjust it. At such times we may scratch or even lacerate the skin of the meatus.

In order to produce the least amount of damage, in manipulations of this kind, we must carefully observe the following precautions: At every step we must know in exactly what direction the short arm of the hook is pointing; and, if the foreign body lies in close proximity to the drum-membrane, we must also constantly keep before the mind an accurate picture of the anatomical relations of these parts. Unless the operator is confident of his ability to do both of these things, he should scarcely permit himself to attempt the removal of a large foreign body from the ear with a steel hook. In the hands of an unskilled person it is certainly as dangerous an instrument as it is useful in those of an expert.

We come finally to the consideration of the operation of displacing the auricle forward. Dr. J. Orne Green, of Boston, Mass., thus briefly summarizes the important facts relating to the history of this operation.[1]

"The operation of displacement of the auricle forward for the removal of foreign bodies is by no means new in theory. The whole subject is thoroughly discussed by Von Troeltsch in the seventh edition of his 'Lehrbuch' (1881). The suggestion of the operation is found in 'Paulus Æginetа' (660), and in recent times has been recommended by Hyrtl. Von Troeltsch approves of it where operative interference is imperative and other methods of removal are impossible, but suggests that in children the auricle and cartilaginous meatus be separated from the osseous meatus by a simple incision above the meatus along the squamous bone, and in adults, that the osseous meatus be reached by an incision along the lower wall of the cartilaginous canal. Neither of these methods seems to me adapted for giving a thoroughly free and large opening for the extraction of expanded bodies like those in this case [one of leaden bullets in the ear], and both seem open to the objection of insufficient drainage after the operation, if such becomes necessary, while the latter method must almost certainly wound the parotid gland and add another element of risk. Von Troeltsch narrates four cases where displacement of the auricle forward was performed, one by Langenbeck and three by Schwartze. All were successful and recovered; one healed *per primam intentionem* and the others by granulation."

On this side of the Atlantic the operation has hitherto been performed only twice, at least for the purpose of facilitating the removal of a foreign body from the deeper parts of the ear, viz., by Dr. J. Orne Green and by Dr. D. B. St. John Roosa.[2] In both instances the foreign body removed from the ear was a leaden bullet.

In the case which I have just narrated I was led

[1] Transactions of the American Otological Society, vol. ii., part 5, 1881.

[2] Dr. Roosa's operation is mentioned on page 477 of the Transactions referred to in the previous foot-note.

to perform the operation of displacing the auricle forward by the belief that I should thereby gain much more space in which to manipulate hooks or forceps, and that consequently I should be able to bring a greater dislodging force to bear upon the foreign body. I must frankly confess that in this particular case the gain in space did not materially diminish the difficulty of extracting the bean. The location, size, shape, and polished, ivory-like surface of the foreign body rendered the employment of forceps of any size or pattern useless; and yet the gain in space and shortness of the canal proves of greatest value in precisely those cases in which such a type of instrument is used.

In this connection I desire to call attention to the great amount of damage that may be done with impunity to the osseous portion of the external auditory canal. In the present case, for example, I may, without fear of exaggerating the truth, say that posteriorly and superiorly there was, probably, not one spot left, along the osseous part of the meatus, from which the periosteum (*i.e.*, the skin) had not been violently torn away; and yet, after the lapse of four or five weeks, all these parts were found to have resumed their natural relations and appearance. I have observed this same regenerative power of the periosteal lining of the auditory canal in other cases, and believe that we may safely trust it to repair any injuries that we may be compelled to inflict upon this part of the ear in our operative procedures.

THE EFFECTS OF RAILROAD TRAVELLING.—The effects of continuous travelling are sometimes injurious. The exact injuries and dangers, however, have not been fully studied. Many business men in this city travel from fifty to one hundred miles a day in going to and from the city, yet generally with no apparent harm. The effects would be likely to be different in conductors, porters, and engineers, who are often on the cars during one hundred, two hundred or more miles. A correspondent of the *British Medical Journal*, Dr. E. A. Cook, relates the history of a Pullman car attendant which is instructive: The patient had been four years in his situation, and had not been a single journey off work. He travelled every alternate night from London to Glasgow, and the next from Glasgow to London, sleeping during the day, when in Glasgow in the car, and when in London at his home. When at home, his sleep was broken and restless, owing, he explained to the absence of noise to which he was accustomed.

When first seen, he looked haggard, careworn, and bleached, but appeared well nourished. There was absolutely nothing the matter with him bodily, except a little indigestion; but he stated that he constantly had illusions that people were behind him, and that there would be an accident; he felt his life a burden, and was sure it was all owing to "the running." The latter idea so beset him, that he had no faith in being able to get well without a rest. He was in the habit of drinking a little beer, and smoked occasionally. The treatment was to stop all stimulants and smoking, to diminish animal food gently, and give drachm-doses of compound syrup of phosphates twice in the twenty-four hours. He got well within a month, and, a year afterward, he had had no return of the symptoms. He said that other carmen had suffered as he had done, and had broken down under it, after taking stimulants for relief.

AN ACCOUNT OF AN EPIDEMIC OF ACUTE DYSENTERY IN PATIENTS CONVALESCING FROM TYPHOID FEVER.

By HENRY LING TAYLOR, M.D.,

LATE HOUSE PHYSICIAN, ROOSEVELT HOSPITAL, N. Y.

ON September 1, 1882, there were in the service of Dr. Francis Delafield eight cases of typhoid fever in Ward 2, the principal male medical ward of Roosevelt Hospital. One of them (VIII.) died on September 6th, having been one week in the hospital; the others all progressed satisfactorily to complete convalescence. Of the latter seven, at least six were attacked with acute dysentery between September 21st and October 1st, while in full convalescence, three in the hospital and three soon after their discharge. Two of these were readmitted for the dysentery.

One of the cases of dysentery (I.) was fatal. The remaining case of the seven (VI.) is said to have had some intestinal trouble after leaving the hospital, but it is uncertain whether this was dysentery or diarrhœa.

This epidemic was confined to patients who had just had typhoid fever, and I do not remember that a single case of dysentery, aside from those I have just mentioned, has ever arisen in the hospital during the eighteen months over which my observation has extended.

There were several cases of typhoid fever in females in another ward at the time of this outbreak. None of these had dysentery.

The same water (Croton) and milk were supplied to all the patients, and many besides typhoid-fever patients were kept on an exclusive milk diet.

No more than the usual number of cases of dysentery was treated in the hospital during August and September last—about ten cases in all. The only fatal case was a man who died in Ward 2, on September 20th, having been ten days in the ward. The autopsy showed a very severe croupous inflammation involving the lower two-thirds of the large intestine, and, to a less degree, a foot of the lower end of the ileum. No ulcers. All of the cases of dysentery in typhoid-fever convalescents began soon after the death of this patient.

It is an interesting fact, though not an unusual one in the disease as seen in New York City, that of the eight above-mentioned cases of typhoid fever, four were constipated or had sluggish bowels throughout the whole course of the fever, and at no time had any diarrhœa; one (VI.) was constipated while in the hospital, but gave a history of diarrhœa for three weeks before admission; in three cases only (I., II., VIII.) was diarrhœa a prominent symptom during the fever. In Case I. the bowels were constipated for a week soon after the fever ceased. In nearly all the cases constipation preceded the dysenteric attack.

These cases had all been treated during the fever by the cold-water method rigorously applied, and were put on an exclusive milk diet. When the bowels were inclined to be loose, bismuth and pepsine, ää gr. x., were given t. i. d., or oftener, and when the opposite condition prevailed, warm enemata containing ox-gall or castor-oil, and in the later stages, one to three pills of aloes and myrrh were frequently resorted to. When the pulse weakened whiskey was exhibited p. r. n., and other indications were met as occasion demanded.

The symptoms and course of the cases of dysen

tery did not differ from those of acute attacks as ordinarily observed. The invasion was marked by pain in the bowels and by a febrile movement (100° to 103°), which latter usually subsided after a few days. To these symptoms were soon added frequent small, painful stools containing blood and mucus.

In Case I. (a colored man), the dysentery continued until the passages finally became involuntary and very frequent. The man became very much emaciated, and finally died of exhaustion, October 1st.

At the *autopsy*, October 2d, Prof. Delafield found the following conditions: *Left lung:* In lower part of upper lobe, cavity size of pigeon's egg, and close to this, lung studded with small areas of cheesy hepatization; in pulmonary pleura are a few miliary tubercles. *Right lung* normal, except for a few miliary tubercles in upper lobe. *Bronchial glands* enlarged and suppurating. *Large intestine:* Pretty general thickening of mucous membrane, with an exudation of fibrin over lower two-thirds. No ulcers. *Small intestines* normal, save for slight smooth, even excavations at Peyer's patches; cicatrized typhoid ulcers. *Mesenteric glands* enlarged; no peritonitis.

There were no signs of phthisis when patient entered the hospital, and Prof. Delafield remarked at the autopsy that in the negro, as in some of the lower animals, any prolonged and exhausting sickness was apt to end in tuberculosis.

It will be observed that the lesion of the large intestine in this case was almost the counterpart of that in the man who died September 20th in Ward 2.

Case I. was treated with dilute hydrochloric acid, castor-oil, and laudanum, starch and laudanum injections, etc.; the others, who all recovered, were put on the following treatment: The bowels were first freely opened with ol. ricini, ℥ j., tr. opii, gtt. xx.–xxx. The patient was then put on the ipecac treatment, with the usual precautions in regard to abstaining from food and drink for a couple of hours before and after the dose. The ipecac was given in two or three gelatine capsules of ten grains each, preceded by a hypodermic of Magendie, five to six minims, half an hour before. In two cases (IV. and VII.) the ipecac was not well borne, and was discontinued after a few days' trial. In Case VII. hypodermics of morphia were given p. r. n. to relieve pain.

After the more active symptoms had subsided it was generally found advantageous to put the patient on a castor-oil mixture, similar to the one recommended by West:

℞. Tr. opii deodorat ..... ℥ j., ℥ xx.
Ol. ricini ..... ℥ j.
Mucilag ..... q. s.
Aq. cinnamoni ..... ad. ℥ iv.
M. Sig.—℥ ss. t.i.d., or oftener.

Since the above observations were made there have been many cases of typhoid fever in the hospital, but no more cases of dysentery have developed.

Many authors have described both catarrhal and croupous inflammations of the mucous membrane of the large intestine as being found in a certain proportion of the autopsies on typhoid-fever subjects, and this has been repeatedly verified at the Roosevelt Hospital dead-house. Murchison, in his treatise on "Continued Fevers" (p. 563), London, 1873, says he has "known the symptoms and lesions of dysentery to coexist with those of enteric fever" and mentions others who have made similar observations. Liebermeister, in "Ziemssen's Cyclopædia" (Wood's edition), speaks (vol. i., p. 155) of "diphtheria of the intestinal mucous membrane" being "an occasional sequel to severe cases of typhoid fever, as it is also to severe forms of other diseases."

All these observations evidently refer to something quite different from the cases of dysentery which occurred at the Roosevelt Hospital, as the fever could not be called severe in any but Case I., and the dysentery began after convalescence had been thoroughly established. I have seen no mention in medical literature of any similar epidemic.

Case.	Age.	Date of admission to Roosevelt Hospital.	Previous duration of symptoms.	Fever ceased.	State of bowels.	Dysentery began.	Dysentery ceased.	Patient discharged cured.	Treatment of dysentery.	Duration of fever.	Duration of dysentery.	Remarks.
I.	21	July 20, 1882.	21 days.	Aug. 15, 1882.	Occasional diarrhœa. Constipated last week in August.	Sept. 21, 1882.	Died Oct. 1.	Died Oct. 1.	Dilute hydrochloric acid. Castor-oil. Enemata.	46 days.	10 days.	For autopsy see above. Dysentery followed dietary indiscretion.
II.	27	Aug. 14.	18 days.	Sept. 11.	Diarrhœa.	About Sept. 25.	About Oct. 5.	Sept. 18.	Unknown.	45 days.	About 10 days.	Patient reported his dysentery but did not re-enter hospital.
III.	22	Aug. 14.	14 days.	Aug. 24.	Constipated most of time. No diarrhœa.	Sept. 30.	Oct. 4.	Sept. 24, Oct. 13.	Castor-oil and ipecac.	24 days.	4 days.	Patient readmitted for dysentery October 24.
IV.	25	Aug. 20.	7 days.	Sept. 9.	Constipated.	Sept. 28.	About Oct. 18.	Oct. 22.	Castor-oil and ipecac.	27 days.	20 days.	Ipecac vomited.
V.	22	Aug. 22.	10 days.	Sept. 7.	Constipated.	Sept. 26.	Oct. 15.	Oct. 19.	Castor-oil and ipecac.	26 days.	19 days.	
VI.	19	Aug. 23.	About 6 to 7 weeks.	Sept. 14.	Constipated while in hospital, before diarrhœa.	.....	.....	Sept. 24.	.....	.....	.....	Reported to have had some diarrhœa after discharge from hospital, which disappeared on taking a cathartic.
VII.	16	Aug. 28.	About 21 days.	Sept. 12.	Constipated.	Oct. 1.	Oct. 16.	Sept. 30, Oct. 31.	Castor-oil, ipecac, and morphia.	36 days.	15 days.	Readmitted for dysentery October 6. Ipecac vomited.
VIII.	30	Aug. 29.	21 days.	Died Sept. 6.	Diarrhœa.	.....	.....	Died Sept. 6.	.....	29 days.	.....	Autopsy showed but one large deep ulcer in lower end of ileum; it had begun to cicatrize.

For convenience of comparison I append the above tabular account of the eight cases of typhoid fever in Ward 2 on September 1, 1882, premising that a few of the dates are only approximate. The periods under the heading "Duration of Fever" are reckoned from the beginning of symptoms to the time after which the temperature never reached 100° F.

THE patient can oftener do without the doctor than the doctor without the patient.

THE PERCENTAGE OF COLLEGE-BRED MEN IN THE MEDICAL PROFESSION.[1]

By CHARLES McINTYRE, A.M., M.D.,

EASTON, PA.

To the American Academy of Medicine:

From conversations at our last meeting and from journal comments upon that meeting, certain questions were suggested, and as possibly the same questions have occurred to others, this paper endeavors to collect some material to aid in a solution.

What relation has the Academy to the profession? What relation does the profession sustain to the Academy? In what does the mission of the Academy really consist? Otherwise, why an Academy? And, how can this mission best be accomplished? Comprehensive questions, and questions of importance to us.

It is essential to their solution that we first of all obtain a clear idea of the exact condition of the medical profession as at present constituted, although I fear that any suggestion of ignorance upon this subject, in the sessions of the Academy, may be deemed presumptuous.

I have endeavored to obtain data for the classification of physicians upon an educational basis by several

METHODS OF EXAMINATION.

I.—I endeavored to collect statistics from the district societies of New Jersey and some of the county societies of Pennsylvania, which would show the number of A.B.s, the number of men who were for a while in a college of arts but did not finish the course, and the number who had no collegiate training at all. I have not received as many returns as I would like, but the results are as follows: Where out of 222 practitioners of medicine, as found on the rolls of county societies, 28 have the degree of A. B., 16 pursued part of a college course, and the remaining 178 have had no college training.

II.—In the "triennial catalogues" of colleges granting degrees in arts, the occupation of their alumni are frequently recorded. In some only those in the sacred ministry are indicated. In these the degree of M.D. can be fairly taken to include all in the practice of medicine. The same cannot be said of LL.B. and the members of the bar, although in some cases these are given under the column of "*law.*" In the older colleges the count begins with the Class of 1826, which will fairly represent the present medical generation. These results give us some interesting comparisons:[2] 58 colleges, with 38,054 alumni graduating with but one exception (where the counting began with 1822) since 1825, give the following relations between the professions: medicine, 9.2 per cent.; theology, 21 per cent., and law, 19.7 per cent. In all cases only the *alumni* are counted, the *alumnæ*, for fairness sake, being omitted, and, wherever possible, the B.A. degree only taken into consideration.

The following table, while not directly belonging to the subject under consideration, may be of some interest from an historical standpoint. It gives the number of alumni and the number of physicians in the periods indicated at the top of the columns prior to the year 1826. It may be well to say that the age of the Massachusetts Medical Society gave Harvard an opportunity to record quite a number as members of that society who had not received a degree in medicine. It is fair to infer that in other States the condition was the same, and that the number of physicians given in the table does not represent all the alumni who practised physic.

College and the Year of the First Class.	1642 to 1700.			1701 to 1750.			1751 to 1800.			1801 to 1825.			Remarks.
	No. of Alumni.	No. of Physi-cians.	Per cent.	No. of Alumni.	No. of Physi-cians.	Per cent.	No. of Alumni.	No. of Physi-cians.	Per cent.	No. of Alumni.	No. of Physi-cians.	Per cent.	
Harvard, 1642	449	9	2.0	1,187	9	0.7	1,871	131	7.0	1,383	171	12.3	
Yale, 1702	...	...	...	630	4	0.6	1,670	23	1.3	1,504	97	6.4	
New Jersey, 1748	...	...	...	...	...	...	924[1]	39	4.2	878	103	11.7	[1] Includes 1748–50.
Pennsylvania (University), 1757	...	...	...	...	...	...	370	16	4.3	283	37	13.1	
Williams, 1790	...	...	...	...	...	...	94	11	11.7	515	36	7.0	
Union, 1797	...	...	...	...	...	...	...	...	...	985[2]	88	9.0	[2] Includes 1797–1800.
North Carolina, 1798	...	...	...	...	...	...	...	...	...	372[3]	56	15.1	[3] Includes 1798–1800.
Jefferson, 1802	...	...	...	...	...	...	...	...	...	200	25	12.0	
Vermont, 1804	...	...	...	...	...	...	...	...	...	142	9	6.3	
Bowdoin, 1806	...	...	...	...	...	...	...	...	...	264	48	18.1	
Washington, 1806	...	...	...	...	...	...	...	...	...	119	21	17.6	
	449	9	2.0	1,817	13	0.7	4,929	220	4.5	6,654	691	10.4	

In this table is seen a progressive increase in the proportion of the alumni studying medicine. The per centum of the first quarter of the present century, 10.4, is, however, greater than the middle quarter, as shown in the previous estimate.

III.—Some of the catalogues give, also, lists of those who did not graduate, with indications of their professional life, and in Pennsylvania (College) and Lafayette I have had opportunity to examine their college book, giving biographical sketches of all their students. From these sources, in every possible case, excluding those who graduated elsewhere, I have endeavored to represent as nearly as possible those who entered upon their professional studies after a part of a course in a college of arts. Here, again, comparisons show the least number of

[1] A paper read before the American Academy of Medicine.

[2] Since making the same, our President has called my attention to the Report of the Committee on Medical Education in the Proceedings of the American Medical Association for 1851, page 421, where a similar examination was made of the catalogues of Harvard, Yale, Dartmouth, Brown, New Jersey, Union, Amherst, and Hamilton, in all 12,400 alumni and 7.5 per centum of physicians.

medical men, the figures being 280 medicine, 282 theology, and 353 law.

IV.—In some of the medical, theological, and law schools, the academical degrees are given in the lists of their alumni; from such data I have tabulated the following, which makes a very interesting study. As a supplement to this, I have added the record of the graduates of the Harvard medical department in three periods corresponding to those already mentioned.

No.	College.	Medicine. Classes.	Medicine. Per cent. of A.B.	Theology. Classes.	Theology. Per cent. of A.B.	Law. Classes.	Law. Per cent. of A.B.	Remarks.
1	Harvard	1825-79	35.3	1817-79	74.0	1820-79	56.3	
2	Yale	1825-80	23.6	1867-80	80.8	1843-80	32.0	
3	Bowdoin	1825-80	9.2	.....	.....	.....	.....	
4	Tufts	.....	.....	1871-80	36.7	.....	.....	
5	Vermont	1824-81	3.2	.....	.....	.....	.....	
6	Michigan	1851-71	4.1	.....	.....	1860-71	5.5	
7	Willamette	1867-81	1.8	.....	.....	.....	.....	
8	Princeton	.....	.....	1826-72	82.7	.....	.....	Matriculates.

HARVARD (MEDICAL DEPARTMENT).

Classes.	Alumni.	Per Cent. of A.B.
1788 to 1800	26	69.2
1801 to 1825	207	56.1
1826 to 1879	2,148	35.8

V.—The reports from the various professional schools to the Commissioner of Education return an estimate of the number of students who have a degree in arts or science. These results are thus collated:

Professional Schools.	Report for 1879. Number Reported.	Report for 1879. Per ct. of those who have a degree in Arts or Science.	Report for 1880. Number Reported.	Report for 1880. Per ct. of those who have a degree in Arts or Science.
Medicine	9,522	8.2	9,876	7.9
Theology	4,362	30.6	5,093	26.4
Law	3,018	25.2	3,134	24.1

In the New York MEDICAL RECORD for September 30, 1882, Professor Tyson, of the University of Pennsylvania, criticises the fairness of some percentages used in an editorial article of THE RECORD, February 11, 1882, founded upon the Report for 1879, because some of the medical schools fail to make a report of students possessing degrees, and they are counted as if none of them had obtained a degree in letters or science. This objection was present to my mind when I prepared the above table, but as my results were to be comparative, I assumed that the proportion of failures to report would be about the same in the three professions, and the ratio would be practically unaffected, so I used the summary as given by the Commissioner of Education. Since reading Professor Tyson's letter, however, I have thought that an analysis of the reports themselves might be of use, and prevent any charge of unfairness as to any of the results obtained. This analysis I put in the following form, which I hope will explain itself:

	Report of 1879. Medicine.	Theology.	Law.	Report of 1880. Medicine.	Theology.	Law.
Whole number of schools reported	68	133	49	72	142	48
Number reporting *no students* at all	2	10	6	5	9	4
Actual number on which to base statistics	66	123	43	67	133	44
Number making no report of degrees in arts and science	39	58	19	37	68	18
Percentage of whole	59.1	43.1	44.2	55.2	51.1	41.0
Number of students reported by these schools	5,614	2,092	1,218	5,279	2,537	768
Percentage of whole	60.9	48.0	40.3	53.6	49.9	34.5
Percentage of students in the schools reporting degrees in arts and science, who have such degrees	20.0	49.0	43.0	16.9	52.6	52.0
Percentage given above	8.2	30.6	25.2	7.9	26.4	24.1
Ratio given above	1.0	3.3	3.0	1.0	3.5	3.0
Ratio in this table	1.0	3.0	2.15	1.0	3.1	1.9

Professor Tyson concludes by saying: "There is no doubt but that most important results will accrue in the course of time from the accumulation of such statistics as Mr. Eaton is annually collating, while it is certain, also, that their value will be much less, if institutions are not willing to take the trouble to make the returns, now rendered so easy by the blanks annually distributed by the Bureau of Education at Washington." Is it significant that the officers of the medical schools seem least willing to make such returns?

But the preceding table does not represent the true state of affairs. In the theological and law schools everything that reports is included; in the medical schools a selection was made.

In the Report for 1879, five homœopathic schools report 760 students, of whom 80 have degrees; and three eclectic schools, 220 students with 27 degrees. In like manner in the Report for 1880, there are seven homœopathic schools with 950 students and 83 degrees; and five eclectic with 518 students and 94 degrees. By combining these with the results in the last table the percentage of medical students possessing degrees in arts or science in the schools reporting such degrees is reduced in 1879 to 18.2, and in 1880 to 15.7, while the ratio becomes 1 : 3.2 : 2.3 and 1 : 3.3 : 2.0, respectively.

Look at these tables, ponder over the results as you will! Can you escape the conclusion that classing the *medical business* among the learned *professions* is altogether a mistake? But to the facts and the testimony. Can not the following propositions be fairly sustained by the above statistics?

1. Only a small percentage of the eighty-three thousand[1] practitioners of medicine are eligible for membership to the Academy.

2. Only a small proportion of the graduates in arts study medicine.

3. Another small proportion pursue part of a course, and then enter upon the study of medicine without being a candidate for the degree of A.B.

[1] This estimate of the number of physicians in the country was obtained as follows: Through the kindness of the Superintendent of the Census, I obtained the number of physicians and surgeons as far as counted, for the Census of 1880 (September 25th). This was compared with the population of the same territory for 1880, and the ratio determined (1 : 588). The Census Reports for 1870 were then consulted, and the ratio determined (*a*) for the territory corresponding to my data for 1880, (1 : 601), and (*b*) for the rest of the country (1 : 630). Assuming that the proportion of increase was the same in the two sections, the ratio of physician to population in the unknown section for 1880 would be 1 : 616. From this the number of physicians was estimated in this section, and added to the counted number makes the above estimate.

4. That a greater percentage of college men enter upon the study of theology and law than medicine.

We are now in a position to ask ourselves again the questions stated above. What relation has the Academy to the profession? We, at least, will claim that our standard represents more correctly the proper sort of training that should be given to medical men. Consequently any requirement falling short of that does not, in the highest sense, properly prepare for the practice of medicine. We are, then, as an organization, trying to show the proper plan of education for medical men, and in so doing to lift the profession to a higher level than it now occupies. In other words, we are a missionary society, and the truth we proclaim is preliminary education.

But how does the profession regard the Academy? We can divide it into two grand divisions: those who *are* and those who *are not* eligible for membership. And another division line separates them each into two subdivisions: those who sympathize with a movement for educational reform and those who do not so sympathize. The first division and the first subdivision in each division, seem to me to have the smaller numbers. For there are in the profession (*a*) those who from pecuniary interest are opposed to decreasing the number of medical students, and a collegiate education would certainly do this. It does not require a very deep study of the history of medical education to show that one of the chief obstacles to the attainment of a better preliminary training lies in the faculties of the medical colleges themselves. From these an influence is exerted over the larger number who make up the lecturers, demonstrators, clinical assistants, etc., as well as their united personal influence upon the profession at large. (*b*) Another class think the society chimerical or quixotic and incapable of aiding at all in the reform which they believe ought to be instituted. (*c*) Others are simply indifferent. With these elements in the profession, one is forced to the conclusion, notwithstanding many need only the objects of the Academy to be brought to their notice to enter heartily into its fellowship, that among the present generation of physicians we cannot attain a large relative membership.

The third question, as to the actual mission of the Academy, must be discussed aside from the constitutional assertions. Is it exceptional to other societies, in that it requires special qualifications, or does it resemble those societies, *e.g.* the ophthalmological or neurological, which require other qualifications than simply being in good standing in the profession? This is not simply a distinction, as might at first sight appear, for if it belongs to the latter class its papers and discussions should be restricted to its specialty, *i.e.* medical education, Leaving this point undecided, the NEED of a thorough preparation for medical men is certainly the cause for the Academy's existence. And the methods which will best cause this *need* to be *felt*, are the methods which should claim the attention of the Academy. If every practitioner in the country—or even a large majority—possessed the qualifications for fellowship, there would have been no reason for organizing the Academy. Because the facts are just contrariwise, there is a very good reason for such an organization.

The mission of the Academy, then, really lies in this: *To convince the public that a preliminary training of the mind is absolutely necessary for the greatest efficiency of medical men.* Nothing short of convincing the public will bring about the desired reform, for so long as the people will employ men without this training, so long will men offer themselves for employment, and others be found to instruct them in their professional studies. It is only a question of political economy: the demand will determine the supply.

Any object that falls short of this fails to give a sufficient reason for the exclusiveness of the Academy. If it be simply to gather together as many as possible of those who have the qualifications in an annual meeting, to indulge in jeremiads over the degeneracy of the profession, we become a pharisaical mutual admiration society, binding our academical degrees as a phalactery over our eyes, and enlarging the borders of our garments to exhibit our blue-ribboned parchments. With such an object we become the radical party of the profession, delving down to the root of the evil, knowing that true reform can only come from a correct principle of action, and that all compromises are but temporary makeshifts. It is true that with radicalism there is odium to bear, and there are calumnies and misrepresentations, especially from those who see the need of reform, yet are not desirous of rudely breaking the repose of the present order of things. "Let the 'struggle for life' go on," say they, "and the 'fittest' survive," and by and by, after myriads of ages, there will be evolved the physician as he should be.

Such I believe to be the mission of the Academy. There remains only to discuss the methods to best accomplish this mission. Just here it may be well to digress a little and ask, What is the character of the society we desire the Academy to be? Shall it be popular, embracing every one who may possess the educational requirements? Or shall it be exclusive—a society which any medical man would regard a great honor to be admitted into membership; a French academy among American physicians, which insists upon preliminary education as an essential qualification, and thus would speak with no uncertain sound to those about to enter the profession, that the highest honor can only be obtained by beginning at the beginning? This idea has been suggested, but it appears to me not to have been the policy of the Academy thus far.

Assuming, then, that the desire of the Academy is to increase her borders, how can it best fulfil its mission? Its work is one of education, of enlightening the people upon a subject of vital importance. The greater numbers of light-bearers will, other things being equal, cause a more rapid enlightenment. Hence an increase of membership is very desirable. But almost the only place left for recruits are the M.D.s in prospect. These, we have seen, consist of three classes: those who have taken a complete college course, part of a course, or none at all. These latter frequently enter upon the study of medicine without a word of warning. Now and then their selected preceptor gives them sound advice and insists upon a proper preparation; but there is a deplorable ignorance and almost a criminal negligence upon the subject.

I am aware that frequently, men who look upon the practice of medicine as a mere trade, will, if refused by one, seek another preceptor or college; and this has been given as an excuse for taking students who have not had the proper preparation. I am also aware that diplomas have been purchased without the formality of a preceptor, attendance upon lectures, or examinations, and the same rea-

soning would compel us to recognize such men as true physicians. Notwithstanding this, I doubt not if the matter were candidly presented to those having the practice of medicine in view as a *profession*, a great many could be influenced to make a proper preliminary preparation.[1]

But how can these things be accomplished? There is a necessity of increasing the zeal of the Fellows themselves. Apparently some men have joined simply because they have no objection in the abstract to the objects of the Academy, and have been invited to join. These people need waking up, and in proportion to their activity we would have brighter centres of light, and a greater influence exerted.

How to arouse them is a more difficult problem. Some means by which there would be a greater attraction to the meetings would probably aid in this direction. That valuable papers are possible need not be doubted after an examination of the *Index Medicus* for the contribution of the Fellows to medical literature. If there could be such attractions, then, in addition to the faithful few, others would be drawn into the meetings, and—enthusiasm is contagious.

In addition to the personal influence of the Fellows, endeavors should be made to a more extended distribution of facts regarding the real requirements of the physician, and the necessity of men completing their preliminary education before entering upon their professional studies, and here I think the columns of the various college journals would be available. But all these are mere helps reaching only the profession and those within the personal influence of the profession; the people must also be led up into a higher plane. Nothing affords greater aid to the proper treatment of a case than a correct diagnosis. We should, by all the means in our power, find out by actual count, and not by mere estimate, the proportion of men whose training has been deficient. The presentation of these figures—and the press of the country would gladly receive them—would set men to thinking. The facts having been presented, the way is paved for additional information. The addresses of our Presidents, papers carefully prepared by the Fellows for the purpose, could be published in other than medical journals, and thus foster and direct public opinion, until the demand for preliminary education and thorough professional training, instead of being the cry of the few, would be *vox populi*.

PILOCARPINE IN POLYURIA.—A patient suffering from polyuria azoturica used belladonna, bromide of potassium, laudanum, injection of morphine, and electricity without effect. Hypodermic injections of nitrate of pilocarpine, 0.20 in water 20.0, diminished the daily secreted urine from ten litres to two litres, and the quantity of urea was reduced from nine grammes to three grammes. The weight of the body increased to eight kilogrammes in two months' time. In polyuria glycosurica the sugar disappeared after a short time. Fifteen injections will generally cure these diseases.—*H. Morgagni Giornale.*

---

[1] And does not the table given in an editorial article in the Boston Medical and Surgical Journal for October 13th, concerning Harvard, demonstrate this? The per centum of college-bred men (B. A., S. B., or their equivalent) for 1877–78, was 42.94; 1878–79, 41.85; 1879–80, 47.15; 1880–81, 48.37; 1881–82, 50.65; while the same increase is not shown in the Law and Divinity Schools.

ARE THE FOLLOWING MEDICINES INCOMPATIBLE?

POTASS. BROMID. AND QUININE SULPH., OR THE ABOVE WITH SULPH. MORPHIA? OR THE WHOLE OF THE ABOVE WITH CHLORAL HYD.? OR THE WHOLE OF THE ABOVE WITH SULPH. STRYCH.? AND IF SO, WHAT EFFECTS DO THEY PRODUCE THERAPEUTICALLY?

BY E. B. TURNIPSEED, M.D.,

COLUMBIA, S. C.

I HAVE for three years or more used bromide of potassium combined with sulph. quinia alone or with either one or all of the other medicines named above, with splendid results in many diseases. When I commenced using the first combination, that of quinine and potass. bromid. in combination, my druggist wrote to the editor of the *Druggists' Circular*, and he pronounced these medicines incompatible. This, if true, would have either given bromide of quinine or proven inert; if the former, in the doses I give it certainly would have been poisonous, whereas we really have the most happy effects of both; this I can testify to in doubtless thousands of cases.

It was some time before I found the proper vehicle for this most excellent formula: it is glycerine. First I have the potass. bromide thoroughly pulverized, then add the sulph. quin.; triturate well, then add glycerine q. s. very gradually, stirring the whole rapidly with pestle; then, by the same means, whatever tinctures are adapted to the case prescribed for, and they should fill out as near as possible the rest of the mixture, as very little water will precipitate either one or both ingredients, especially the quinine. The following are some of my formulas:

℞.	Potass. bromid.....	ʒ ijss.
	Quin. sulph.....	ʒ ss.
	Morph. sulph.....	gr. ss.
	Tinct. hyoscyami.....	gtt. lxxx.
	Tinct. zingib.,	
	Tinct. calamus.....āā	ʒ ss.
	Syr. pruni virg.....	ʒ ij.
	Ess. frag. virg.....	ʒ ss.
	Glycerine.....	q. s.
	Aqua.....q. s. ad.	ʒ ij.

M. Sig.—Shake well and give one teaspoonful in water every two or three hours when awake.

This is given in headache, neuralgia, malarial fever, sleeplessness, hysteria, and in typhoid fever at beginning, when there is much headache, pain in the neck, etc., combined with two or three drops of spt. terebinth. to the dose, the latter being always added first to the glycerine. Any of the tinctures commonly prescribed by the profession can be combined. As we often need tonics in protracted diseases they can be combined in the form of tinctures, such as gentian, cinchona, or veg. cathartic bitters in periodic fevers. Strychnia in such cases is an excellent adjuvant, being careful always to add it already well dissolved. Chloral hydrate in combination with the base of the formula answers well in allaying almost any nervous trouble, provided the pulse is over normal in rapidity; without this, except in small doses, there might be paralysis of heart. This medicine I never use in larger doses than two or three grains. The following is my formula:

℞. Potass. bromid..... ʒ ijss.
Quin. sulph..... ʒ ss.
Morph. sulph.,
Strychnia sulph.....aa gr. ss.
Chloral hyd..... ʒ ijss.
Tinct. hyoscyami..... gtt. lxxx.
Tinct. zingib.,
Tinct. calamus.....aa ʒ ss.
Syr. zingib..... ʒ ij.
Ess. vanilla..... ʒ ss.
Glycerine..... q. s.
Aqua.....q. s. ad. ℥ ij.

M. Sig.—Shake well and take one teaspoonful in water three times a day, ten or fifteen minutes before eating.

In great nervous trouble I have combined tinct. calabar bean, tinct. gelsem., tinct. cannab. ind., either one or all. When womb, kidney, or bladder trouble exists, I have combined with the base of the formula first given fld. ext. sec. cornut. for the first disease, the second fld. ext. buchu or digitalis, and for the last tinct. cubebs, or matico, or uva ursi. In fact, almost any of the medicines derived from the vegetable kingdom may be combined. I know no base for a formula in all my experience with medicines that has given better results. I hope the profession at large will give this remedy a fair trial, either in the doses indicated or smaller ones. So far as I know, it is a new combination and one I claim to have originated.

November 22, 1882.

Progress of Medical Science.

Pathology and Treatment of Gonorrhœal Cystitis.—Dr. P. Geffrier presents in the *Revue de Chirurgie*, No. 6, 1882, an elaborate study, based upon clinical observations, of gonorrhœal cystitis. The disease, he finds, may appear within a few days after the commencement of a gonorrhœa, or it may not be noticed until several months after the primary trouble has subsided. In the former case it is caused by too forcible urethral injections, by which the virus is swept up the canal into the bladder. In the case of the appearance of cystitis long after the initial gonorrhœa has disappeared, careful questioning of the patient will usually establish the fact that there had been some transient symptoms of bladder trouble, which, however, were hardly noticed among his other troubles and soon passed away. In such cases, then, we have to deal with a relapse. In addition to the ordinary signs of cystitis, such as frequent and painful micturition, etc., we have one very important symptom in hæmaturia. The blood is not intimately mixed with the urine, but appears only toward the end of micturition. This may be seen by instructing the patient to pass his water into two vessels successively, in the first of which the urine will be clear, in the second, tinged with blood. Usually the blood appears just at the end of urination and is accompanied by a sharp, painful, spasmodic urethral contraction. Then for a time after the flow of urine has ceased blood will continue to pass drop by drop, or else in jets accompanied by the involuntary reflex contractions. The mechanism by which this hæmaturia is produced has been clearly explained by Guyon. The mucous membrane of the neck of the bladder is normally very vascular, and the turgescence of the capillary network is greatly increased by gonorrhœal inflammation. Now, at the end of micturition, even in health, there always occurs a series of reflex contractions which serve to expel the last drops of urine. These contractions are not limited to the bulbo-cavernous muscle, but are participated in by the smooth fibres of the bladder, and especially by those about the neck. Thus it is that by this contraction, rendered the more energetic as the neck of the bladder is more irritable, the mucous membrane is compressed and the blood is squeezed out as from a sponge.

The duration of gonorrhœal cystitis is indefinite. Occasionally the disease subsides together with the initial gonorrhœa, but if it outlive its course it seldom undergoes a spontaneous cure. The symptoms are the same whatever may have been the duration of the disease, and the division into acute and chronic can be based only upon the length of time during which the affection has existed. Sometimes the urine presents no appearance of admixture with blood. In such cases the patient should be instructed to pass his water into two vessels. That which was first passed will be perfectly clear, but at the bottom of the other vessel, containing the urine passed at the end of the act, there will be found a whitish deposit, more or less abundant, and not infrequently tinged with blood.

Gonorrhœal cystitis is liable to be confounded with stone in the bladder or with tubercular cystitis, chiefly because of the bloody urine present in each of these affections. In calculus, however, the blood is always mixed with the urine, and never comes with the last drops only, as is the case in the disease under consideration. The symptoms also are always in abeyance at night in the case of vesical calculus, while in gonorrhœal cystitis they are often more urgent at that time.

The differentiation between gonorrhœal and tubercular cystitis is frequently quite difficult. The pain of tubercular cystitis is seldom absent; in gonorrhœal cystitis there is usually but little complaint in the periods between the calls to urinate. In gonorrhœal cystitis the pain is more readily controlled by opiates than it is in the tubercular variety. The hemorrhage also differs in the two varieties. In tubercular cystitis there is almost always some premonitory hæmaturia, analogous to the hæmoptysis occurring at the beginning of pulmonary phthisis, which appears before any of the other signs of vesical inflammation. We should always make a careful examination of every organ in the body with a view to the discovery of signs of tuberculosis in any of them, even when there is little doubt of the gonorrhœal origin of the inflammation. It is not infrequently the case that a tubercular cystitis will become engrafted upon a gonorrhœal inflammation, when a tuberculous diathesis is present, just as we see a simple bronchitis become the point of departure for pulmonary tuberculosis.

The treatment consists in the local application of a two per cent. solution of nitrate of silver to the diseased mucous membrane. The instruments employed are a flexible catheter with an olivary point, of the size 18 or 20 (Charrière)—unless a stricture compel the use of a smaller one—and a small Auel's syringe. The catheter is attached to the nozzle of the syringe, and both are filled with the solution. The instrument is then oiled and passed up the urethra until the bulbous extremity is felt to enter the bladder. It is then slowly drawn back until the

point is arrested at the entrance of the urethra. When in this position the piston of the syringe is pressed upon and a few drops of the nitrate of silver solution are slowly dropped upon the mucous membrane of the neck of the bladder. For the first injection, fifteen drops of a two per cent. solution suffice—this amount is subsequently increased to twenty, thirty, or even fifty drops. The injections are to be repeated every other day. The pain caused by the application is slight and but of short duration. Internal treatment by copaiba or sandalwood oil may be conjoined with the local applications, but it is not necessary. The injections should be continued as long as the frequent desire to urinate exists, even though all the other symptoms have subsided; otherwise there is danger of a relapse. In some severe forms of gonorrhœal cystitis the inflammation is not limited to the neck of the bladder, but involves, in greater or less degree, the entire vesical mucous membrane. In these cases it is advisable to wash out the bladder thoroughly with a solution of nitrate of silver of one part in five hundred, in place of the local application of a stronger solution. The injections should always be made soon after the patient has passed water, in order to avoid the precipitation of the silver by the chloride of sodium in the urine.

Obliteration of the Hepatic Veins in Cirrhosis of the Liver.—In an article on the above subject in the *Revue de Médecine* for August, 1882, Dr. Sabourin concludes that in the great majority of cases of true cirrhosis of the liver the hepatic veins are obliterated. This obliteration may be limited in extent or it may involve the entire intralobular system of veins, even including branches of very considerable size. The obliteration is due to a true adhesive phlebitis.

Fatal Tetanus complicating Typhoid Fever.—Dr. Simoneau relates the following: A man, sixty-six years of age, was attacked with typhoid fever of rather severe form, and a little irregular in its symptoms. The fever had begun to abate, and the patient was supposed to be entering upon convalescence, when he was suddenly seized with vomiting and pain in the epigastrium. On palpation a rigidity of the muscles of the right side of the abdomen was noticed. A few days later the muscles of mastication became affected, and the patient developed all the symptoms of tetanus and died in thirty-six hours. The hygienic surroundings of the patient were of the best, and no cause for the tetanus could be discovered. Dr. Simoneau could find no similar case reported of tetanus complicating typhoid fever, and regards this one as unique.—*Journal de Médecine et de Chirurgie*, August, 1882.

Fatty Heart.—Leyden distinguishes two varieties of fatty heart, in the first of which there is an increase of fat about the heart, but no disease of the muscle itself. Of the second variety, in which the heart-muscle is involved, there are two forms: pure fatty heart with muscular degeneration, dilatation and weakness of the heart; and fatty heart with sclerosis of the aorta and coronary arteries. The latter form is often accompanied with attacks of angina pectoris, and may result in sudden death from syncope or rupture of the heart. It is important to recognize this form of fatty heart, since here any measures taken to reduce the amount of fat can only be productive of harm through a general lowering of the vital powers. The diagnosis is often very difficult. The age of the patient, hereditary history, and condition of the radial artery must be taken into account. A very important symptom is angina pectoris, as is also dyspnœa occurring without reference to exertion or the ingestion of a hearty meal. In uncomplicated fatty heart (abnormal increase of fat about the heart and in the muscular substance) the author recognizes two stages. In the first, before the heart-muscle is involved, the patients suffer from shortness of breath after exertion or after eating. The apex beat is weak, and the area of cardiac dulness slightly increased. Upon the supervention of muscular degeneration and dilatation of the heart, graver symptoms appear. The earliest signs of failure of the heart are repeated attacks of cardiac asthma, and the appearance of cyanosis and anasarca. Treatment should be directed toward the removal of the causes—a deficient amount of exercise, the ingestion of rich food, alcoholic liquors in excess, etc.—and especially to the reduction of obesity. Muscular exercise should be insisted on.—*Prager Medicinische Wochenschrift*, August 23, 1882.

Vesical Calculus in a Child One Month of Age.—Dr. J. W. Troitzky relates the case of a child, one month of age, who was brought to him with the following history: The child, apparently healthy in other respects, was noticed to cry frequently when passing water. The mother found that the urine flowed in a full stream and without pain if the child's pelvis were raised above its head, but this manœuvre had failed in the last attack, and the flow of urine was entirely stopped. Examination revealed a distended bladder, and a hard body could be felt in the urethra. After the injection of a few drops of oil, the stone was gradually pressed out of the meatus. It was a calculus composed of urates, 8 mm. long, and 5 mm. in thickness, weighing 25 centigrammes. The urine contained numerous crystals of uric acid and the urates.—*Allgemeine Medicinische Central-Zeitung*, No. 99, 1882.

Shepherds' Ophthalmia.—Dr. Eduardo Mañez describes three cases of conjunctivitis, caused by the presence of the larvæ of the *musca carnaria*, observed by him in shepherds. The first symptom noticed was that of a foreign body in the eye, accompanied by a pain like the pricking of pins, referred to the oculo-palpebral fold of the conjunctiva. Then followed lachrymation, agglutination of the eyelashes, swelling of the lids, and injection of the conjunctiva. Small whitish worms, moving about with great rapidity, could be seen in the eye. If these could be extracted in the beginning, the conjunctivitis subsided without further treatment; but later their removal was difficult on account of the tumefaction of the lids. After a trial of various remedies in a similar conjunctivitis excited in rabbits, the author found that the best was the essential oil of juniper. This, when dropped into the eye, caused the death of the worms in a few minutes, and the conjunctivitis then disappeared under the ordinary treatment.—*Revista de Medicina y Cirurgia Prácticas*, September 22, 1882.

Ergotine in the Treatment of Typhoid Fever.—The following case, occurring in the service of Dr. Siredey, is reported in the *Journal de Médecine et de Chirurgie* for August, 1882. A young woman, in the third or fourth month of pregnancy, was admitted to hospital on the eighth day of typhoid fever, presenting the usual symptoms of the disease

in a marked degree. The temperature was 40° C. There were present a trembling tongue, tympanitis, bronchitis, diarrhœa, and a plentiful eruption of rose-colored spots. The patient soon became delirious, and all the symptoms continued to increase in severity. On the morning of the eleventh day of the disease, the temperature was 104° F. A hypodermic injection of ten centigrammes of ergotine was administered. The following day the general symptoms remained about the same, but the temperature had fallen to 103° F., and did not rise above this figure in the evening. The injections of ergotine were continued for six days, when the temperature became normal, and all the symptoms were ameliorated. They were then discontinued. Four days later the woman was delivered of a dead fœtus. This case is noteworthy as showing the undoubted effect of the ergotine upon the temperature. The abatement of the fever followed immediately upon the first injection of the drug, on the eleventh day of a severe typhoid fever. The abortion was not attributable to the effects of the ergotine, as the injections had been discontinued four days previously.

Corrosive Sublimate in the Treatment of Gonorrhœa.—Dr. Leistikow thinks he has confirmed, by a series of experiments, the discovery made by Neisser, of the presence of a special form of bacteria in gonorrhœal discharges. In the first stage of a gonorrhœa, when the discharge is thick and abundant, but few of the bacteria can be seen. They exist, however, in great numbers in the thin and scanty secretion of the later stages, sometimes even when the disease has existed over a year. In the treatment of gonorrhœa the author employs an injection of corrosive sublimate, which Koch has found most fatal to the various forms of bacteria. He uses a solution of 1 part to 20,000, 1 in 10,000 being found to be too irritating. In private practice a still weaker solution of 1 part to 30,000 is employed. The injections are made three times a day, and should be continued for three or four days after all discharge has ceased. The bacteria disappear, or are greatly diminished in number, after one day's use of the injections, but return again if the latter are discontinued too soon. Treatment by injections should not be begun until after the acute inflammation has subsided.—*Deutsche Medicinal-Zeitung*, September 7, 1882.

Fibroma of Renal Capsule.—Dr. Hüe recently presented to the Société Anatomique, of Paris, a specimen of a tumor discovered post-mortem in the body of a woman who had died of pulmonary disease. Its presence had not been suspected during life. The tumor was ovoid in shape, of the size of a large nut, and was attached to the convex border of the right kidney by a pedicle which allowed considerable motion. On section, its texture was exactly like that of a uterine fibroid, composed of a mass of irregularly woven grayish white fibres. Its tissue was distinct from that of the cortex of the kidney. The capsule of the kidney was closely adherent to the tumor at its junction with the pedicle. —*Le Progrès Médical*, September 23, 1882.

The Distoma Hæmatobium as a Cause of Vesical Calculus.—Dr. Zancarol, surgeon to the Greek Hospital in Alexandria, states that vesical calculus is a very common affection among the native Egyptians. He attributes this frequency to the presence of an entozoon, the distoma hæmatobium, in the water of the Nile. The Fellaheen drink this water just as it comes from the river, while the Europeans use it only after careful filtering. The former are frequently the subjects of stone in the bladder, among the latter it is of rare occurrence. In nearly every case of calculus the eggs of the distoma hematobium are found in the urine. The parasite inhabits chiefly the portal, mesenteric, hemorrhoidal, and vesical veins. Its eggs are deposited in great abundance in the latter, and accumulate in the submucous tissues of the bladder in such masses that the mucous membrane often breaks down, giving rise to frequent and intractable hemorrhages. From these hemorrhages result ecchymoses, infiltrations, and ulcerations of the mucous membrane. The uneven surfaces thus formed offer a favorable seat for the deposit of the urinary salts, and these incrustations being detached and agglutinated together form a nucleus for the stone. The eggs of the distoma and their broken shells are often found in the fragments of the calculi.—*Revue de Chirurgie*, August, 1882.

Contusions of the Abdomen.—In regard to contusions of the abdomen, Dr. Lentz states that they are often very grave in their results, even when no external signs of injury are present. In such cases they are accompanied by internal injuries, contusion, or rupture of some portion of the alimentary canal. Death results usually from peritonitis, or may be due to shock conjoined with hemorrhage. If other lesions exist together with the symptoms of severe abdominal contusion, the surgeon should give his attention chiefly to the latter condition, and should abstain from any active interference.—*Revue de Chirurgie*, August, 1882.

Hereditary and Congenital Malaria.—In an article on this subject in the *Revue de Médecine*, No. 7, 1882, Dr. Charles Leroux concludes as follows: "Owing to a lack of sufficiently numerous and definite observations it is impossible as yet to affirm the existence of congenital malaria, or to determine the rôle played by heredity in the etiology of infantile malaria. The fact, however, of congenital hypertrophy of the spleen, accompanied by certain characteristic lesions of malarial cachexia in the infants of women suffering from intermittent fever, would seem to point to a congenital or hereditary malaria. Some children appear to have at birth an hereditary predisposition to malarial fever, even when not exposed to any causes from without. They are often seized, shortly after birth, with a remittent fever of the same type as that displayed by the mother." The author leaves unsettled also the question whether the theory of heredity is able to explain the intermittent character of certain infantile affections, and the effect upon them of antiperiodic medication.

Hydatid Cyst of the Pleural Cavity.—Dr. Arzelà reports the case of a shepherd boy, twelve years of age, who was admitted to hospital with a diagnosis of pleurisy. The right side of the chest was enlarged, the intercostal spaces level with the ribs, and the respiratory movements absent. The percussion note was dull, and no respiratory sounds were audible. The boy died suddenly three days after admission. At the autopsy there was found an echinococcus cyst in the right pleural cavity, containing a clear fluid and a number of daughter cysts varying in size from a pin's head to a bean. The reporter stated that no traces of the right lung were discoverable.—*Lo Sperimentale*, September, 1882.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, December 16, 1882.

CONSTITUTIONAL ANOMALIES IN RELATION TO DISEASE.

PROFESSOR F. W. BENEKE'S elaborate researches upon the constitutional anomalies of men in relation to disease deserve a careful attention from physicians. It is impossible to summarize them entirely here, but the following will give some idea of the nature of his work.

There are, says Beneke, two kinds of anomalous constitutions: In the one, the organs are smaller than normal, and the mean of work done is below the healthy standard; in the growth and changes of tissue there is a tendency to hypoplasia. In the second class, most of the organs are above the normal standard, and there is a tendency to hyperplasia of organs, as well as to sclerotic changes generally —or, as it is termed, "fibromatosis."

In the first combination there are: a small heart, narrow arteries, large lungs with wide pulmonary arteries, small liver, and short intestines; there are generally weak muscles, weak, bony frame, and little adipose. Adults often have nervous weakness, phosphaturia, and oxaluria. In such constitutions the children are delicate, the stage of puberty is delayed, the various scrofulous and phthisical diseases develop, and also chronic anæmia. The author found, for example, in eighty-seven cases of phthisis, that the intestines were shorter than normal.

In the second combination there are relatively long intestines, a well-developed heart, wide arteries, small lungs, and large or very active liver. In such cases there develop rachitic diseases, obesity, atheromatous degeneration of arteries, psoriasis, cancer, and various connective-tissue hyperplasiæ. These hyperplasiæ, or fibromatoses, may be general or local. In the latter case, if it affects the lungs, there may be fibrous phthisis; if the kidneys, interstitial nephritis; in the nervous system, sclerosis or pachymeningitis, etc. Children with such anomalous constitutions are likely to be muscular and healthy in appearance. As they grow older, they may become victims of obesity, atheroma, arthritis urica, carcinoma, or of interstitial induration of various organs. The anatomical base of carcinoma, for example, was found to be long intestines, having great capacity, an active liver, small lungs, large heart, wide arteries, a strong, bony frame, well-developed muscles, and adipose tissue. In rachitic children the arteries of the neck are especially large and wide.

Beneke does not claim that individuals with the above-described anomalies are necessarily attacked with disease. They are, however, more liable to be affected; and if the anomaly is very marked, it will be almost impossible for its subject to remain healthy.

The physician who recognizes these types may do something to help his patient. Thus, when a child has, as a constitutional anomaly, organs below the normal size, their greater development may be helped by "gymnastics, friction with cool water, some wine, pure air, especially that of the seashore." When the individual grows up, and shows evidence of anæmia, or of a phthisical tendency, he must have, in addition, a "light, digestible food, not too poor and not too rich in albuminates and phosphates. Effort must be made to secure a larger absorption of food."

In children with relatively large organs, we must restrict by a proper diet the process of absorption, assimilation, and blood-making. The food must not be too albuminous; alcohol and phosphates should not be given. Fresh vegetables, moderate exercise, mineral waters, especially those containing chloride of sodium are indicated.

THE SURGERY OF THE LIVER.

THE subject of the surgery of the liver, revived some years ago by Dr. Sims, has been of late studied with renewed interest, sharing in this respect the impulse that has been given to abdominal surgery in general. It must be confessed, however, that no very brilliant results have yet been obtained in operations either upon the gall-bladder or the liver. In the former class of operations especially, Lawson Tait seems to have been almost the only fortunate surgeon. There has also always been a certain amount of doubt attending the diagnosis in many of these cases, which has interfered with placing the operation for cholelithectomy upon any solid basis. The plan advocated by Dr. J. T. Whittaker, of making an exploratory puncture and thus feeling for the gall-stones, helps to give greater certainty to diagnosis, and may possibly pave the way to a wider employment of the operation.

That it will always be hazardous and uncertain cannot be doubted, however, by any who have seen

the manner in which gall-stones often impact themselves in the ducts as well as in the gall-bladder. Even in apparently favorable cases the operation may prove fatal, as is shown by Dr. Jos. Ransohoff in a recent article upon cholelithectomy, read before the American Medical Association (MEDICAL RECORD, vol. xxi., p. 662). This gentleman reports a case which he claims to be the first instance where a diagnosis was positively made before the operation was begun.

The patient, a man seventy-six years of age, had suffered for six months from evidence of obstructed gall-duct. The needle of an aspirator thrust into the bladder plainly revealed the presence of concretions. An operation was performed. The gall-bladder was reached, opened, and half a pint of bile which distended it allowed to escape. Four stones, three in the bladder and one in the duct, were found and removed without much trouble. A sound passed through the cystic duct showed it to be open. The sides of the incision in the gall-bladder were sewed to the abdominal wall, a drainage-tube was inserted and the wound dressed with iodoform and absorbent cotton. The patient rallied well, but subsequently sank, and died next day, evidently from heart-failure.

The practice of aspirating the liver in cases of abscess is a general one, and often attended with good results. Dr. Ransohoff, however, cites another of the cases, now quite numerous, which show that it sometimes may be necessary or better to cut directly into the liver, making a large and free incision.

A married woman, thirty-two years of age, suffered from hepatic abscess. The aspirator was used twice at an interval of about a month, and a quart of pus removed each time. The patient's condition then grew rapidly worse, and, as a last resort, hepatotomy was resorted to. An incision was made into the abdomen, and the liver tissue over the site of the abscess was sewed to the borders of the abdominal wound. The abscess was then opened and washed out, about four quarts of pus being removed. The cuts were made with a galvano-caustic knife, and little hemorrhage took place. Subsequently the wound was kept irrigated with lukewarm water from 9 A.M. to 5 P.M. daily for two weeks. The patient's condition was for a time extremely critical, but she finally recovered.

The view that large incisions with copious irrigation is the better method of treatment in many cases has received support recently from M. Rochard. At a meeting of the Académie de Médecine he reported two successful cases treated in this manner. Some attempts to weaken the force of his views were met by reference to many other clinical histories which showed that large incisions would accomplish what neither the aspirator-needle nor the trocar could do.

NEGRO MORTALITY.

IT is well known that different races have a different susceptibility to disease as well as a difference in mortality rate. The racial peculiarities in this respect of the negro are especially well marked and interesting. The President of the Memphis Board of Health, Dr. G. B. Thornton, has recently discussed the subject in the *Sanitary Engineer*.

In the city of Memphis the negro mortality is much greater than that among the whites, the ratio varying between 5 to 3 and 5 to 4. In all the Southern cities this same preponderance occurs. In five of them, for example, the death-rate among the whites is about 18 per 1,000, among the blacks 32 per 1,000.

The birth-rate, on the other hand, of negroes living in cities is, we believe, a low one. In Memphis the number of births among this class in 1881 was 216, while the deaths during the same time were 806!

City life seems to be a poison to the negro. He dies quickly, and breeds slowly. The fact that he lives under the disadvantages of poverty does not alone explain this. The city population is being constantly supplied from the country, otherwise the excess of deaths over births would soon lead to a negro depopulation.

In the country the negro still thrives, and, as a whole, the race has multiplied since the war more rapidly than the whites.

The causes of the high death-rates among the Memphis negroes are chiefly consumption and acute lung diseases. These destroy this race whenever the climate is at all severe or the temperature inconstant. But, besides this, the negro has a particularly hard struggle for life in childhood and old age. There is a slight excess of population, and a considerable excess of births among the whites of Memphis as compared with the colored; yet in three years there were 789 deaths among negro children under five years of age, and only 376 deaths among white children under the same age.

Negro families are not held together, as a rule, by the same domestic ties which exist among the whites; consequently the aged and infirm have not so strong a claim upon their families or relations. Not having proper care, the aged soon yield to their infirmities and furnish a large contingent to the death-list.

The other causes of negro sickness and mortality in the cities are numerous. There is, first, the change from a tolerably regular and temperate country life to one which is quite the reverse. The city negroes are licentious in habits, improvident, irregular in work and careless in all their domestic habits and arrangements. Venereal diseases abound, and are a frequent cause of premature births and infantile deaths. If the syphilitic children reach adolescence, it is with impaired constitutions, which readily succumb to other diseases.

Of epidemic diseases there are two which seem to affect the negro with especial violence. These are cholera and small-pox. Among three hundred and thirty-eight cases of the latter disease which occurred in Memphis since January 1st, three hundred and eleven were among the negroes. It cannot be said positively that these diseases affect the negro by reason of a special susceptibility, but rather because of his gregarious and improvident mode of life.

There are, on the other hand some physical and mental characteristics of the negro race which help them in the struggle for existence. They are less susceptible to the endemic malarial fevers of the South; they are not so severely affected by yellow fever.

Another advantage which they possess is a more obtuse nervous organization. Though emotional and imaginative, they are rarely "nervous." When attacked by acute disease, they are less liable to nervous complications, such as convulsions, insomnia, and delirium. The negro is rarely the subject of chorea or epilepsy, nor, according to Dr. Thornton and others, is insanity so frequent or varied among them. The negro does not become a victim of nervous exhaustion or mental depression.

The negro race is a permanent part of our population, and is a social factor which cannot be ignored. It is increasing in the country more than it is dying in the city. By reason of less amalgamation, the half-breeds are steadily becoming less numerous, and the tendency is for the negro to revert to his original and pure type.

The lesson of mortality statistics, so far given, is that the negro is not yet prepared to cope with the white man in the more active struggle for existence in cities. He fails because he is morally and mentally weaker. He should remain in the country, at least until he is more civilized; and municipal governments would be wise to discourage the entrance of a population which dies at the rate of forty per thousand annually.

QUACKS AND QUACKERY IN MISSOURI.

Missouri is a quack-ridden State. There are 4,834 persons practising in its limits, which gives a ratio of one doctor or quack to every 450 inhabitants. Among these practitioners there are 3,453 who belong to regular medicine, and over 1,300 eclectics, homœopaths, and nondescripts. Hardly more than half (2,546) of the entire number of physicians, however, are graduates of regular schools.

The above are figures collected with much care by Dr. Willis P. King, President of the Missouri State Medical Society. They were presented to that body at its last meeting.

But this does not represent all of Dr. King's investigations. It is bad enough to learn in general that nearly half of the persons who practise medicine are not graduates of reputable schools. Further analysis, however, reveals particular facts which are still more disagreeable. He states that 269 persons are known to be or suspected of being abortionists; that there are 1,904 persons who are deemed by competent judges to be quite incapable of practising medicine intelligently; and that there are 452 persons who are considered to be of an immoral character, 34 of these being women.

Estimates made by local physicians throughout the State place the annual loss of life from quackery at 5,570 persons—an estimate that is considered by Dr. King to be too low. The sum of from one million and a quarter to two millions of dollars is paid annually into the hands of these quacks.

Still further, of the 269 or more abortionists, many make it their sole business, and at a moderate estimate over 8,000 children are destroyed annually before they are born!

The array of statistics thus given is certainly a startling one. They make the subject of quackery so real and practical that it should appeal to every class. It may be thought that there is some exaggeration, but a perusal of the entire address will certainly do much to allay incredulity. Citations are given from letters received from 114 counties; nearly all telling the same kind of stories.

One correspondent writes: "The Physio-Eclectic Medical College of Cincinnati, O., has agents in the State, selling diplomas—the terms being an examination and the payment of a fee of eighty dollars."

Says another: "Deaths from post-partum hemorrhage in the hands of ignorant men, are more common here than from any other cause." Another reports 25 quacks among the 75 doctors in his county; while in a neighboring county the proportion of quacks is estimated at two-thirds, "scarcely one of whom can write his name without running his tongue out."

A travelling cancer-doctor makes sometimes fifty dollars a day for services that are utterly worthless. In one county it is estimated that there are fifty people suffering from curable diseases who are prevented from submitting to proper treatment by the promises of quacks.

Unique cases are reported in which quacks have blistered the glans penis for strangury, punctured the caput succedaneum, mistaking it for the bag of waters, plunged a knife into an aneurism, killing the patient, and so on. A medical man in one county promises to cure a nasal catarrh in one sitting, in proof of which he "removes the catarrh and places it on a saucer!"

Some statements are made which almost stagger credulity, and which might be most fittingly emblazoned in the *Police Gazette*. A correspondent

from Central Missouri writes: "An advertising swindler here is guilty of crimes every day that he lives which ought to send him to the penitentiary. He deliberately castrated one of his male patients, and then took his wife away from him, and has kept her in open and notorious adultery ever since. He is an abortionist, and scarcely tries to conceal the fact."

Such recitals make one pant for breath, and ask if the Code of Ethics is not a somewhat futile moral agent in Missouri.

Dr. King very strongly urges that the medical profession of Missouri use its influence to secure a registration law. It seems impossible that the profession can fail to be aroused to some activity by the facts that have been disclosed. We wish that some one equally earnest with Dr. King might investigate medical affairs in other States. We fear that Missouri does not stand alone in the peculiar character of its medical advisers.

THE COMPULSORY NOTIFICATION OF INFECTIOUS DISEASE.

THE medical profession in this country has very universally allowed itself to be saddled with the obligation of notifying cases of infectious disease. A doctor in many cities of the United States must make these notifications without recompense, or be subject to fine or even imprisonment. The profession has allowed the law to get this hold upon it, partly because there was a desire to help along preventive medicine, partly from indifference. In the latter respect it is an illustration of Herbert Spencer's charge that Americans are careless of their individual rights.

We refer to this now because, after much struggling, one of the chief English advocates of compulsory notification by medical men has withdrawn from his position. At least, we are told by the *Medical Press and Circular* that such is the case as regards the editor of the *British Medical Journal*, who has heretofore been an ardent advocate of this particular form of compulsion.

The violent opposition to the measure in question developed among British medical men is in striking contrast to the apathy shown by Americans. There is no question that the notification by doctors is a humane and useful public act. But society has no right to ask special favors of or place special obligations upon medical men without some recompense.

BODY-SNATCHING IN PHILADELPHIA.

THE recent accounts of body-snatching in Philadelphia are well calculated to arouse public indignation, not only in that city but throughout the country. It is particularly to be regretted that the Jefferson Medical College should be so intimately associated with the affair. The scarcity of subjects for dissection will hardly be considered an excuse for obtaining bodies by questionable methods. From the evidence offered, it would appear that the college authorities could not have been in entire ignorance of the means to the end. At least the public will hardly give credit for so much innocence. The necessity for anatomical material is always great, even in the larger cities, but that will hardly be an argument for grave-robbing. The latter crime is only calculated to arouse the public to the pitch of resisting every measure calculated to legalize dissection. Pennsylvania has long wanted such a law, but there is no chance for its passage on the plea that if bodies cannot be obtained by fair means, they will be forthcoming nevertheless. For the present, at least, cadavers will be scarcer than ever in Philadelphia.

Reviews and Notices of Books.

ECZEMA AND ITS MANAGEMENT. A Practical Treatise based on the Study of Two Thousand Five Hundred Cases. By L. DUNCAN BULKLEY, A.M., M.D. 8vo. New York: G. P. Putnam's Sons.

THAT eczema—one of the most frequent and troublesome of skin diseases—has not received the attention it deserves and demands from the general practitioner cannot be denied. We welcome, therefore, any teaching giving us so practical an idea of the diagnosis and management of the affection as does the present volume.

The author leaves no doubt as to the constitutional character of eczema, and lays particular emphasis on the gouty, strumous, and neurotic diatheses as predisposing causes. The polymorphous nature of the disease is clearly shown, as is also the necessity of an accurate diagnosis to render treatment effective.

The book is throughout readable and instructive. We would particularly commend, however, the chapters on etiology and differential diagnosis to those who have been in the habit of prescribing alike for all non-contagious eruptions.

THE BUSY PRACTITIONER'S VISITING LIST, CLINICAL AID, AND POCKET LEDGER. Detroit: Geo. S. Davis.

THIS little work possesses certain features which may be considered an improvement on other forms of visiting lists. Besides the usual necessary contents, very conveniently arranged for the busy practitioner, there are a few pages devoted respectively to the metric system, the treatment of certain emergencies, points in differential diagnosis, treatment of various poisons, a table of new remedies, etc., etc., all of which will be found to convey some exceedingly useful information.

HANDBOOK FOR WATER-DRINKERS. By G. L. AUSTIN, M.D. Boston: Lee & Shepard; New York: Charles T. Dillingham.

IN this little work the author has endeavored to place before those who are not expert in chemistry, a simple and easily applied method of water-analysis, to the extent necessary for determining the presence or not of various contaminating matters affecting the purity of water for drinking purposes. An appendix is also added, giving the formulæ for the several solutions mentioned throughout the work. It is hoped that the book will prove very useful in this direction.

THE SPINAL NERVES. By A. H. P. LEUF, M.D. Brooklyn, N. Y.: F. B. O'Connor, Jr. 1882.

DR. LEUF, in a work of sixty pages, gives an excellent description of the spinal nerves. Others have done this before, however, and the chief merit of the present treatise lies in some very good diagrams and charts. These are carefully made and will be helpful to students.

A TREATISE ON THE PRACTICE OF MEDICINE By ROBERTS BARTHOLOW, M.A., M.D., LL.D. Third Edition. New York: D. Appleton & Co. 1882.

THE mere fact that a third edition follows so closely the first publication of this admirable treatise is sufficient evidence of its excellence. The present volume represents the revised work bestowed on the two previous editions, plus about fifty pages of new subject-matter. Almost the first impression one gets in turning its leaves, one after another, is that the articles on the various diseases follow one another in more rapid succession than is usually the case, but a close and critical inspection shows that there is a completeness of statement, a breadth of experience, and a practical bearing in what he reads such as is not characteristic of many medical works placed in the practitioner's hand. Debatable questions are not even alluded to, the author evidently having made it his aim to utilize only such material as has been tested by himself and other reliable men. As a result of such a selective course, each disease is described in as few words as are requisite to give a clear conception of it. The treatment is of a most practical kind, because those remedies and measures are advised which have in the greatest number of cases been efficient supplements to the natural restorative forces. If this book possesses any one distinguishing mark which more than all else enforces its far-reaching usefulness, it is the personality that endorses every method recommended for the deliverance of the sick from their maladies. If some of the statements concerning the therapeutical effects of drugs seem too positive, it must be remembered that there are few men whose actual experience in the line of careful investigation in the use of different medicines has been more extended than that of Professor Bartholow. The diseases incident to the cerebro-spinal system are very fully discussed, while there are many invaluable points given on the management of fevers. The chapters on the inflammatory disorders of the respiratory and digestive organs are of special interest. The illustrations are very distinct and furnish great aid in the elucidation of certain subjects. In thus referring in a most general way to the merits of this work, we merely bring to the notice of our readers that which will attest its own value in its adaptability to the diverse needs of the general practitioner.

TRICHINÆ ARE KILLED BY COLD as well as heat, according to the experiments of Bouley and Gibier. These gentlemen used birds to test the viability of the parasites, since they do not enter the muscles of birds, but remain in the intestines. It was found that if a ham weighing five pounds were subjected to a temperature of 12° to 15° C., for five hours, the trichinæ would be killed. According to this, pork can be safely eaten raw, provided it first be frozen.

HABITUAL CRIMINALS in English prisons are stated to be a healthy class of people, and to be remarkably free from any scrofulous taint.

Correspondence.

A STUDY OF LEPROSY AT MOUNT LEBANON, SYRIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: At the stated meeting of the Medical Society of the County of New York, June 26, 1882, my former professor, Dr. H. G. Piffard, presented one patient and gave the interesting history of another, both leprous. I at once compared his views and statements with my own practice, after having seen about a dozen cases or more of both tubercular and anæsthetic leprosy. My limited experience fully corroborates all he says. I am able to get hold of the histories of only five patients at present, all of the same village on the slopes of Mt. Lebanon. Four of the five are members of the same family. I will give the history of that family in full as the other six members were not contaminated by the disease.

Ishak Ibriheem (male) married Merriam Ammoora. Both were in perfect health at the time.

Merriam gave birth to her *first* child Hannie, who married and gave birth to three children. She subsequently died at the age of about thirty, but had no skin disease of any kind. Her widower and children are in perfect health.

Merriam's *second* child, Briheem (No. 1), died in infancy with no lesion of the skin.

Merriam's *third* child, Jurjus, died of tubercular leprosy at the age of about twenty-five. He was the second member of this family so affected. He was of a gloomy disposition. He had frequent attacks of turning "as black as a darkey" (as his brother expressed it) from the age of puberty till about his twentieth year, when tubercles appeared on his extremities and face. Another chap ran off with his intended bride, which was considered by the natives as the exciting cause. But the true cause undoubtedly was this: he had a scratch on his leg and his mother put her stocking on to this wounded leg; the scratch never healed. She was a leper at the time.

Merriam's *fourth* child, Yakoob, is about twenty-eight years of age, married and has one child. He and family are in the best of health.

Merriam's *fifth* child, Briheem (No. 2), is twenty-five years old, lost his only child the past week of diphtheria. He and his wife are in perfect health.

Merriam's *sixth* child, Helany, died at the age of about eighteen of tubercular leprosy. She had been out gathering bitter herbs, was caught in a very heavy rain and got thoroughly soaked. She had high fever followed by large red plaques which disappeared after some time (could not tell how long). She then had five or six pimples about the root of the nose which soon became real tubercles, and ulcerated before long. Her legs, feet, forearms and hands were about the same time the seat of tubercles, and the phalanges, though not dropping entirely off, were very deeply ulcerated. She never menstruated and the tubercles appeared at the age of ten or twelve. She was the third member of the family affected with leprosy.

Merriam's *seventh* child, Sara (No. 1), died at the age of three with no lesion of the skin.

Merriam's *eighth* child, Sara (No. 2), is now about fifteen years of age, and has tubercular leprosy fully developed. She is the fourth leper of the family, and became such five years ago. Tubercles

cover all her fingers and toes. The little fingers are so enlarged by them as to be the size of her thumbs. The left hand is worse, and has already commenced to ulcerate. Tubercles are also to be found in large numbers on her nose, ears, temples, over her malar prominences, on her cheeks, and over the rami of the lower jaw, giving a most decided leonine expression. There are no tubercles on the trunk, the skin being as soft and smooth as an infant's. They extend only to the knees and elbows, and not lower than the neck, and many of them are ulcerated. There is no discharge, and, in most cases, a scab covers the ulcer. The roof of her mouth—both hard and soft palate—is ulcerated. She has no pain at all. She has never had any attacks of vomiting—nor, indeed, any member of her family.

She has never menstruated, and has no signs of womanhood. Her breasts and nipples are no larger than a babe's, nor are her genitals developed. The mons veneris is devoid of its usual covering of hair. She is not willing to put herself under treatment, with the hope of only *possible* improvement and no *promise* of recovery.

Merriam herself, the mother, died at the age of forty-five or fifty, of tubercular leprosy. She was the first leper in this family. She has had no relations affected with any skin disease, nor have there been any previous cases of leprosy in this village or in all this region. There is no possible history of syphilis, and she seems to be a case of *sporadic leprosy*. Her son contracted the disease, not by inheritance—for she was not a leper till long after his birth—but by means of her sock, which she used as a dressing for his scratched leg. In the cases of her two daughters, I could not trace any contagion except that, at first, all the family ate together, but finally the lepers had a separate dish, and ate alone. Her daughters may have, and probably did contract the disease before the separation took place. The cause for the appearance of leprosy in Merriam is generally believed to be the following: When Sara (her eighth child) was three days old, she got up and carried the obstetric chair on which she was confined, to the waddy, or brook, and washed it there. This was in the month of January; and on her return, she complained of great heat in her hands and legs. Tubercles appeared, as in the cases of her children. She subsequently had a miscarriage, and did not cease to menstruate till within three years of her death.

Her husband, Ishak, died suddenly at the age of about fifty, and presumably of heart disease. He was visiting in a friend's house, and was rolling up a cigarette, when suddebly it dropped from his hand, and he fell forward dead. He was ever an unfaithful mate, but had no venereal disease of any kind. He copulated frequently during his wife's menstrual flow, and long after she was a marked leper—in fact, up to within a few months of her death, but had no manifestations of leprosy. What might have appeared had he lived long enough no one can say. The natives believe that if congress takes place during the menstrual flow the *offspring* will be leprous, but in this case are at a loss to account for the fact that Merriam, and not her children, was the first to be attacked, and that without any leprous intimacy.

In another part of the village lives an old man of seventy or seventy-five years of age, who has had anæsthetic leprosy for five years. He denies entering the house of or having anything to do with the above-mentioned family. Merriam used to sell milk in the village, but after it was well known that she was a leper she could sell no more milk, and gave up the business. This is the only mode in which it is admitted he could have contracted the disease from her. She and her children had *tubercular*, he *anæsthetic* leprosy. The interesting features of these brief histories are,

First.—That there was no syphilitic disease in any of the above-mentioned cases.

Second.—That the leprosy appeared in the two girls at an early age, before puberty—preventing all development.

Third.—That the disease was sporadic in the case of Merriam, at least, and possibly in the case of the old man.

Fourth.—That the leprosy was not inherited. Professor James C. White, M.D., of Harvard University, says, in his article on "Surgical Diseases of the Skin," in the "International Encyclopædia of Surgery," vol. ii., page 647: "We only know one fact certainly: that it (leprosy) is hereditary; that a certain proportion of a leper's children are liable to the disease in after life." On page 671, same vol., Neisser says, "Leprosy is not hereditary." Merriam had no children after she became a leper, and so her case only proves that her children came by the disease in some other way than that of heredity.

Fifth.—That Merriam's husband was not contaminated or inoculated during ten to thirteen years. Neisser states that "leprosy is probably an infectious disease." Professor White says, "On the other hand there can be no doubt that in individuals without such hereditary taint, the disease is much more liable to develop in regions where leprosy abounds—that is where lepers live—than in other localities. This suggests the possibility of contagion by direct or indirect personal contact." Ishak would seem to disprove contagion and inoculation, while his son would prove the latter, and his daughters the former, or both.

Sixth.—However, all that is positively proved from the above cases is that leprosy is not the *fourth stage* of syphilis, Dr. Fitch to the contrary notwithstanding.

November 1, 1882.

After writing the above, I have read with the deepest interest the article on "The Question of Contagion in Leprosy," by Prof. James C. White, M.D., published in the October number of "The American Journal of the Medical Sciences" of the current year. The Professor is clear and decided in his belief in the contagiousness of the disease, while he does not exclude "hereditary transmission." The histories I have given confirm me in a similar belief. But while the Professor accepts with "great mistrust" the term *sporadic* leprosy, I must say that Merriam's case would seem to prove it, and four of my other patients—as I now recall their histories—confirm me in the belief that the disease may appear without any leprous intimacy. I shall hope to get the histories of these patients before long, to either prove or disprove the above.

CHAS. WM. CALHOUN, A.M., M.D.

TRIPOLI, SYRIA, November 10, 1882.

A STRINGENT EXAMINATION OR DULL STUDENTS.—Out of one hundred and fifteen medical students who went up for the first professional examination at Glasgow University, fifty-four were "plucked."

A FEW WORDS ON THE INCARCERATION OF PERSONS SAID TO BE INSANE.

To the Editor of The Medical Record.

Sir: The detention of persons in our insane asylums under legal commitments—sanctioned by physicians "duly qualified" under the laws of the State—has, of late, created so much excitement, denunciation, and delirious indignation in many of the secular newspapers, that I think some remedy should be suggested to protect our own profession against the infamous assaults that are made on those who perform the innocent and benevolent offices of medical advisers to the insane.

The assaults of the so-called moral secular press are made—not by the owners or principal editors—but by a class of persons who revel in the publication of fictitious language and flaming abuse of all those occupying a dignified and responsible position before the public. When a remonstrance is made to these gentlemen, the answer is: "Well! the public likes this sort of thing." When appeal is made to the principals to redress the wrong, an offer is made in a kind and bland way to make any correction suggested by the injured person. But it is invariably too late. The ability they possess to injure finds no counterpart in their expressions of regret to repair the wrong done. The pleas of justification—"in the interests of, and for the public good"—is the mere twaddle and subterfuge rung in the ears of the public with more eloquence than sincerity. The recent assault on the character and integrity of a banker of unsullied fame and reputation found no redress at the hands of a jury—a small minority of whom were "for the defendant." A recent libel of the most infamous character, that appeared a few weeks ago in an evening paper, reflecting on the private character and professional reputation of a distinguished and estimable chemist, has never been retracted—nor is it in the power of any such newspaper to repair the wrong—its good offices are impotent to render any good service to any person or any cause. But to the main issue: when a plundered and outraged public finally demands an exposure and cessation of the wrongs, the witnesses who could throw light on "the ways that are dark," are too frequently intimidated and prevented from giving their testimony by the presence of persons whose etiology no one can mistake. Aided by the gentlemen of the press, the investigations fail in finding any persons on whom they can fasten the responsibility of wrong-doing.

Let me suggest some means of remedying and averting the abuse of physicians.

Let no one be deprived of his liberty on the ground of insanity without an order from a justice of a court of record, and a certificate signed by two responsible and competent physicians, whose examinations are certified to have been made in the presence of two disinterested persons, and whose signatures shall be attached as such witnesses.

I speak of responsible and competent physicians. It is useless to deny that persons are daily restrained of their liberty—on the ground of insanity—on the certificate of so-called physicians, whose incompetency to judge is soon manifested to the expert alienists of the asylums. The wrong is repaired as soon as possible, but the injury is not repaired by release from confinement. Let no one be permitted to sign a medical certificate who has not had some general experience in the treatment and management of the insane. It is absurd to assume that because a person has a degree in medicine he is *per se* an expert alienist or an expert surgeon. I doubt whether a post-graduate or policlinical course will add sufficiently to the intelligence of a large portion of those *regularly* graduated to entitle them, at any period of their lives, to be distinctively known as experts in any department of medicine.

This, of course, need not deter any of them from advertising themselves as specialists or volunteering as experts in any and every branch of medicine. But I should like, with all deference to the presiding justices of our courts, to suggest that they shall not permit any medical person to offer any testimony or evidence as an expert in medicine until he has first by proper answers to interrogations satisfied the court of his *fitness and competency* to give such testimony. This course is pursued abroad, and is followed, I am told, with great success, in many of the higher courts of Pennsylvania. If this plan were generally pursued it would add dignity to medical testimony, save the time of the courts, and relieve befuddled jurors from differentiating on the relative testimony and merits of professors and others representing divers schools and interests.

M. H. Henry, M.D.

427 Fifth Avenue, New York.

WEIGHT AND PULLEY EXTENSION FOR SCIATICA.

To the Editor of The Medical Record.

Sir: Having been aware for many years of the value of extension in some cases of sciatica, and not having seen anything of the kind in any journal or text-book, I venture to report three cases which I have recently treated by extension made with adhesive plaster, weight, and pulley.

Perhaps many physicians could recall the tenderness and muscular irritability attendant upon some of their cases; this has been the condition in many of mine. Coupling this fact with a personal experience when a boy, I was led to believe that relief could be obtained with a greater degree of satisfaction by mechanical means than by the administration of remedies, especially of the narcotic class. It has been my experience that muscular relaxation *must be secured* before relief could be obtained; I therefore resolved to try an expedient that at least could do no harm. After putting the measure to the test, the thought came to me that I might be mistaken as to the originality of the treatment. I wrote a letter to Dr. R. L. Rea, Professor of Surgery and Clinical Surgery in the College of Physicians and Surgeons of Chicago, Ill., in which I stated my treatment and its results. I will append his reply after giving my cases.

Case I.—Was consulted August 5, 1882, by an old lady; widow; corpulent; of sanguine temperament. Complained of severe pain from hip to heel in posterior of leg; said her joints ached. An inspection showed no redness about the joints, no pain on pressure, no constitutional disturbance, tongue clean and moist, bowels regular, kidneys active, skin dry and harsh, temperature normal, pain lancinating. Patient said she had been in this condition for seven months, that she had not been free from pain since January, 1882. Diagnosis sciatica. Prescribed cinchonidia sulph. and salicylate of soda, ää ʒij. M. fiat in capsules No. 10, et sig. one every four hours. The night of the 6th I was hurriedly summoned to go and see her; found her in terrible agony; proposed to administer hypodermic injec-

tions of morphia. She refused, saying that it "made her so sick" she would "rather die than take it." Something had to be done, as I knew she was a woman who would not say she suffered unless she did. I thought of my own experience when a boy. I was suffering from sciatica, and whenever I could get my foot fast in the foot of the bed, would experience relief by drawing myself up in bed and making extension.

I put on the extension, and hung to the cord eighteen or twenty pounds of sad-irons; in less than twenty minutes my patient was easy and getting drowsy. I left her for the night and went home, wondering why I secured so good a result so soon. The next morning I called to see her, and found as happy a patient as it is the lot of any to find. The pains had almost wholly subsided; the patient said she had kept on the apparatus about three hours, and then the limb began to feel tired, so she unbuttoned the foot-piece and slept a little, when she again began to feel the pain. She fastened the weights on again, and was relieved, and so on through the night.

I advised her to continue it through the day and following night. Next morning I found my patient up and dressed, declaring that she was well; advised her to take the capsules as before prescribed, three daily instead of one every four hours.

Patient at this writing still remains free from pain; health much improved.

Case II.—Married woman, thirty-five years of age; teacher in one of the departments of our public schools; consulted me August 27, 1882; is of slight build, a blonde of nervo-sanguine temperament. Said she had a severe pain in the hip, and referred it to the region of the great sacro-sciatic notch. Said the pain ran down the back of her leg at times, especially when sitting or in a recumbent position. She was poorly nourished and quite nervous; was fearful that she would be unable to go on with her work, and, being quite an enthusiast, this contributed not a little to her anxiety. The treatment was the same as in the previous case, except that I commenced with the extension and then gave the cinchonidia sulph. and salicylate of soda. Patient relieved in two nights. Has since had a slight relapse, but a single night's extension for a few hours at a time put an end to it.

Case III.—Commercial traveller; consulted me October 5, 1882. Had an attack of sciatica about one week before, and it was growing worse. Said he had syphilis six months ago; had taken potassa iodide with hydrargyri iodidum until the last month, when he contracted gonorrhœa, which up to date was discharging freely. Treatment same as in the foregoing cases. Cured of his sciatica in less than twenty-four hours, with no return up to the present.

I find that by taking hold of the foot and making extension, by pulling for a few minutes to the extent of fifteen or twenty pounds, if it eases my patient, it is a suitable case for the weight and pulley extension. I make button-holes at the foot end of the adhesive straps, so that the foot-piece can be loosened and rest the patient if the leg gets tired, or for any other purpose. I also place the pulley a little above the axis of the leg. I see to it that the leg is thoroughly extended, and make it a point to relax the muscles by hanging on sufficient weight. When the leg tires and the pains subside, I tell my patient to unbutton the foot-piece and rest until the reappearance of the pain, which in most cases is after the lapse of considerable time. In all my cases the recoveries have been perfect and all that could be asked. I will close by quoting Professor Rea's case:

"Chicago, September 8, 1882.

"Dr. Shoemaker: Your case of sciatica is very interesting to me. A student (physician) in the Chicago Medical College, two winters since, had an attack of it, and when he came to attend lectures was still suffering and had contracted the morphine habit—not very bad, but he had to take it regularly. I advised its immediate abolition and use self nerve-stretching, that is, by lying on his back with limb extended, bringing it up as straight as he could—practise it regularly, so as to put the sciatic nerve on the stretch, and exercise it, bringing the limb up and down, and before the session was half over he was clear of his morphia and sciatica—a parallel to your own case in a different way. You ought to report your case in The Medical Record, and you can quote my case if you wish.

"R. L. Rea."

Having already taken more of your space than I intended, and with the hope that it may benefit some one in the effort to relieve this painful malady,

I am, very respectfully,

M. Shoemaker, M.D.

Tipton, Cedar Co., Iowa.

New Instruments.

SELF-RETAINING SEMI-PRONED SPECULUM.

By ALEXANDER S. HUNTER, M.D.,

new york.

The cut (on p. 696) illustrates a modified Sims speculum attached to a modified Erichs holder. When in use the fulcrum *A* rests on the sacrum; the lever *B* is raised to nearly a right angle with the fulcrum, and from its buckle at *B*, the loop of the strap extends under the right arm over the left shoulder.

This instrument has been in daily and exclusive use in and out of my office for more than two years *since I have ceased to modify it.*

This fact would lead to show that I am entirely satisfied with it. And further, in the same direction it may be stated that the designer was independent of the instrument maker, having himself made the model and all its changes, while the instrument was doing months of service under strict criticism. It, therefore, represents not approximately but exactly his conception.

For it the following claims are made:

First.—It is made to be used in that position of the patient now adopted by all leading gynecologists.

Second.—It is adapted to all cases, and but one size is required.

Third.—It will retract the perineum and elevate the superior labium as perfectly as can be done by the most skilled assistant. Moreover, it will maintain the position required *without correction* for hours, if needed, irrespective of the movements of the patient.

Fourth.—The third claim is equally true at *all degrees of penetration.*

Without this latter excellence a "self-retaining" "semi-proned" speculum is in my opinion nearly

valueless; and it was to secure this advantage *for all cases* that I was led to modify Erichs' holder.

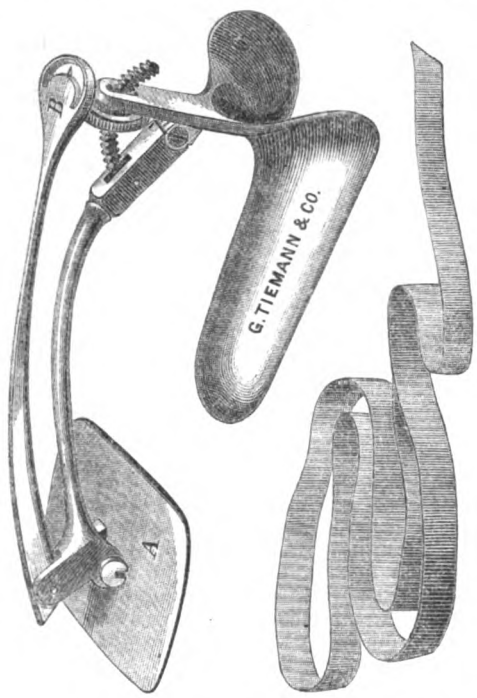
In comparing this instrument with that of Dr. Ehrichs the following advantages are claimed; but to him should be accorded all credit for having placed at our disposal so important a mechanical principle.

First.—It secures a better field through which to operate.

Second.—The shape and divergence of its flanges secure such equal distribution of pressure that its use is attended with the least possible discomfort to the patient.

Third.—The lowering of the fulcrum pinion, the change in the shape of the fulcrum, and the altered direction of the lever render the instrument self-retaining *at all degrees of penetration.*

Fourth.—The fulcrum pinion is so modified that



it can be detatched in an instant, thereby rendering the instrument less bulky than an ordinary Sims, and, with the fulcrum thus detached, it is just as convenient and, on account of its flanges, even more efficient than the latter when used in the same manner for the simple purpose of inspection.

Fifth.—The lever buckle is but half the size of Erichs', is round instead of angular, and its tooth is at all times guarded.

It can be attached, disengaged, or the tension varied in an instant, it will never let go while at work, and will not get out of order.

The instrument can be adjusted as quickly as an ordinary Sims, except for the time required to pass the loop of the strap over the patient's left shoulder. This delay is much more than compensated for by the fact that the strap secures a more perfect extension of the spine, and therefore removes the necessity in nearly all cases of loosening the clothing about the waist of the patient. Moreover, the strap supports and rests the spinal muscles in this condition of abnormal tension.

After the strap is once buckled, it does not require to be changed in order to change the position of the blade in the vagina, for by lifting the fulcrum from its bearing on the sacrum, and drawing the tissues upward, downward, or laterally, the blade will assume the position required. The necessity for having the instrument correctly made cannot be too strongly urged, for a slight variation in the direction of the lever will render its use inefficient; but if correctly made it will work in all cases without subsequent change.

Tiemann & Co. have copied mine, and have shown me several of their manufacture, which imitate it exactly.

32 East Twenty-ninth Street.

ARMY NEWS

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from December 2, 1882, to December 9, 1882.

Moore, John, Major and Surgeon. The extension of leave of absence granted November 3, 1882, is further extended one month. Par. 4, S. O. 283, A. G. O., December 6, 1881.

Caldwell, Daniel G., Captain and Assistant Surgeon. Leave of absence granted in Special Orders No. 105, October 3, 1882, Department of the Platte, extended three months. S. O. 279, A. G. O., December 1, 1882.

Crampton, Louis W., Captain and Assistant Surgeon. Granted four months leave of absence. S. O. 280., A. G. O., December 2, 1882.

Gorgas, W. C., Assistant Surgeon. Relieved from duty at Fort Brown, Texas, and will accompany the Nineteenth Infantry to Forts Clark and Duncan, Texas. S. O. 130, Department of Texas, November 27, 1882.

Maddox, T. F. C, Assistant Surgeon. Relieved from duty at Fort Brown, Texas, and will accompany the Nineteenth Infantry to Forts Clark and Duncan, Texas. S. O. 130, Department of Texas, November 27, 1882.

Reed, Walter, Captain and Assistant Surgeon. Assigned to duty as Attending Surgeon, Headquarters Department of the Platte. Par. 2, S. O. 127, Department of the Platte, December 4, 1882.

Taylor, Marcus E., Captain and Assistant Surgeon. The leave of absence granted August 14, 1882, is extended two months. Par. 6, S. O. 283, A. G. O., December 6, 1882.

Gray, William, First Lieutenant and Assistant Surgeon. The leave of absence granted on surgeon's certificate of disability, October 31, 1882, Department of the South, is extended five months, on surgeon's certificate of disability. Par. 3, S. O. 278, A. G. O., November 29, 1882.

The Proper Vehicles for Absorption.—Dr. Vigier has observed as the result of a series of researches he has made on this point, that lard is the best fatty body when medicinal absorption is desired, vaseline coming next, and glycerine next. This last, therefore, is a bad vehicle when cutaneous absorption is in view, but an excellent one when we wish to avoid this; so that we may by its aid avail ourselves of the parasiticide action of corrosive sublimate without fearing the production of mercurial poisoning. —*Gaz. Hebdom.*

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending December 9, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Dec. 2, 1882.	0	8	26	1	32	51	0	0
Dec. 9, 1882.	0	13	42	5	42	34	0	0

Dr. Joseph Hearn and Dr. O. H. Allen have been elected surgeons to the Jefferson College Hospital, Philadelphia.

Bellevue Hospital has undergone its annual castigation at the hands of the Visiting Committee of the State Charities Aid Association. We are told that the plumbing, originally bad, is growing worse every year. Unpleasant smells pervade the wards in consequence, while the rats and mice make matters worse by gnawing away the rotten closets.

Malaria and Skin Diseases—A Correction.—Dr. Lunsford P. Yandell desires to be put right upon the matter of malaria and skin diseases. His views are the following: "Malaria is *the chief source* of *acute* skin disease. Scrofula is *the chief source* of *chronic* skin disease. The more inveterate cases of skin disease are often due to the co-existence of these two things. The specific exanthems, of course, are not included here." He adds: "The proofs of the truth of my views are, in the first place, that the diseases of the skin are cured more certainly and more quickly by the antimalarial remedies on the one hand, and by the antistrumous on the other, than can be done by any other line of therapeutics; and in the second place, that careful and painstaking investigation will, in the majority of dermatoses, make apparent the existence of the malaria or the struma, as the case may be."

Weekly Report of Sickness.—The *Sanitary Engineer* has undertaken an enterprise which will prove very useful to its readers and the public. It has arranged with the various dispensaries of the city to have a weekly report of the new cases of sickness that occur at these places. For the week ending November 18th, it publishes statistics from seven dispensaries. These show a total of 2,813 cases of sickness.

A Bill for Preventing the Spread of Contagious Diseases is to be favorably recommended to the Pennsylvania Legislature at its next session, by the committee to whom it was referred.

A Hospital at Dartmouth.—The Faculty of Dartmouth Medical College have bought a lot of land in Hanover, N. H., as a site for a hospital, and are now looking around for the money wherewith to build it.

A New Morgue is to be erected in this city soon.

The Body of Guiteau has not been made a skeleton of, says Dr. H. C. Yarrow. It will be produced and turned over to the proper owner whenever such person can be found.

A Policlinic in Philadelphia in connection with the German Hospital is likely to be established.—*Philadelphia Times.*

The Bogus Bellevue Medical College.—The Dean of the so-called Bellevue Medical College of Massachusetts, Dr. C. J. Eastman, has been arrested on a charge of using the mails to defraud. Dr. Noyes, the President, has also been arrested. It appears that a genuine certificate of incorporation was obtained in May, 1880. Many diplomas have been sold in this country and abroad.

A Higher Degree in Medicine.—It is proposed by the Faculty in Medicine, in Paris, to create a higher doctorate than the simple M.D. It will be a doctorate of medical sciences, and will be given only after special examinations, and, perhaps, only after special original work has been done.

America catches European ideas very quickly; perhaps we shall soon hear of a similar degree in this country.

The Annals of Anatomy and Surgery.—Few American medical journals have reflected more credit upon the profession than the *Annals of Anatomy and Surgery.* We are glad to learn, therefore, of its continued prosperity, and that during the coming year special arrangements have been made to add to the value of its issues.

Mr. Oscar Clayton, F.R.C.S., has been knighted in consideration of his services to the Prince of Wales.

Death from Oil of Tansy.—A servant-girl, living in Trenton, N. J., recently died from the effects of oil of tansy. It was bought for her by a young man who was "keeping company" with her, and was taken, it is believed, to produce abortion. Post-mortem examination showed, however, that the woman was not pregnant.

Dr. E. C. Seguin.—At a stated meeting of the New York Academy of Medicine, held November 16, 1882, the following preamble and resolutions, reported by a committee appointed by the President at a former meeting, were unanimously adopted:

Whereas, Dr. E. C. Seguin, an honored Fellow of this Academy, has been stricken with a domestic calamity so overwhelming as to paralyze him with despair, and so heart-rending as to command universal compassion; therefore,

Resolved, That the Academy of Medicine offer to Dr. Seguin the expression of its profound and respectful sympathy and commiseration.

Resolved, That, while the Academy regards with solicitude the effect which this tragic bereavement may have upon a useful and brilliant career, it will cherish the hope that Dr. Seguin may recover the spirit and the strength to return to his home, and to take up his work in the sphere in which he has already achieved wide and well-merited renown.

Resolved, That a copy of these resolutions, signed by the President and Secretary of the Academy, be forwarded to Dr. Seguin, and be published in the medical journals of this city.

Dr. J. Solis Cohen has been elected Honorary Professor of Laryngology in Jefferson Medical College.

Multiple Sarcoma of the Skin.—Dr. R. S. Harnden, of Waverly, N. Y., sends us the following: "I met with a patient a few months since whom I believe to be suffering from multiple sarcoma of the skin, or subcutaneous cellular tissue. The patient, Mr. F—— H——, an American, aged twenty-six,

residing in Waverly, N. Y., in fair health, came to my office June 2, 1882, complaining of a bunch below the right breast. Upon examinntion I found a tumor which seemed to be beneath and partially adherent to the skin, but not adherent to the ribs, appearing about the size of a small orange, and pressed outward against the skin, causing considerable pain. The apex, which was somewhat conical, was of the color of a purple plum or darker, and showed through the skin. The patient said he first discovered the bunch in January, 1882. I removed the tumor, and being struck with its peculiar appearance, and fearing it might be a malignant disease, I prepared a portion of it for microscopical examination, Dr. Edwin R. Stone, an expert in the use of the microscope, very kindly assisting me. We found the cells to be spindle-shaped mostly, and comparing exactly with a beautiful specimen of sarcoma procured by Dr. Stone in New York. The growth returned in one month, regaining one-half at least of its former size, whereupon I removed it again, dissecting out all the adjacent cellular-tissue to which it had been attached, and also an elliptic-shaped portion of skin over it, and to which it was firmly adherent, cauterizing the interior of the wound. It had not returned at that point, but after two months the patient returned to me with one tumor over the clavicle, about the size of a large tomato, raising the skin about an inch above the surface; also one in the right axilla, size of a small apple; one over the humerus at insertion of deltoid, size of an almond; one in left inguinal region, size of a very large tomato; and one quite small one in perineum, the appearance of the skin over all of them being normal. He had repeated chills, and, at times, considerable fever. September 5th I sent him to Drs. Wey and Squires, of Elmira, who confirmed the diagnosis, and also prognosis, which was unfavorable. The patient afterward went out of my hands, and from bad to worse, became very weak and had frequent chills accompanied with much prostration and emaciation. Finally he became icteric, the tumors turned purple, and he died."

Ladies' Doctors.—The decay of the curate and his supplantation by the ladies' doctor is the subject of a very clever and witty sketch which appeared recently in the London *World*. The writer's portrayal of the modern ladies' doctor is not in every point flattering, but there is much truth in it, and it is well to have a mirror held up before us occasionally. The day in which the curate ruled the drawing-room in its less intellectual corners is, says the *World*, rapidly passing away. Coincident with his decay is the rise in popularity of the ladies' doctor. This new luminary is a modern institution. A century ago, to be sure, says the writer, incomes as large as any of to-day were made by fashionable physicians; but these physicians were only "medical men," and held no social sway. "Astley Cooper and Abernethy were surgeons of weight and even wit, but their *brusquerie* made them more the terror than the darlings of a drawing-room, and men of their type were no more welcome in their non-professional capacity than are the plumbers after they have soldered a leaky pipe."

The writer follows with a sketch of what constitutes, or should constitute, the successful ladies' doctor of to-day—a person who is called upon to minister to weak nerves, feeble livers and the other incidentals to late hours and much caring for many things.

He must, we are told, be a skilful physician, perhaps, but certainly, and above all things, he must be a man of the world. "He must know the ways and the weaknesses of his clients, and not dream of playing the part of their moral instead of their medical mentor. Hence he is familiar with all the topics of the day, and yet is not pronounced on any one of them, for he is too wise to offend the patients by whom he thrives. He may know the winner of the Derby, but he must not be seen at Ascot and Epsom, and, though his coachman may drive the best of blood, it would ruin him were it reported that he had been seen behind a four-in-hand. He may write medical works—the more the better—but society is skeptical regarding omniscience. Sir Charles Bell's popularity fell off after he published his book on the hand. Yet art, being only an elegant amusement, may be pursued. Sir Henry Thompson collects china and pictures, and Mr. Seymour Hayden etches, while a good many doctors garden, as did Sir William Lawrence, without finding their practice suffer. The ladies' doctor must not be an atheist—society has not come to that yet, and women who are nervous are always pious—but unless he cultivates a Dissenting connection, experience proves that it is safest for him to keep to a strictly orthodox course, neither too Broad Church, nor yet with a suspicion of incense and the eastward position. For ladies with a taste for ritualism instinctively lean on the curate, and between him and his supplanter there can never be anything in common."

The above sketch shows only what every one learns very soon—that in order to be a successful and especially a fashionable physician, tact and worldly knowledge are the essentials; knowledge and skill are only useful supplements. Too much knowledge, especially if it be of a more purely scientific character, is likely, in this country, to call down the reproach that its possessor is not "practical." To offset the ladies' doctor of to-day however, we have the specialist, who can generally be as scientific and unworldly as he pleases.

Empyæma in a Child—Antiseptic Drainage—Recovery.—Dr. W. Wotkyns Seymour, of Troy, writes: "On March 30, 1882, I saw the patient, a female child, two years and eleven months old, in consultation. Ten weeks before the child had had an attack of scarlet fever, but had continued to run down after the period of desquamation had passed. At the time of my first visit the temperature was 103°, pulse 130 and weak, and the child very much emaciated. The abdomen was very prominent, the veins on the right side greatly enlarged; the right intercostal spaces were effaced, and only the left side moved on respiration. Percussion showed flatness from second rib to umbilicus in the mammary line. Auscultation, absence of respiration on right side, and puerile respiration on left. Diagnosis—effusion into right pleura, probably purulent. I introduced an aspirator needle just beneath the angle of right scapula, and drew off twelve ounces of thick pus, and advised permanent drainage. This was deferred by the attendant until April 5th, when I operated. It was my intention to excise a portion of a rib, so as to introduce a very large drainage-tube, and make or not a counter-opening, according to the apparent freedom of drainage. The incision was made in the eighth intercostal space, below the angle of right scapula. I opened the pleura, and found I could introduce a drainage-tube with a quarter-inch lumen without difficulty, and that it permitted a free discharge of twelve ounces of pus.

The chest was washed out with a lukewarm carbolized solution, and the drainage-tube, about four inches long, inserted. The tube was fastened in by a thread passed through it and tied around the body, and prevented from slipping by strips of Leabury & Johnson's rubber plaster. Over this, after the chest was again washed out, a thick layer of cotton, soaked in carbolic solution, was placed, and outside a thick layer of dry cotton, fastened down by a broad roller. The temperature for a few days was 104° and 105°, with a tendency to drop after each washing out of the chest, which was done daily with slightly carbolized lukewarm injections. After four or five days the child began to mend and eat and sleep better. The chest was washed out once a day, and quinine, cod-liver oil, and iodide of iron given internally. To cut a long story short, the larger tube was changed gradually for smaller ones, until finally strands of carbolized catgut replaced the tube. The middle of June the discharge had ceased, and the wound healed. The child had grown as fat as a seal, and on examination the lung had returned to its normal condition, as shown by the respiration, though there was a slight dulness of the side, which might be accounted for by the thickened pleura. When I first saw the patient it seemed almost a forlorn hope, and I am satisfied that nothing but free antiseptic drainage, and the careful and judicious attention of the attendant, Dr. Magee, who took charge of the case a week after the operation, could have saved the child's life."

A Case of Paroxysmal Hæmatinuria.—Dr. L. E. Borcheim, of Clifton, Arizona, sends us the following history of an interesting case which was admitted to the Mount Sinai Hospital of this city in 1881, while he was the house physician of that institution.

Upon his admission, December 22d, the patient gave the following history: F. C——, aged thirty-nine; Portuguese; sailor by occupation, but for the past five years, owing to his having been incapacitated by reason of his disease from seafaring life, now labors along shore. His appearance is that of a rather anæmic but muscular person, with a well-formed chest and medium-sized stature. Has always enjoyed good health with the exceptions that in 1861 he had yellow fever, and in 1869 had intermittent fever. This last attack lasted sixteen months, but since its cessation he has considered himself perfectly well until the beginning of the present trouble some five years ago. He then observed that upon his exposing himself to cold his urine would, as he supposed, become quite bloody, becoming, after a period varying from five to ten hours, normal again, and as it gave rise to but trifling and temporary inconvenience the patient gave it no further consideration. This condition obtained every winter for three consecutive years, and he began to be troubled with dyspnœa, which gave him some uneasiness. The fourth winter, while on board a vessel, and after having been exposed more than usual to cold, he was suddenly seized with a severe chill which lasted an hour or more, after which he felt greatly exhausted and unable to resume his occupation. In about an hour following the chill he passed urine, as he describes it, the color of "strong coffee;" later, upon passing water, it had the appearance of port wine, and at each subsequent micturition the urine appeared a shade lighter, until after ten hours it had resumed its normal appearance. The above described condition has obtained ever since, greatly weakening the patient, giving rise to extreme dyspnœa upon slight exertion, and he finally comes for advice and treatment.

Upon physical examination the heart and lungs were found normal and the spleen slightly enlarged. Urine, amber color; sp. gr., 1.014; acid, negative chemically and microscopically. Patient's temperature, 99° F.

The patient having shown no symptoms of bloody urine since his admission, he was, at the advice of Dr. H. N. Heineman, the visiting physician, warmly dressed, and on December 26th, it being quite a frosty day, sent out for a walk in the open air; returning in three hours he complained of chilliness. His temperature was immediately taken in the rectum, and showed 99.8° F., being one degree higher than it was previous to his chill. One hour after his return he passed urine, which upon examination gave the following result: Color resembling English porter; sp. gr., 1.036; acid, albumen present in large quantities; microscopically negative; spectroscopically hæmoglobin.

The urine tested subsequently gave similar results, quantities of abnormal ingredients diminishing. After a lapse of ten hours urine again became normal. Various methods of treatment were employed with quite unsatisfactory results. A tonic course of iron and quinine was persevered in with the view of improving the general condition rather than prevent the recurrence of the paroxysms.

An Important Medico-Legal Decision.—A decision of much importance was rendered by Judge Donohue, in the Supreme Court, recently. The question for determination was as to the effectiveness of physicians' certificates alleging insanity in cases where insanity has not been legally proved. Judge Donohue held that such certificates are not *prima facie* evidence of insanity, and that the persons who procured them are bound to support the certificates with testimony in the course of a legal inquiry as to the mental state of the alleged lunatic.

The law says that no person shall be held in a lunatic asylum upon physicians' certificates for more than five days unless the certificates shall have been approved by a judge of a court of record of the district in which the alleged lunatic resides. Before granting his approval the judge may, in his discretion, take proofs as to the alleged insanity. The usual practice of the judge is, however, to approve the certificates without delay, upon the assumption that the persons who procured them will not proceed until the mental unsoundness of the subject of the inquiry is definitely determined. There can be no good reason, therefore, that they should be held to be anything else than a warrant for temporary detention.

Broken Thermometers.—Dr. A. A. Lyon, of Shreveport, La., writes: "I feel assured that I echo the sentiments of no less than thousands of our medical brotherhood when I assert that another one of the many 'opprobria,' so to speak, of our profession is found in the frequent destruction, by breakage, of our clinical thermometers. The present writer purchased this afternoon the fourth one he has possessed within the past thirty days. I am not a reckless man, neither have I failed to exercise due care in the preservation of these valuable little instruments, yet I never unscrew the cap and lift my thermometer from its case without a feeling of slight perturbation lest I leave the lower half within. This latter was my experience yesterday. Such

has been my experience many times before, and such, doubtless, has been the experience of every physician who uses them. How, when, or where these fractures occur oftentimes cannot be even remotely guessed at; neither can we, under the present system, guard against their continued repetition.

"Such losses are pecuniarily burdensome, to say nothing of the inconvenience one experiences in finding his thermometer a wreck at a moment when he most needs it. Now, it is plain that this evil is in the main due to the existing style of cases. Does it not seem most irrational to place a delicate and fragile instrument of glass within a tube of guttapercha, almost as hard as flint, there to be rattled like dice in a box by trotting horses and jostling buggies, week in and week out?

"The conclusion, then, is manifest that the cases should be lined with velvet, or some similar material, and the thermometer fitted closely and immovably therein. There is a wide field for some inventive genius to devise a thermometer less easily broken than those now in use, but until this is done very much can be gained by the adoption of the common-sense suggestion just made. Will you not, in the interest of the profession, and through the columns of your able journal, endeavor to inaugurate this needed improvement?"

DIABETES.—Professor Lasèque, of the Hôpital de la Pitié, makes some new classifications of diabetics. He says that there are the great and small cases, the former passing over thirty grammes of sugar a day, the latter less. These two classes no not run into each other. There is also a class of "diabétiques fixés" in whom the amount of sugar does not vary much, no matter what the diet or medicine. M. Lasèque does not believe in rigid diets or in gluten bread. The cachexia is the principal indication for treatment.

THE EYE AND THE LIVER.—Dr. Litten tries to show (*Zeitschr. für klin. Medic.*) that retinal changes take place in various diseases of the liver. He found especially retinal hemorrhages in cases of catarrhal jaundice, cholelithiasis, carcinoma, cirrhosis, abscess, and acute yellow atrophy. In two cases of cirrhosis he found pigment degeneration of the liver. In nine similar cases he detected hemeralopia, without any evident retinal change. Directly after tapping in a case of ascites the patient developed a neuro-retinitis. The important relation which the liver bears in pigment-formation may have something to do with the conditions described.

THE NUMBER OF PHYSICIANS IN THE WORLD.—According to calculations made by the Medical Academy of Paris, there are at the present time 189,000 doctors scattered over the world. Of these there are 65,000 in the United States, 26,000 in France, 32,000 in Germany and Austria, 35,000 in Great Britain and its colonies, 10,000 in Italy, and 5,000 in Spain. Putting aside pamphlets and memoirs innumerable, it is estimated that 120,000 works have been published on medical subjects. Among the writers 2,800 are American, 2,600 French, 2,300 German and Austrian, and 2,100 English.

A STUDENTS' UNION SOCIETY has been organized among the London medical students and younger medical men. The Society has fixed quarters, which will be a place of meeting for all the various local student associations. The association will undoubtedly be a useful one.

INFLUENCE OF NICOTINE UPON THE GASTRIC SECRETION.—W. Auress, of St. Petersburg, found that subcutaneous injectons of one-twentieth to one-fifth of a drop of nicotine in dogs, increased the secretion of gastric juice sometimes even to seventy per cent. above normal. It is often stated that tobacco has an opposite effect. Dr. Auress found that quinine decreased and pilocarpine increased the gastric secretions.

THE UNTIMELY DEATH OF DR. E. EVETZKY.—Dr. E. Evetzky, formerly of this city, where he was well known as a talented and successful professional worker, met his death under very distressing circumstances. Several months ago Dr. Evetzky moved to Durango, Col., and entered into professional partnership with Dr. H. A. Clay of that place. On Sunday evening, December 3d, he suddenly entered his office and shot his partner and then blew out his own brains with the same revolver, dying instantly. Dr. Clay died the following morning. No difficulty is known to have existed between them until the day previous, when Dr. Evetzky received a severe cowhiding from a Mrs. Moore and a Miss Hawkins, who accused him of talking disparagingly about them. Evetzky was under the impression that his partner had something to do with his being cowhided, and this, it is thought, led to the shooting.

ILLEGAL PRACTITIONERS.—On Wednesday, December 6th, the President of the New York County Medical Society appeared before Justice Ford, at the Jefferson Market Police Court, and entered complaints against the following illegal practitioners: "Dr." John C. Adams, 29 Bleecker Street, not registered; "Dr." Geo. H. Schwab, 59 Bond Street, not registered; "Dr." F. E. Ruhrenberg, 80 Christopher Street, not registered; "Dr." William H. Fuller, 429 Canal Street, registered, but bogus diploma, not indorsed; Dr. Marini, bogus diploma, not indorsed.

THE NEW CODE AND HERKIMER COUNTY (N. Y.) MEDICAL SOCIETY.—"*Whereas*, The New York State Medical Society, at its last annual meeting, adopted a new system of ethics, in place of the code hitherto in force, for the guidance and conduct in practice of the medical profession in this State; and,

"*Whereas*, We believe that in making the radical changes therein contained they have placed us directly in conflict with the parent organization, the American Medical Association; therefore

"*Resolved*, That we, the Herkimer County Medical Society, hereby declare our continued allegiance to the precepts and ethical code of the American Medical Association, adopted June 5, 1847.

"*Resolved*, That the delegate to the State Medical Society be instructed to urge by all honorable means the repeal of the existing code."

MEDICO-LEGAL SOCIETY OF NEW YORK.—The following officers have been elected for the ensuing year: *President*, Clark Bell, Esq.; *Vice-Presidents*, R. O. Doremus, M.D., and D. C. Calvin, Esq.; *Secretary*, L. P. Holmes, Esq.; *Treasurer*, J. Shrady, Esq.

THE LIVER-PAD OUTDONE.—An exchange tells of a doctor in Iowa who has invented an anal pad, by which the fæces are changed into gas, and the gas is deodorized, purified, and burned as a chamber light. It acts on the same principle as a liver-pad, and if worn over the mouth sweetens the breath, prevents cursing and swearing, and destroys the appetite for tobacco.

Original Lectures.

ON THE TREATMENT OF CROUP.[1]

By PROFESSOR DUJARDIN BEAUMETZ,

MEMBER OF THE ACADEMY OF MEDICINE; PHYSICIAN TO THE HÔPITAL ST. ANTOINE, PARIS, FRANCE.

Part II.

I now pass to the description of the slow methods. Here we proceed layer by layer, and the incisions are made with a deliberation and a slowness which necessitate that the child should be held perfectly still, and that there should be a sufficient light. You must have good assistants (these are sometimes difficult to find when you are with your little patient alone, or almost alone, in the country). First, then, obtain suitable assistants, so that your young patient may be held fast on the operating-table. I say *table* with intention, for you can operate best with your patient extended on a table, which should be strong and firm. Place under his neck a small hard cushion, which makes prominent the neck in front. Let one of the assistants hold the head firmly, another putting his hands upon the shoulders of the child should keep him fixed immovably upon the table, a third should take charge of the pelvis and the lower extremities, and all struggling should be rendered impossible. Finally, opposite you, and on the left of the table, you place the colleague or assistant on whom you are to depend for the most important services, such as sponging the wound, keeping it wide open by means of dilators, and illuminating the field of operation.

Trousseau placed great stress on this illumination, and advised the use of candles instead of bougies, as the former give a stronger and steadier light. The operation for croup is often performed in the night time, and the operator ought to have a good view of the tissues which he successively incises.

All these preparations are of the utmost importance, and you ought, gentlemen, never to commence the operation of tracheotomy till you have fully instructed each of your assistants in his respective duties. I have, in fact, seen the operation very badly done here in this city, and even left unfinished, because all these little details had not been attended to with promptitude and exactness.

For instruments, you want two bistouries, one of which should be probe-pointed; hæmostatic forceps, threaded needles, ligatures, a pair of retractors,[2] then the dilators and canulas.

It is understood that the patient shall not be put under ether. In Germany anæsthesia is practised; in France we never resort to anæsthetics, for sufficient reasons. Furthermore, in a great number of cases your patient is pretty thoroughly anæsthetized by the asphyxia under which he is laboring, so that he can very well support the pain of the operation.

Then you take your scalpel, and you make in the median line of the neck, just about the middle of the trachea, an incision which comprehends the skin and cellular tissue. As for the height to which this incision should be made, there exist different procedures, which are three in number: the super-cricoidean, the inter-cricoidean, and the infra-cricoidean processes. In the first process the incision is made on the crico-thyroidean membrane; in the second on the cartilage; in the third, which is the process of Trousseau and Bretonneau, the first rings of the trachea are divided. As far as possible, you ought to avoid making the incision of the skin and tissues too near the base of the neck, for the lower down you go the more blood-vessels of considerable size you are sure to find, and the greater the danger of serious hemorrhage.

Moreover, I cannot too strongly recommend you, gentlemen, to have fresh in your minds the surgical anatomy of the region on which you are going to operate.

You make a straight incision of suitable length in the median line; you cut through, layer after layer, the aponeurosis and the muscular interstices, and you come down to the trachea. As soon as you get a clear view of the rings of the trachea, fixing the latter firmly with your finger, you perforate the trachea with your bistoury, taking care not to go too deeply, and you cut, with the same bistoury, or with the probe-pointed bistoury, the three first rings of the trachea. Then, without removing the index finger of your left hand, using this as your guide, you introduce the dilator into the wound which you have made. The air escapes with force and a hissing noise, and the child respires freely; you sponge the wound carefully, let your little patient sit up, and wait a little while before passing to the last part of the operation—the introduction of the canula.

In the first stage of tracheotomy two kinds of accidents may supervene; on the one part hemorrhages on the other symptoms of asphyxia. The more turgescent the venous system, the more frequent and alarming the hemorrhage, but by your hemostatic forceps you can sufficiently arrest these venous hemorrhages, and even those which are produced by section of the thyroidean arteries; moreover, these hemorrhages cease promptly with the restoration of respiration. It has been proposed, in order to avoid hemorrhage, to perform tracheotomy with the thermo-cautery. Krishaber is one of the most determined partisans of this method. If the thermo-cautery offers advantages in constituting the operation a bloodless one, it offers serious inconveniences; it extends its destructive action beyond the limits traced by the operation, and gives rise to considerable sloughing, which renders the wound large and formidable. It is also likely to excite violent tracheitis. I opine, then, that, except in the case of adults and in exceptional cases, tracheotomy by the thermo-cautery should be discarded.[1]

---

[1] Translated from advance sheets by E. P. Hurd, M.D., Newburyport, Mass.

[2] [Dr. A. Caillé, of New York, has described a very ingenious tracheal retractor in The Medical Record, Vol. XX., page 724. It consists of a rubber band, at each end of which is fastened a short brass chain, and attached to the latter are two curved and sharp hooks. This retractor keeps the edges of the wound well apart; it may be hooked into the fascia as the several layers are divided, and finally into the tracheal wound. The trachea may be examined at leisure, and there need be no haste in getting the tube into its place.]

[1] Amussat, in 1870, was one of the first to apply galvano-canterization to tracheotomy. This method has since been employed by a great number of physicians. But it was found to be poorly applicable to the operation for croup, for the galvano-cautery demands a special apparatus, which it is difficult to obtain in an operation of urgency. So galvano-canterization was abandoned. De Ranse and Maron have advised to employ bistouries heated to a red heat, and St. Germain has employed a similar process.

Since the discovery of the thermo-cautery of Paquelin, this apparatus has been exclusively employed in the practice of tracheotomy, and the Societé de Chirurgie has discussed its application to this operation.

By the thermo-cautery you avoid hemorrhage—this seems to be its principal advantage. St. Germain and Pauly have shown that the eschars produced by the cauterization have considerable dimensions, making the wound a troublesome one to deal with, and even Krishaber now reserves the operation for adults (Amussat, Bull. de Ther., 1872, p. 472: Bourdon, Tracheotomy by the Thermo-Cautery, Arch. Gen. de Med., 1873: De Ranse and Maron, Gaz. Méd., 1874, etc.).

Apropos of hemorrhages, you will do much to avoid them by carrying your scalpel straight in the median line, and by taking pains that there shall be no involuntary deviation to the right or left. You will thus keep out of the way of the principal blood-vessels. The carotid even has been incised by a bungling operator. A high division of the innominates has sometimes been an element of danger.

As for the accident of apnœa with impending death, it is of frequent occurrence during the operation. It results from the hindrances opposed to the circulation (already profoundly troubled) by the position of the child, and especially by the immobilization of the trachea; immobilization absolutely necessary at the moment when you incise the tracheal parieties. If this accident happens to you, you must terminate the operation in haste, and by insufflations made through the wound endeavor to recall the child to life. In fine, there is another cause of asphyxia, it is the escape of blood into the trachea; you can combat this complication by aspirating the effused liquid through a female catheter introduced into the air-passages.[1]

The operation has been performed on children in such a state of asphyxia that they were like veritable corpses, and Trousseau used to take pleasure in relating the story of his patient whom he resuscitated.

The introduction of the canula constitutes the second stage of the operation, and this is, I must say, the most difficult part of tracheotomy. This difficulty results partly from the emotion of the operator, partly from the incessant hawking of the patient, who expels by the tracheal opening, blood and pseudo-membranous *débris*, in fine, from the tracheal wound itself, which when it is not made exactly on the median line, is not easily adapted to the introduction of the canula.

Therefore it has often happened that the canula has been placed in the peritracheal cellular tissue, and it has even been forced into the œsophagus. To escape these inconveniences, dilators have been multiplied. Laborde, Meunier, Lüer, etc., have invented instruments more or less perfect, which all have this inconvenience, that their branches, when introduced into the trachea, take up considerable room, and diminish the opening by which the canula should be passed. In certain cases, it has even been proposed to dispense with dilators, and to introduce the canula directly into the trachea, or to precede the introduction of the canula by the passage of a hard-rubber sound, to serve the purpose of a guide. I cannot advise you as to the best dilator to use, for in my opinion the best instrument for a surgeon to use is that which he is used to.

There are very many kinds of tracheal canulas; the perfection which has been attained in these instruments has contributed largely to the success of tracheotomy, and the invention of the double canula has rendered the dressings relatively easy and satisfactory.[2]

These canulas, which you proportion to the age of the child, are fastened around the neck, then with sticking-plaster or collodion you take care to protect the circumference of the wound and the inferior part of the neck from the mucosity which escapes each instant by the mouth of the canula.

In fine, you surround the neck of the patient with a little thin muslin or gauze, which filters the air before it enters the tracheal orifice. The child is then carried to its bed, made warm by bottles of warm water, and the third stage of tracheotomy begins—I refer to the dressings.

If tracheotomy has enabled the surgeon to recall to life the croupy child, it is only by the consecutive dressings that he can save the patient, where such a thing is possible. Hence the care and pains which these demand. They consist in the frequent removal of the inner canula, and in changing the entire canula, when occasion requires; also in medicinal pulverizations.

Whenever the canula becomes obstructed, and you will know this by the loud noise made during breathing, you need to take out the inner movable canula and cleanse it, or, leaving it in place, remove by means of a small pair of curved forceps the mucosities and pseudo-membranous *débris* which are in the trachea. Or you may mop it out with suitable swabs.

You ought early to remove the entire canula; this is a capital point in the operation. After the second day it is proper to make this change. Now the introduction of the canula, which was so difficult at the time of the operation, becomes an easy matter, for it has already made for itself a lodgement in the trachea.

The next day you again remove the entire canula, and you take advantage of the opportunity to close the tracheal opening, and thus test the permeability of the larynx. You repeat this process every day, taking care to prolong each day the time during which you leave the canula out, in order that in from five to seven days after the operation the child may be able to breathe through the natural passages.

The medicinal pulverizations, by means of steam apparatuses, render us great service all this time. Having no longer the larynx to traverse, these vapors penetrate profoundly the air-passages, and modify the state of the mucous membrane. You ought, then, to make free use of these pulverizations, and atomizations[1] of chlorate of potash. In fine, an alimentation the most tonic possible, and alcoholic potions are administered to the child.

Such is the operation of tracheotomy; let us see now what results you are to expect from it.

Tracheotomy, as you see, is directed to a symptom, viz.: the asphyxia resulting from the presence of false membranes in the larynx; it has not, remem-

[1] [W. Pugin Thornton has had a syringe made for the withdrawal of membranes or blood from the trachea, different sized flexible nozzles can be adapted to the syringe. In cases of hemorrhage, Trendelenburg's tampon canula may be adapted to Durham's right-angled tube; with the india-rubber bag of the tampon canula distended, blood is prevented from passing down the trachea. The syringe may be of use after the tampon canula is adjusted, to assist in withdrawing the blood which has already passed down into the bronchi (*Vide* Lancet, September, 1881, p. 274., Am. Rep.).—Tr.]

[2] In the infancy of the operation a canula with trocar was used; the trocar was withdrawn after puncture of the trachea, and the canula left in place. In this way Santorio performed tracheotomy. Bretonneau first employed a straight, then a curved canula. Trousseau, following the advice of an officer of the artillery, on whose daughter he operated, made use of the double canula, which enabled him to cleanse the instrument with facility. Lüer gave this canula a bevelled extremity, and made the wings of the canula moveable. Boardillat's canula is composed of two valves which close like a speculum, and which open when they are introduced into the trachea.

According to Lüer, the diameter of the internal canula should be seven millimetres for a child up to three years of age; eight millimetres for a child from three to five years; nine millimetres for a child from five to ten years; ten millimetres for a child from ten to twenty years. For adults the canula should have a diameter of from twelve to fifteen millimetres.

[1] In Germany great account is made of atomized liquids after tracheotomy. These pulverizations have the advantage of keeping the canula always moist, and rendering the frequent removal of this instrument less necessary. Besides the vapor of warm water, some (as Barthels) employ a one per cent. solution of common salt; Fitzau, a weak solution of salicylic acid (one-half per cent.); Pauly, Eidam, and Benson prefer lime-water (aqua calcis), as being the best solvent of false membranes.

ber, the slightest influence on the march of the diphtheria. It simply enables the patient to live pending the abatement and disappearance of the general affection. This first consideration goes to show that the happy results which have been claimed for tracheotomy are in direct relation with the malignity, greater or less, of the diphtheria. When the disease is benign you will save a good many patients, when it is grave you will save only exceptionally a case, and what I have just said finds a striking confirmation in the statistics of the last thirty years.

Trousseau pretended that half the patients were saved. When I was interne of the Hôpital Sainte-Eugénie, in 1860, we saved one patient in four or five. To-day the proportion is still less, and it is as much as ever if we save one patient in six or seven. There are even disastrous periods, as that of last year, when we saw—whether at the Hôpital des Enfants, Rue de Sèvres, or at the Hôpital St. Eugénie—almost all our tracheotomy patients die.[1]

These results do not imply that the treatment is less judicious to-day than it was thirty years ago. This is not the case. They simply indicate a greater malignity of the disease. This shows you once more what I cannot too much impress upon you, that statistics applied to therapeutic methods do not alone enable you to judge of the value of those methods. Moreover, consult the numerous statistics published in the important work of Sanné, and you will see that all arrive at this result; that on an average you may expect one recovery in every five or six tracheotomies.

Another preponderating influence affecting the results of diphtheria is the age of the patients. It may be affirmed that below two years of age recovery is exceptional after the operation. It is now six years that I have been physician of the Hôpital St. Antoine, it is now six years that I direct the service of the "Crèche" [Infants' Hospital], where we receive, as you know, no infants above two years of age, and during all these years we average twenty cases a year of tracheotomy for croup. Very well, we have yet to observe a single case of recovery! This does not mean that children under two years of age cannot be cured, and several writers, and particularly Revillaud of Geneva, have cited several examples. Scoutteten operated with success on his own little daughter aged six weeks, but these are extraordinary cases.[1] Authorities are agreed that the chances of success are the greater the older the child who is the subject of the operation;[2] I say child, for in the case of the adult the chances of recovery diminish.

In order to render the results of tracheotomy more favorable, authorities have attempted to formulate with extreme care the indications and contra-indications of the operation. You will see, gentlemen, that in spite of the numerous tentatives which have been made in this direction, we have no positive data forbidding tracheotomy. Whenever croup manifests phenomena of asphyxia you ought to operate. There are really no contra-indications, for the most serious cases, where all the contra-indications seem grouped together, may get well.

It has, in fact, been said that when the diphtheria tends to invade the nasal cavities, and especially the bronchi, it is no use to operate. This is not so. I have seen children recover after the operation who were affected with both nasal and bronchial diphtheria, and the latter to such an extent as to discharge by the tracheal wound, false membranes that were perfect casts of the bronchial tubes.

It has been said that in the last stage of the disease, and when the child is ready to succumb, it is useless to operate. This, again, is contrary to the facts, for the annals of croup are full of observations

---

[1] We have no reliable statistics of tracheotomy in France of a date prior to 1839. At this epoch, in a discussion which took place in the Academy, they reckoned 138 tracheotomies, and 29 recoveries—1 in 4.75. In 1844, 212 operations were reckoned, 40 recoveries—1 in 5.3. From 1849 to 1858, at the Hôpital d'Enfants, there had been 466 tracheotomies and 120 recoveries, about one-fourth; at the Hôpital St. Eugénie, 198 tracheotomies and 38 recoveries, or 1 in 5.

In the great discussion which took place in 1858 respecting catheterization of the larynx and tracheotomy, Trousseau showed that out of 186 operations there had been 73 recoveries, or 1 in 2.54.

The statistics published by Sanné, at the Hôpital St. Eugénie and the Hôpital des Enfants Malades, show that on an average, from 1864 to 1875 there had been 2,312 operations at St. Eugénie, with 509 recoveries, or 1 in 4.54. At the Enfants Malades, from 1851 to 1875, there had been 2,351 tracheotomies for croup and 644 recoveries, or 1 in 3.82.

Note, moreover, that since these last years, and especially since 1873, the mortality from tracheotomy seems to have increased, for in 1873 recoveries were only 1 in 6.48 at St. Eugénie, and 1 in 4.76 at the Enfants Malades.

Archambault has made independent statistics in these two hospitals for the term of years included between 1866 and 1879, and this is the result which he has obtained: At the Hôpital Enfants Malades, 1,513 tracheotomies and 335 recoveries, or 1 in 4.5; at St. Eugénie, 2,154 operations and 454 recoveries, or 1 in 4.6.

In Portugal, according to Sanné, tracheotomy has given better results—21 recoveries out of 59, or 1 in 2.80.

In Spain tracheotomy is only exceptionally practised.

In Belgium (Hospital St. Peter in Brussels), from 1870 to 1875, out of 38 cases there were 8 cures, or 1 in 3.50.

In Switzerland, according to the statistics of Billroth, Revilland, d'Espiné, Picot, and Rapin, 148 tracheotomies and 57 recoveries, or 1 in 2.59.

In Germany, according to the statistics of Bartels, made at the Grand Hospital of Bethanie, from 1861 to 1872, out of 385 tracheotomies there were 105 cures, or 1 in 3.25; and, according to the total statistics given by Sanné, out of 812 operations there were 297 recoveries, or 1 in 2.97.

In England the results of the statistics of the hospitals give 1 recovery to every 5 cases. Statistics of private practice in the cities speak more favorably for the operation—60 recoveries out of 185 tracheotomies, or 1 in 3.86.

In America, according to the statistics cited by Sanné (Traité de Diphtherie), and borrowed from the memoir of J. Solis Cohen, of Philadelphia, out of 325 cases of tracheotomy performed in America, there were 84 recoveries, or 1 in 4.86.

The following are Kroenlin's statistics of tracheotomy, account being here rendered of the results of surgical treatment of diphtheria from 1870 to 1876, at the surgical clinique of Langenbeck: Children of one year and under, a mortality of 84 per cent.; children of eight years, 44 per cent.; adults, a mortality of 25 per cent. Total mortality of tracheotomy, 78 per cent. 11 out of 85 under two years recovered. The youngest infant that got well was six months.

When the operation is put off to too late a period, the mortality is 99.9 per cent. In the greater number of cases the canula can be removed the fifth or seventh day. A good many patients, however, die after this epoch.

All the operations of tracheotomy were peformed with the bistoury. The incision was in every instance made at the upper part of the trachea. Chloroform was employed in every case where asphyxia was not imminent (Kroenlin: Diphtheritis and Tracheotomy, Arch. für Klin-Chirurg., Vol. XXI., fas. 2, p. 253, 1877).

[In this connection it is proper to call attention to the valuable papers on Tracheotomy in Croup by Dr. John H. Ripley, published in this journal for 1880, Vol. 18. The results of Dr. Ripley's statistics are rather more favorable—*i.e.*, twenty to thirty per cent. of cases reported by him recovered. Dr. Ripley considers tracheotomy always a justifiable procedure in croup if the paramount feature in causing death be apnœa.—Tr.]

---

[1] [To the instances on record (only seven or eight) of successful tracheotomy where the patient was under two years, we must add the recent operation performed by Dr. George F. Shrady, of New York, on an infant eleven months old. The child recovered after a severe struggle with the disease. Vide MEDICAL RECORD, November 4, 1882, p. 512.—Tr.]

[2] That the chances of recovery after tracheotomy are generally in the ratio of the ages of the patients is apparent from the following tables:

(*a*) Jacobi of New York, sixty-six tracheotomies, thirteen recoveries, ages as follows:

Age.	Tracheotomy.	Recoveries.	Percentage.
2 to 3 years.....	5	1	20
3 to 4 years	16	3	16
4 to 5 years.....	23	7	30
5 to 6 years.....	7	2	28

(*b*) Hôpital des Enfants Malades, Paris:

Age.	Tracheotomy.	Recoveries.	Percentage.
1 to 2 years.....	10	1	10
3 to 5 years.....	359	68	18
6 to 10 years.....	122	68	55
11 to 15 years.....	3	0	0

when tracheotomy has produced a veritable resurrection. It has been said also that in malignant diphtheria it is of no use to operate. This is very generally the case, for the whole organism being poisoned by the virus, the individual dies before false membranes have had the time to invade the larynx, and if there are asphyxiating phenomena, they are due to tumefactions of the glands, and the dyscrasic condition of the blood; the indication for tracheotomy is wanting. As you see, there are no contra-indications, properly speaking; all that you can say is that the chances for tracheotomy are more or less favorable according to the age of the child, the extent of propagation of the false membranes, the morbid genius of the epidemic, and finally the period of the disease when the operation is performed.

In fact, the period chosen has much to do with the success of the operation, and if it is not well to wait till the last stage of the malady, it is well not to be too hasty, for croup is susceptible of spontaneous recovery. Here then is, in brief, the line of treatment which I advise.

When you are in the presence of a patient affected with croup, you commence by giving an emetic, with directions to have it renewed when the urgency of the case shall demand; you also order pulverizations with chlorate of potash or antiseptic solutions; you watch carefully the temperature and respiration of the child; you keep informed by these and other particulars as to the state of the circulation, and you have care to maintain as tonic a regimen as possible; then if you observe that in spite of this medication, the attacks of dyspnœa become more frequent, the temperature rises, the oppression augments, the child takes on the pale, leaden hue of slow asphyxia, *then* it is your time to intervene.

These rules apply to every case whose evolution you may have been able to follow from the commencement to the moment of your intervention. But when you are called in during the asphyxiating period of croup, you ought to forewarn the family that surround you, and anxiously await the result of your examination, that tracheotomy gives the only chance of life to the patient. You should add, moreover, that the chances are doubtful at the best, and yet, that they may expect for a day or two, at least, from the operation, a real relief and amelioration.

I have just shown you, gentlemen, how tracheotomy should be performed. I ought, in concluding, to indicate the complications that may follow the operation. These complications are of several kinds. Some result from the wound which you have made in the skin and trachea, others from propagation of inflammatory or diphtheritic trouble to the lungs.

As for the first, you will occasionally see phlegmonous erysipelas, ulcerations of the skin and of the trachea—all complications of greater or less gravity, which will claim at your hands earnest and minute attention.

As for the second, it has been maintained that tracheotomy predisposes to broncho-pneumonia. This is, I believe, an affirmation which lacks proof, for when this operation is performed in cases that are not diphtheritic, it is rare to see phlegmasia of the lung supervene. It is then to the diphtheritic disease that we must attribute the greater part of those secondary broncho-pneumonias, which we so often see ensuing in the final periods of the malady.

After having operated on your patient by tracheotomy, after having by a most precise and careful treatment cured the laryngeal diphtheria, do not take for granted that all is done. Another series of accidents may supervene which will still put the life of your patient in jeopardy. These tardy complications of diphtheria are of different sorts. I have already spoken to you of the paralysis,[1] so grave, which may accompany diphtheria; I will add albuminuria, and all the evil consequences which it brings. In fine, I will mention the exuberant outcropping of granulations on the tracheal cicatrix, and which produces in certain cases, as Peter and Krishaber have shown by examples, asphyxia and sudden death.

These considerations, gentlemen, terminate what I wished to say *a-propos* of croup and its treatment. As in my lectures on pleurisy and pleuritic effusions, I dwelt at length on thoracentesis and the operation for empyema, so in this lecture I have deemed it for your interest to devote the larger part to tracheotomy. I know too well, from having experienced them myself, the anxiety and the hesitation which the young practitioner experiences when called to face emergencies such as I have described. He ought to be guided, encouraged in the course which he should take, and this is what I have endeavored to do in describing thus minutely the operation of tracheotomy. But let him be assured, and with these words I desire to finish, that whatever may be the skill with which he performs the operation, however great his zeal and devotion in the consecutive treatment, his success will not so much depend on his exertions as on the nature of the epidemic which prevails at the time of the operation.

A Convenient and Delicate Test for Albumen.—Dr. A. W. Abbott, of Minneapolis, Minn., sends us the following description of an easy and delicate method of testing albumen:

"Pour a few drops of urine gently down the inside of a glass vessel containing acidulated water at the boiling point. If albumen be present a more or less dense cloud will form just at the dividing line between the fluid tested and the clear water above. As the contrast in opacity is between the clear water and the milky albuminous cloud, the test is very delicate, one-twentieth of one per cent. of albumen making a very perceptible clouding. It has all the advantages of the ordinary heat and acid test and Heller's nitric acid test. It is even better than the latter in a cloudy fluid as in urine, with urates in excess, because the clear water above makes a perfect medium in which to detect the faintest cloud, while the layer of coagulated albumen in Heller's test may be entirely obscured by the opacities in the fluid itself. If no test-tube or nitric acid is at hand, pour boiling water into a common tumbler, let it stand a moment to ensure the heating of the bottom of the tumbler, empty, refill, acidulate with *vinegar*, and proceed as before. While this is a modification of the heat and acid test it has the advantage of being applicable under all possible circumstances, whether special apparatus is at hand or not. It is as convenient and accurate in the farm-house as in the laboratory."

---

[1] Diphtheritic paralysis, and in particular that which affects the pharynx, is a grave complication in the case of tracheotomized children. It not only prevents feeding, but we have even seen, in certain cases, foods and drinks pass out by the tracheal wound. Several measures have been proposed to obviate this inconvenience. Perin advises to place the patient on his abdomen and make him swallow his nourishment with his face toward the floor. In these cases the most efficacious way to feed the child is by the stomach-tube of Faucher.

ON ABSTRACTION OF BLOOD FROM THE RIGHT HEART,

As a Means of Relieving Intense Pulmonary Congestion.

By BENJ. F. WESTBROOK, M.D.,

LECTURER ON ANATOMY AT THE LONG ISLAND COLLEGE HOSPITAL; PHYSICIAN-IN-CHIEF TO THE DEPARTMENT FOR DISEASES OF THE CHEST, ST. MARY'S HOSPITAL, BROOKLYN.

About a year ago, while engaged in the demonstration of the anatomy of the thoracic viscera, it occurred to me that in a case of very acute and intense pulmonary congestion, with over-distention of the right side of the heart, it would be practicable to withdraw a quantity of blood directly from the heart, and so restore the equilibrium of the lesser circulation.

In order to have some exact anatomical data for the discussion of the question of the accessibility of the organ and the determination of the proper point for puncture, I have made, during the year, a series of dissections of bodies of those who have died of various diseases. Though my observations are not yet sufficiently numerous to justify their publication, they have been carried far enough to enable me to describe a mode of procedure which may safely be undertaken by any one who is competent to make an ordinary physical exploration of the chest.

The *right auricle* is the most available point for tapping, inasmuch as its position is less variable than that of the ventricle, and its accessible portion more globular, with a greater antero-posterior diameter to allow of free penetration of an instrument without danger of its passing through into the posterior wall. As an additional advantage, the walls are thinner than those of the ventricle, and not beset by the projecting fleshy columns and papillary muscles which exist in the latter.

In order to determine the best point for puncture I have measured the extent to which the auricle projects beyond the right border of the sternum in the different intercostal spaces, its perpendicular depth from the anterior surface of the sternum at its right edge, the amount of overlapping of the anterior border of the right lung, and the course of the internal mammary artery and vein. The variation in regard to all these points except the last is very considerable in different subjects, and under different conditions of circulation and of the respiratory organs; but I am, nevertheless, enabled to state, with a considerable degree of certainty, the following propositions:

First.—The right auricle projects to the right about equally in the third and fourth intercostal spaces.

Second.—Its perpendicular depth varies greatly, according to its distention and the condition of the left heart and lungs.

Third.—The projection to the right is greatest, and the perpendicular depth least when the right heart is distended, as in death from coma and asphyxia.

Fourth.—The internal mammary vein, which lies upon the sternal side of the artery, is very constant in its course, and situated, on an average, about one centimetre external to the right border of the sternum.

Fifth.—The anterior border of the right lung almost always extends inward beyond the border of the sternum, reaching, or even passing the median line in many subjects.[1]

An instrument inserted into either the third or fourth intercostal space, at the right edge of the sternum, and carried directly backward in a plane parallel to the median plane of the body, will, after piercing both layers of the pleura and the lung, enter the pericardium and penetrate into the right auricle. This would occur in almost any thorax when the heart was not displaced by pressure from pleuritic effusion, contraction of the lung, or other similar conditions. I say *almost any*, because, in one case of marked emphysema, with a depressed diaphragm[2] the upper limit of the auricle was at the middle of the third interspace.

The conditions alluded to as displacing the heart are all readily diagnosticated by those skilled in auscultation and percussion.

The third interspace is better suited for the puncture, for two reasons: first, because it is much wider than the fourth, and the needle passes with less difficulty; second, because the line of the fourth would direct the needle more toward the auriculo-ventricular opening, where it might come in contact with the tricuspid valve. The necessity for going directly backward, in a line parallel to the median plane, will appear further on.

The pressure in the right auricle, in cases of considerable obstruction, though it *departs* from the normal negative standard, does not rise sufficiently to be relied upon to force blood out through a small canula with any degree of rapidity, hence it is necessary in introducing a tube to have it connected with a vacuum chamber, in other words, it is necessary to operate by means of aspiration.

When these points were satisfactorily settled, a further question arose, as to the danger of leakage, occurring from the orifice of puncture.

This was deemed improbable, on the ground of experimentation and of comparison with the results of puncture of other hollow viscera. As I was anxious, however, to avoid every possible risk of increasing the peril of any patient, I chose for the subject of the operation, which I am about to describe, a case in which all chance of recovery had disappeared.

The patient was a German, fifty years of age, the father of a family of healthy children. He had always been strong, though not plethoric, was very temperate in his habits, and had not been sick for twenty years. On November 10th, he had a slight chill, followed by fever and severe lancinating pain in the right side. He sent for the family physician, Dr. Paul H. Kretzschmar, who attended upon him, and from the above symptoms, and a loud friction sound, diagnosticated an acute pleurisy in the lower portion of the right chest. On the following day the rusty sputa of pneumonia appeared, and on auscultation, bronchial respiration was found in the upper portion of the right lung. But, though the apex was the seat of the most active pneumonic inflammation, the pulse was full and bounding, the delirium active, and the fever of the sthenic order. As hepatization occurred, the fever did not abate, but the disease steadily advanced. The rusty sputa

[1] While these propositions are based upon actual dissections, I claim no originality for them, as they are mainly confirmatory of the observations of other anatomists, though no one, as far as I know, has investigated the subject from the same standpoint.

[2] The term *depressed* diaphragm is partly relative; the change of position is largely due to elevation of the ribs.

continued to be quite copious until the 15th, when they diminished materially, and the cough became less frequent and less effectual.

On the 15th, Dr. Kretzschmar requested me to see the patient with him, as he had become alarmed by the persistence of the severe symptoms, as well as by the fact that the respiratory murmur upon the left side was becoming rough with an occasional moist râle. On the morning of the 14th, the temperature had been at 102° F., the pulse 132 per minute. In the evening the temperature had risen to 104°, pulse 140, and respiration 28. On the morning of the 15th, the temperature was 101½°, pulse 134, respiration 27.

At six P.M., when I first saw him, the record was temperature, 103¼°; pulse, 140; respiration, 28. The breathing was very labored, and loud, mucous râles could be heard from any part of the room. The countenance was anxious and the mind wandering. The pulse was of fair strength and regular. On examination of the chest, we found dulness on percussion over the entire *right* side anteriorly and laterally, most marked above the fourth rib. Typical bronchial respiration extended from the clavicle to the third interspace, while, below, there was a mixture of large and small moist râles and friction sounds. The *left* side presented the usual evidences of compensatory respiration, viz., increased resonance, and exaggeration of the vesicular murmur, together with some roughening in places, and a few moist râles. The cardiac impulse was strong, the epigastric pulsation well marked, and the distention of the right side so considerable that its movements could be felt in the third and fourth right intercostal spaces. The second sound over the pulmonic area was very much accentuated.

As the patient was a man of vigorous frame, bearing the struggle well, as shown by the force of the heart, and the slowness of the labored respirations, we concluded that, though very serious, his condition was not hopeless, and endeavored by stimulation, nourishment, and counter-irritation to help him to recover the equilibrium of his circulation. He was ordered the following mixture:

℞. Ammon. carb..... ʒij.
Tr. digit..... ♏xlviij.
Tr. opii..... ♏xij.
Tr. nuc. vom..... ♏xvj.
Aqua. menth. pip..... ʒj.
Sig.—One teaspoonful every hour.

He was also to have a tablespoonful of brandy every hour.

On the following morning, at 9.30, we found him in much the same condition, only a little weaker; temperature, 100¼°; pulse, 128; respiration 36. The temperature and pulse had fallen somewhat, but the respirations were more rapid and noisy. He coughed but little, and expectorated a little tough bloody mucus. However, as the heart retained its strength and the temperature was lower, we still had a slight hope, and continued his treatment with the addition of a little more alcoholic stimulant.[1] At 2 P. M. I saw the case in Dr. Kretzschmar's absence. He had lost perceptibly since morning. The temperature was 101½°, pulse 140, respiration 45, and very labored. Moist râles were increasing upon the left side, and the breathing was harsh and indicative of considerable bronchial congestion. His pulse was still remarkably strong, but quick and nervous with an occasional intermission. The respiratory muscles kept at their task with remarkable vigor, but the struggle was evidently hopeless. It was plain that there was no longer any chance of recovery, nevertheless I hesitated to attempt any operation in the absence of the physician in charge, though Dr. Kretzschmar had signified his desire that I should do whatever seemed best. Accordingly I ordered ten drops digitalis to be given every hour in addition to his other medication. On my return at 6.30, the pulse had risen to 150, respiration 40. and there was no sign of improvement.

After consultation with my friend and assistant, Dr. Emilio Buchaca, who accompanied me, I proceeded to attempt the aspiration of blood from the right auricle with a view to unload a part of the burden under which the heart was staggering. We used for the purpose one of Codman's aspirators, manufactured by Geo. Tiemann & Co., selecting the finest needle, which was about twice the calibre of an ordinary hypodermic needle (.75 mm.). The instrument worked well, and a good vacuum was secured. The needle was then warmed over the chimney of a student lamp, and passed through the third intercostal space. close to the edge of the sternum, to the depth of about five centimetres, when it communicated to the hand the sensation of being in the auricle.

The sensation referred to is that familiar to every surgeon, by which we know that the point of the instrument has passed into a cavity or fluid; with the addition of the motion of the auricle, which causes the needle to move slightly to and fro with the pulsations of the heart. The stop-cock connecting with the vacuum was then turned, but only a few drops of blood fell into the bottle. Thinking that I might be mistaken as to the whereabouts of the needle, I passed it a little farther, when it entered a hard substance that felt somewhat like soft spongy bone, or calcareous matter, and its point began a series of such active movements that it was evident that it had punctured the aorta. It was withdrawn a little way and replaced in the auricle, but though the suction was increased by more pumping, only about a drachm of blood was abstracted, and finally, not daring to leave the needle longer in the heart, for fear of coagulation upon it, I discontinued the operation. The introduction of the needle, which was very sharp, occasioned no more pain than does that of the hypodermic syringe, and its entrance into the heart was accompanied by no unpleasant symptoms; indeed, the heart's action did not seem to be affected at all When the aorta was punctured the patient complained of a feeling of distress in the sternal region, and remarked that he thought I had struck a bone.

The failure of the operation was due to two causes: first, in order that the needle should impinge as squarely as possible upon the convex auricle, I directed the point a little inward, which caused it to penetrate at the base of the auricular appendix, and, when more deeply inserted, to perforate the latter and strike the outer side of the aorta. The second cause of failure was that the needle selected was too small, and the blood could not be delivered very rapidly through it, so that it coagulated in the rubber tube above.

I hesitated to repeat the operation at once, but preferred to wait a sufficiently long time to see if the first attempt was to be followed by any bad effects. After waiting half an hour, and observing none, I took my departure, promising to return

[1] The brandy ordered the night before had not been regularly administered.

later in the evening. At seven o'clock Dr. Kretzschmar called and found the patient much as I had left him; pulse, 150; respiration, 40. There were no sensations referable to the puncture. At 10.45 P.M. we saw him together. The pulse was 144, respiration, 44. We determined to make another attempt at local bleeding, as a *dernier ressort*. I selected a needle, the outside diameter of which was 1.5 mm. This was thoroughly cleaned, heated over the lamp chimney, and introduced through the third intercostal space, directly backward, till, at a depth of about 5 ctm., it was free in the cavity of the auricle. The cock was then turned and the blood ran freely into the bottle. No pain or distress was experienced during the operation. After abstracting a little over three ounces of blood I withdrew the needle. It was followed by a few drops of very dark venous blood. A towel was applied to the spot for a moment, after which there was no further oozing. Five minutes after the operation the pulse was 150; respiration, 40. At the end of half an hour the pulse was 148; respiration, 40. The character of the pulse, however, was somewhat changed; instead of the quick, hard, nervous beat, it was softer and less irritable; there was no intermittence. When asked how he felt, he simply said: "I feel better." We then ordered him the following prescription and withdrew:

℞.	Ammon. carb.	ʒ iss.
	Tr. digitalis.	ʒ iiss.
	Tr. nucis vom.	ʒ ss.
	Tr. opii.	♏ xxiv.
	Spts vini rect.	ʒ iij.
	Tr. cardam. co.	ʒ iiss.
	Syr. pruni virg.	ad. ʒ vj.

M. Sig.—One tablespoonful, in water, every hour.

Dr. Kretzschmar saw him at seven o'clock on the following morning. The friends said that he had been more comfortable during the night than for the three or four days previously, so much so that they had begun to entertain hopes of his recovery. Dr. Kretzschmar, however, was unable to confirm their hopes, for on auscultation he found numerous moist râles in the left lung, which was becoming œdematous. The pulse at this time was 138, and the respiration 38 per minute.

He remained in about the same condition until half-past ten, when he suddenly became restless, rolled over to the back of the bed, rose up on his elbow, and fell back dead.

The autopsy was made on the following day, thirty hours after death. On examination two minute spots, indicating the points of puncture, were found in the skin at the side of the sternum in the third interspace. The deeper layers of the skin, superficial fascia, and pectoralis major were infiltrated with blood in a district one-fourth of an inch in diameter.

The costal and visceral pleuras, three-fourths of an inch from the anterior border, also bore a slight blood-stain about one-half inch by three-fourths of an inch. The slight hemorrhage had come from a small branch of the internal mammary vein, which ran inward toward the sternum (perforating branch). On the posterior surface of the edge of the lung there was a slight roughness at a point corresponding to the mark of puncture on the anterior surface, bnt no distinct trace of the passage of the needle could be discerned. Immediately below this point on the mediastinal pleura were two minute red dots, one about one centimetre nearer the median line than the other. These dots were about five millimetres in diameter, but the inner one was a little the larger. The inner surface of the parietal pericardium presented two dots corresponding to these just described. On the auricle it was impossible to identify the site of penetration unless by comparison with the spots on the pericardium, except that corresponding to the innermost spot there was a very indistinct roughness of the surface, as if from a slight scratch. This was at the base of the auricular appendix. Drawing the appendix outward, I found in the outer side of the aorta, near its base, a round, dark-red mark three millimetres in circumference in the adventitia. This was, no doubt, the place where the needle struck the aorta after piercing the auricle. No corresponding mark could be found on the inner coat. The pericardium contained from three to four fluidounces of thin serous fluid of a dark claret color. It was not distended, as its anterior portion lay in contact with the right ventricle. Along the inferior border of the heart lay a filament of coagulated fibrin one and one-half inch long and very narrow. Its color was a pinkish white. A thin, membraniform, pinkish white coagulum was spread out upon the anterior surface of the right auricle, in its lower and internal half, extending into the auriculo-ventricular groove, where it became thicker and darker. The whole amount of coagulum might have represented two or three drachms of blood, at a very liberal estimate, but my impression is that some of it was due to inflammation, for the right side of the pericardium adjacent to the inflamed pleura showed some thickening. We were, however, unable to make any microscopical examination of the fluid, owing to the difficulties attending the getting and making of the autopsy. All the cavities of the heart were distended with black clots, which occupied the venæ cavæ, pulmonary veins and artery and aorta. In the right ventricle we found a small, whitish coagulum clinging to the columna carneæ, but not extending into either the auricle or pulmonary artery.

The upper lobe of the right lung was passing into the stage of gray hepatization. The pleura, over the entire surface was very red and thick, though masses of coagulated lymph covered its surface below the second rib. The base of the lung was almost black, partially collapsed at the periphery, and covered by thick curdy masses, such as are found in the most acute and pronounced pleuritis. This condition also extended to the mediastinal pleura. There was very little fluid in the pleural sack. The left lung was universally adherent from an old pleurisy. It was dark, and oozed black blood upon section. The bronchi contained a good deal of frothy muco-pus, slightly tinged with blood.

The important points established by this operation are: in the first place, that the right auricle may be readily aspirated, and secondly, that the introduction of a canula into its interior is not accompanied by any alarming symptoms, or followed by any unhappy results. I am convinced, that had the operation been done earlier, say on the 14th or even on the 15th, and had a larger quantity of blood been removed, the prospects of recovery would have been greatly enhanced. But, as already remarked, I did not feel justified in making the first attempt upon any one who had the slightest chance of recovery. The reason for withdrawing the needle before a larger quantity of blood was abstracted, was that, although it would be perfectly safe to leave the instrument in the heart of a healthy animal for a much longer

time, I was not sure that the blood of the pneumonic subject would not coagulate upon the needle, but at another time I should not hesitate to leave it long enough to withdraw at least eight or ten ounces.

The length of time the needle remained in the heart was not ascertained, but it was probably not over half a minute.

The slight amount of leakage that occurred was undoubtedly caused by the first puncture, when the needle was moved to and fro by the pulsations of the aorta, and allowed of oozing by its side. At the second trial the needle was held firmly in one place, and I do not think that there was any leakage.

ON THE TREATMENT OF CONGESTIVE HEADACHE.

By J. LEONARD CORNING, M.D.,

NEW YORK.

If we examine the literature of our theme we are astounded by the apparently hopeless confusion in which the whole is involved. Everywhere attempts at ill-founded generalization are encountered. We are compelled to admit, after perusing long debates in regard to the relative merits of various therapeutic measures, that those who were foremost to disparage the treatment pursued by others, were totally ignorant of the fact that those same symptomatic manifestations which they were considering might be owing to entirely different causes from similar conditions described by others. Hence a commensurate modification in therapy might not only be admissible, but eminently desirable. It is more especially of recent years that a laudable attempt to differentiate the various etiological factors involved in different forms of headache has been made. In 1832, Dr. James Mease, of Philadelphia, published a monograph on "The Cause, Cure, and Prevention of the Sick-Headache," which is substantially a treatise on the dietetics of this particular form of headache. The work, however, is conspicuously lacking in those philosophical qualities which are so necessary to a true understanding of the questions involved. Dr. E. H. Sieveking published in 1854[1] a most interesting paper on "Chronic and Periodical Headache." The views therein expressed are remarkable for their succinct and thoroughly scientific elucidation of the two great physiological principles involved in the consideration of by far the greater majority of instances of cephalalgia. I refer namely to the importance ascribed by this eminent physician to the fluctuations of the blood-stream within the cranial vault. In speaking of this subject Dr. Sieveking says: "Nothing is of more importance in reference to the pathology and therapeutics of the head than clear and well-defined notions on the physiological subject of the circulation within the cranium; for, among the various sources of medical scepticism, no one is more puzzling or more destructive of logical practice than a contradiction between the doctrine of physiology and the daily practice of medicine."

What Dr. Sieveking said in 1854 holds equally good to day; and, indeed, the position then taken has received substantial indorsement through the positive results of more recent experimental physiology. Conspicuous in this connection are the inductive researches of Durham, Fleming, and Hammond, touching the modifications in the cerebral circulation during sleep and wakefulness. By these experiments it has been conclusively proven that the amount of blood in the brain is decreased during sleep and increased during wakefulness. More recently I have had occasion to confirm the experiments of Fleming in this direction, and have published the results of those researches in various papers and articles.[1] "What Hippocrates said of spasm," says Dr. Sieveking, "that it results either from fulness or emptiness, or, to use more modern terms, from hyperæmia or anæmia, applies equally to headache; but, to embrace all the causes of this affection we must add a third element, which, though most commonly complicating one of the above circumstances, is not necessarily included in them, namely a change in the constitution of the blood." While I agree with Dr. Sieveking as regards the importance to be ascribed to the first two factors —cerebral hyperæmia and anæmia, in the production of the group of symptoms known as "headache" —I fail to perceive why especial prominence should be given to the third condition mentioned by Dr. Sieveking. Indeed, I am quite unable to imagine how the periodical, and more especially the intermittent form of headache, is to be explained by what Dr. Sieveking describes rather ambiguously as a "change in the constitution of the blood." It is quite evident, admitting that such a change is capable of producing an amount of cerebral irritation sufficient to develop well-marked cephalalgia, that the latter must of necessity be within certain limits continuous. This is not the case, as the causative factor is constant and not fluctuating. I am, therefore, not prepared to accept this third causative factor, without question. Nevertheless I am perfectly willing to admit that other factors besides cerebral hyperæmia and anæmia may produce the functional variety of headache. There would seem to be ample ground for ascribing great causative importance to excessive irritation of the brain plasma itself. Hence, those forms of headache which, while being unaccompanied by any especial circulatory derangements, succeed, oftentimes, with relentless regularity upon any considerable degree of mental work. It is not my purpose to discuss the treatment of the multifarious forms of cephalalgia on this occasion, did time permit. As regards the so-called "neuralgic" variety, I must content myself by referring to the admirable work on "Neuralgia and Kindred Diseases of the Nervous System," by Dr. John Chapman of London, in which will be found many interesting facts bearing on the question. Accepting the propositions, then, that the more adjacent causes of headache are, (1) cerebral hyperæmia, (2) cerebral anæmia, and (3) irritation of the cerebral plasma itself, let us now consider how these morbid factors are most scientifically and speedily met at the bedside; and how, more particularly, those distressing conditions of engorgement, which are so baneful an item in the causation of a certain form of cephalalgia, are best overcome.

Two years ago I began a series of experiments on epileptics and maniacs, which involved the application of protracted pressure to the common carotid artery on both sides. In the course of these experiments the thought suggested itself that suppression of the carotids might prove a salutary means of reducing that form of cerebral congestion

[1] On Chronic and Periodical Headache, by E. H. Sieveking, M.D., Medical Times and Gazette, London, August 12, 1854.

[1] *Vide* Carotid Compression and Brain Rest, by J. L. Corning, M.D. New York: Anson D. F. Randolph & Co.

which is so prolific a source of headache and vertigo. Accordingly I made a protracted series of experiments with carotid compression upon those suffering from congestive headache, and I can only say that I have been so far pleased with the uniformly good results obtained, that I have felt it a duty to call the attention of the profession to a procedure which, for obvious reasons, possesses all the advantages of local depletion by leeching or cupping, without the manifest disadvantages of either of these methods. The instruments which I have devised as substitutes for the primitive procedure of digital compression of the carotids have already been described in former communications. It is only necessary to say that the implements in question are of two kinds: one, the "carotid fork," is an adjustable instrument, which being held in the hand of the operator, permits him to exert any degree of pressure upon both carotids for any desired length of time. The other instrument, which I have designated as the "carotid truss," for lack of a better name, is a circular spring provided with adjustable pads at each extremity. The spring is placed about the neck of the patient, and by suitable appliances the pads at the extremities can be placed directly above the trunks of the two common carotid arteries. By turning the screws to which the pads are attached the desired amount of pressure can be applied to the arteries, and the apparatus can be worn for any length of time by the patient.

With these instruments I have frequently succeeded in arresting the most obstinate form of congestive headache in an incredibly short time (on one occasion in about five minutes). Where, however, the headache is of manifestly nervous origin and uncomplicated by any especial circulatory derangements, I have never been able to achieve notable results with this method. Indeed, pressure upon the carotids is an excellent method of differentiating the congestive form of headache from the nervous varieties of head-pain.

Of galvanism this much may be said, that it is one of the most valuable methods which we possess for treating the form of headache under consideration, for not only does it cause contraction of the smaller arteries, but it also exerts a soothing influence upon the plasma of the brain itself.

A powerful therapeutic agent, and one which has been more or less extensively employed in the treatment of various forms of head and spinal symptoms is cold.

A very excellent method of applying both cold and galvanism to the head, at the same time, is afforded by a species of refrigerating electrode, designed by myself for this purpose. The apparatus in question consists of a concave sponge electrode, the concavity of which corresponds to the convexity of the external aspect of the cranium. Above the electrode is a chamber of metal or india-rubber, designed to contain ice. The whole is secured to the head of the patient by a single chin-strap, and connection established with an ordinary galvanic battery by means of an appropriate clamp and insulated cord. The indifferent pole is applied over the sternum or other convenient point. Care should be taken not to employ too strong currents, as otherwise vertigo and other unpleasant symptoms may be produced. An application of from five to ten minutes is usually sufficient to arrest the head-pain. As an additional security it is well to recommend the patient to take a hot foot-bath, and to remain as quiet as possible for twelve hours succeeding the treatment. In hyperæmic headache cupping and blood-letting have been recommended; but as a rule both procedures are not only unnecessary but positively inadmissible, as exclusion of the superfluous amount of blood by compression upon the carotids, followed by a corresponding dilatation of the peripheral circulation by means of the foot-bath, will almost always be sufficient to cause a permanent cessation of the symptoms. Among the internal remedies which may be employed with good effect, in certain cases are, aconite, bromide of potassium, and Indian hemp. The inhalation of from five to ten drops of chloroform is an excellent expedient in some instances. Chlorodyne, which is nothing more than a mixture of sedatives, often works well, and indeed frequently excels other remedies. The regulation of the heart's action is also of very great importance in these cases, and the physician should have no hesitancy in resorting to such remedies as digitalis and belladonna for the purpose of reducing the tension in the domain of the cerebral circulation. As a matter of course the digestive functions should be carefully looked to; the bowels should be kept open, and in all cases where there are indications of a congestive origin, alcohol in all forms should be absolutely forbidden.

A CASE OF LITHOLAPAXY,

INCLUDING THE CRUSHING AND REMOVAL OF A PHOSPHATIC CALCULUS, AND THE CUTTING UP AND REMOVAL OF ABOUT SIX INCHES OF AN ENGLISH WEB CATHETER.

BY HOLT C. WILSON, M.D.,

PROFESSOR OF SURGERY, WILLAMETTE UNIVERSITY, PORTLAND, OR.

MR. B——, farmer, aged forty-two, a resident of Washington Territory was admitted to the Good Samaritan Hospital, some time in June, 1882, and gave the following history: About one year previous to admission was struck across the back by a falling tree, and as an immediate result of the injury became paralyzed in the lower extremities, with accompanying paralysis of bladder and rectum. The patient was given a No. 8 English web catheter by a physician, who, living at a distance, could not attend regularly, and instructed in its use. After some time the catheter became cracked and rotten, and one day, about four months after the injury, while in the act of withdrawing it, being accidentally jolted, it broke short off, about one inch from the meatus, leaving in the canal from four to six inches of its length.

Efforts on the part of a physician and others to seize the stump, failed, and during the manipulations, the instrument slipped into the bladder. From that time on Mr. B—— suffered more or less acutely from cystitis, the bladder being already in an unhealthly condition from insufficient drainage. From time to time, previous to admission, bits of phosphatic deposit and fine shreds of catheter had been passed, the bladder gradually regaining power, rendering micturition possible.

Exploring with a Thompson's stone-searcher, I touched a calculus immediately. Bearing in mind the friability of the catheter, I felt assured that with a proper lithotrite, I could cut it into pieces, after crushing the stone. On experimenting with a piece of rotten catheter, using Thompson's litho-

trite, found that it would cut it into three pieces, one piece dropping to either side and the other passing through the fenestrum. The operation was unavoidably postponed for three weeks, until Bigelow's apparatus could be sent to me, patient's condition in the meantime became bad, and somewhat alarming. Had at intervals severe rigors and high fever, urine also greatly decomposed and fetid. Condition improving somewhat, determined to operate without further delay, so, July 25th, patient was etherized and placed on the table, and in the presence of several physicians, who rendered important assistance, I proceeded with the operation. Found that a curved catheter, No. 27 French, would pass; divided the meatus in the hope of passing a No. 31 straight catheter; but the urethra would not admit it; hence used the No. 27 curved. After washing out the bladder with a strong solution of borax, leaving in about three ounces of fluid, I introduced the lithotrite, seized the stone with no difficulty, the jaws of the instrument showing the diameter to be three-fourths of an inch. After moving the instrument gently from side to side, and finding the movements free, screwed the blade home, crushing the stone easily, and cutting the catheter as with a knife. No clogging whatever. It (the catheter) could be recognized by the elastic resistance at first offered, followed by a sudden giving way. Seizing the different fragments as rapidly as possible, crushed as before. After twenty minutes the lithotrite was withdrawn and catheter introduced, much *débris* dropped into the bottle, calculus material and pieces of the catheter, incrusted; slight amount of blood also. Reintroduced the lithotrite, divided other pieces and washed as before. Nothing more being discovered by the instrument, and the water coming clear from the bladder, operation was suspended. More time was consumed than ordinarily required, because of the difficulty experienced in seizing the oblong oval pieces after the calculus material had been worked off. Patient then put to bed, and ten grains quin. sulph. ordered morning and evening. No bad symptoms ensued, and patient was up and about in his perambulator after three days, feeling, as he expressed it, perfectly well. In a week from date of operation I washed out the bladder with the evacuating apparatus, in order to be certain that nothing remained, and discovered the presence of a remaining bit by the characteristic click against the end of the catheter, as the force of the water in returning carried it against it. So without etherizing the patient, introduced the lithotrite, and succeeded in seizing this remaining piece after a little manipulation, divided it once, withdrew the instrument, and the two fragments came out through the catheter into the bottle at the next washing, clearing the bladder of its unwelcome visitor. At this date, November 10th, the bladder is in a normal condition, urine clear, no traces of catheter or calculus could be discovered in repeated washings.

Result shows what can now be accomplished by litholapaxy in cases formerly requiring lithotomy.

THE CAUSE OF SICK-HEADACHE.—The fact long known to the profession, that errors in visual refraction may cause sick-headache, is now being widely circulated again. Hypermetropia and astigmatism are the things that most often have to be corrected.

Progress of Medical Science.

TETANUS FROM SLIGHT CAUSES.—Two cases of fatal tetanus, induced by slight injuries, are reported in the *Maryland Medical Journal* of October 1, 1882. The first case is related by Dr. H. J. Berkeley. The patient, a strong healthy man, forty years of age, was vaccinated in January, 1882. A few days later, after exposure to cold, the arm became swollen and inflamed. Three weeks after the vaccination had been performed symptoms of tetanus appeared and continued to increase in severity for several days, until death ensued. The second case, reported by Dr. R. B. Davy, was that of a woman suffering from a uterine polypus. Dilatation of the os was effected by means of laminaria tents, and the new-growth was removed by the curette. Four days later the patient experienced some uneasy sensations about the throat, tetanus set in, and death resulted within one week after the insertion of the tents.

PRURITUS ANI often proves a most annoying and obstinate symptom, persistently refusing to yield to our therapeutic endeavors. It is therefore quite comforting to be assured that we have in two well-known drugs, two equally efficient specifics. Thus Dr. Steele, of Denver (*Lancet and Clinic*), has found quinia sulphate, rubbed up with only sufficient lard to hold it together, a never-failing specific in this affection. He uses it in both pruritus ani and vulvæ. The nearer you get to the full strength of the quinine the more efficacious it will prove. And some other physician is similarly confident about the local application of Peru balsam. Hence there can now be no more troublesome itching about the anal aperture, and medicine has achieved a new triumph.

THE CARDIAC RHYTHM.—M. Dastres has forwarded a note to the Paris Académie des Sciences, describing his researches undertaken with the object of finding an explanation of the laws which determine the beat of the heart and its periodic variation. M. Marey has shown that cardiac excitability, which disappears during systole, reappears during diastole. The causes of these variations are: 1, pressure of the blood on the walls of the heart; 2, the action of the intracardiac nerves; 3, the action of the extracardiac nerves. M. Dastres concludes, from his observations, that the period of repose observed after every systole and diastole is independent of muscular action, and is determined by the action of the intracardiac nerve apparatus, which regulates the beat of the heart.

SOME OBSERVATIONS ON ALBUMINURIA.—From a study of numerous cases of the various forms of Bright's disease, seen in private practice, Dr. A. V. Meigs concludes: 1. That in no ordinary, uncomplicated case of Bright's disease should a prognosis of speedy death, or even of incurable disease be given, for he has observed cases in which the disease was chronic, lasting more than two years, and which ended in complete recovery, and others in which the person affected has lived nearly nine years. 2. That dyspnœa, usually taking the form of renal asthma, is much more common than is usually supposed, and, when properly appreciated, is a valuable diagnostic sign of the disease; also that severe coryza is a complication or accompaniment, and has a diagnostic value. 3. That Bright's disease, as a cause of death, is on the increase. 4. That it is a very common cause of the death of old people,

probably being the direct cause in many deaths reported as of old age. 5. That the passage of gravel, even when microscopic in size, but particularly if large enough to cause nephritic colic, is a prolific cause of the disease. 6. That the occurrence of tube-casts in the urine, without, or in advance of, the presence of albumen, is very common, and *vice versâ*, persons may die of Bright's disease, and the most careful examination fail to show any tube-casts, although there may be albumen constantly present in the urine. 7. That the abuse of alcohol is certainly a cause of kidney disease is proved by a case in which it has again and again caused hemorrhage from the kidney, with the temporary presence of albumen and tube-casts in the urine, disappearing again with the cessation of its consumption.—*Boston Medical and Surgical Journal*, November 2, 1882.

A Case of Proctitis caused by Two Hundred and Thirty-five Prune-stones is related by Professor Fuerbringer in the *Deutsche Med. Wochenschr.*, No. 10, 1882. A woman was admitted into the hospital in June, suffering with alleged "syphilis." This diagnosis had been made on account of a monstrous ring of inflamed varix nodules studded with flat ulcerations, situated in the anus. Involuntary thin evacuations, slow dyspeptic symptoms, and general marasmus; bedsores were also present. Finger introduced struck upon hard, sharp-edged body. Ninety-eight prune-stones were chiseled out by the finger, and the next day 137. Last October, suffering with hunger, she begged for bread, but in vain, and happened to see a large quantity of prunes; swallowed the fruit, with the stones. Eight weeks later 235 stones were removed from the rectum. Woman was well in six weeks.

The Therapeutic Use of Soft-Soap.—From a large experience with the use of soft-soap, Dr. Beetz (*Ærztliches Intelligenz Blatt*, 1882) concludes that this agent is of decided value in many cases of subcutaneous suppuration, glandular inflammation, and similar affections. A whitlow, if not already too far advanced, yields very promptly to the influence of warm applications of spiritus saponis kalinus. This preparation is a solution of two ounces of green soap in an ounce of alcohol, to which, after filtration, are added two drachms of spirit of lavender. An elegant preparation is obtained by dissolving the soap in eau-de-Cologne. But one of the most satisfactory affections to treat is bubo. And since Beetz has introduced this treatment, he has never found it necessary to treat buboes otherwise.

For the last nine years his treatment in certain other affections has been as follows: For chronic glandular indurations or abscesses in places in which it is difficult to apply dressings, he uses inunction in the evening with green soap, which is washed away the next morning and repeated during three or four days, with a subsequent interval of a day or more, according to the sensitiveness of the skin. For acute glandular inflammation, whitlows, and abscesses in easily accessible positions, linen rags are steeped in spirit of soap, applied to the part, and covered with gutta-percha paper. These dressings must be accurately applied if they are to fulfil their object. For example, in inflammation of the inguinal glands, a good result can be expected only if the surgeon himself fixes the dressing with a spica bandage and safety-pins, not leaving it to the skill of the patient himself. There will be, not a tedious suppuration but a very small abscess, with little or no trouble in walking (as there will be no infiltration). A number of other more serious diseases are enumerated in which, it is stated, a similar mode of treatment has been successful. Professor Senator also considers that soft-soap has fallen undeservedly into disuse (*Berl. Klin. Woch.*, No. 38, 1882). He has used inunctions of soft-soap in numerous cases with most distinct benefit, viz., in chronic non-scrofulous glandular swelling, in indolent syphilitic glandular swelling, and in serous exudations, including the exudations in synovial cavities. He cannot come to a definite conclusion as to the *rationale* of its action, whether it is the massage employed, or the irritation produced, or the alkali absorbed. But the fact of the increased absorption under this treatment he considers undoubted.

Action of Salicylic Acid upon the Skin.—Dr. Unna (*Monatshefte für pr. Dermatologie*, i., 4) recounts his experience with this drug. It is a sure remedy for the removal of the normal or pathological epidermis without pain in a whole, non-desquamated membrane. It would be interesting to determine whether such an action is caused through the medium of the acid upon the epidermis itself. The displacement always takes place in the epidermis, and is deeper the stronger the concentration of the acid and the denser the epidermis. The author has never seen a wet surface after the removal, but one covered with so small an epidermis that its shiny surface seemed deep red, and proved very painful to the touch. In all kinds of callosity, with or without papillar hypertrophy, in syphilitic and non-syphilitic psoriasis of the volar surfaces of the hands and feet, in aggregations of squamæ of every source, salicylic acid is the most pleasant and surest keratolytical remedy, as it is inodorous, painless, and colorless, and does not irritate the surrounding tissues. The total removal of the epidermis can only take place with the contemporaneous use of other substances which soften the epidermic cells. The collodium of salicylic acid is an efficient remedy. The application of a ten per cent. ointment with a gutta-percha covering acts well also. But evidently the simple application of gutta-percha-tissue covered with salicylic acid ointment of five to twenty grammes, according to the thickness of the horny layer, is the most efficacious. The bandage lies undisturbed for four to eight days, when it can be taken off like a glove. Salicylic acid ointment is therefore the best corn-plaster.

Aspergillus in the Ear.—Dr. Charles H. Burnett reports a case of the rare form of the parasite, the aspergillus glaucus, in the *Medical News* of November 4th. The patient was a lady, aged thirty, living in the best of hygienic surroundings, who had felt for a long time an itching in the ear, to relieve which she had repeatedly and imprudently scratched her auditory canals with hair-pins, etc., and irritated the skin of the ear. The itching was followed by lancinating pains at long intervals, some watery discharge, and a muffled sense of hearing. The walls of the meatus of each ear became swollen and the ears tender in front of the tragus. On the left side, the first attacked, the process of growth in the fungus and the inflammation had been arrested apparently by the patient's forcing, in her manipulation of the ear, some cerumin inward upon the fungus, showing what Dr. Burnett has already called attention to, that aspergillus will not flourish in or upon healthy cerumen. Underneath the ear-wax, however, the perfect aspergillus was found preserved, but arrested in growth. In the right ear the fungus

was in active growth upon the membrana tympani, its favorite habitat, and the inner end of the auditory canal. These parts were deeply injected, sensitive to the gentlest touch, even with cotton on a probe, excoriated, and exuding serum. The sides of the meatus, too, were swollen, and the ear in front of the tragus sensitive. Dr. Burnett's treatment in such cases consists in first syringing the ears gently with warm water, in order to remove as much as possible of the mycelial false membrane, which may come away as a glove-finger coat of the fundus of the auditory canal and membrana tympani. Then into the ear there is blown pulverized boracic acid. Should it subsequently be found that some spots of the false membrane still remains, there may be blown into the ear a powder consisting of salicylate of chinoline, ʒ i., boracic acid, ʒ i. Under this treatment, on the third day, the left ear had become normal in every way, and on the sixth day the right ear was well. Dr. Burnett thinks it is well to allow some of the boracic acid to remain over both drum-membranes and the inner end of the auditory canal about the membrana tympani, in order to sterilize the region and render it unfit for the growth of the fungus. Alcohol is now no longer employed by this author as a parasiticide in these cases.

Chinolinum Tartrate.—Dr. Carl Rosner (*Prakt. Arzt*) writes: Chinolinum, a constituent of coal-tar as well as the Dippel's tar, was introduced into medicine as a substitute for quinine a short time ago. The tartrate is the only preparation adapted for internal use. It is found in silk-like shining crystals. If at the start it must be conceded that quinine will not be displaced by the new preparation, it deserves, nevertheless, some attention and further trial on account of its antiseptic and antisedative effects, and the more so as the price of this article is five times less than quinine. The tartrate of chinolinum is used in single doses of from five to fifteen grains. The daily maximum dose for an adult at present is placed at ʒ ss. Children of five to ten years receive the third part of the adult dose. Rosner has ceased to use this remedy in practice of children, however, on account of its nauseous and disagreeable taste. On the other hand, in adults he recommends emphatically chinolinum in febrile diseases, and has obtained excellent results in the treament of pulmonary phthisis. The formula which he employs is as follows:

℞. Chinolin. tartrat ..... gr. 45
Ext. Cinchon. ..... gr. 135
M. Ft. pil. No. xx.

D. S.—Two pills every two or three hours (thus 0.3 (gr. v.) per dose). Under some circumstances, as in phthisis, an addition of opium (0.005 per pill) can be recommended. A good way of administering the pill is in a boiled prune.

Lycoperdon as a Hæmostatic.—Dr. E. Thompson, of the Tyrone Infirmary, writes to the following effect: Some months since, I directed attention to the use of the puffball as a hæmostatic and surgical dressing. My attention was first directed to this substance in the case of a poor woman who had suffered for a long period from an open cancer of the right breast. I visited this patient, and ascertained that she had tried almost every form of surgical dressing without being in the least relieved either of her sufferings or the constant hemorrhages which weakened her. In despair she sought the aid of a country quack, who suggested the use of the puffball, or *lycoperdon giganteum*, which grows close to the roots of trees in some of our woods. From the day the patient commenced the use of this substance her sufferings were greatly mitigated, and she improved in health and strength. The frequent bleeding ceased, and the foul odor from the sore was greatly diminished; and the poor woman lived in comparative comfort for seventeen years after the first appearance of the cancerous ulceration. The puffball is a most soft and comfortable surgical dressing, and the powder it contains seems to possess antiseptic and anodyne properties. When mature and fit for use it is almost as large as a man's head; it is enclosed in a thin capsule which must be removed, it can then be torn in pieces and used either as a styptic or for applying any required surgical dressing. It is, however, its hæmostatic properties that seem to me to be so especially valuable; it has the power of stopping instantly even the most violent external hemorrhages upon which iron, matico, turpentine, etc., have been tried in vain. A leading surgeon in Belfast told me that when removing a large tumor from the neighborhood of the orbit, he encountered a violent hemorrhage from large arteries in the bone, which even plugging with pieces of wool failed to control; yet a small piece of the puffball at once restrained all bleeding. I have directed attention to this useful substance, whose value my own experience has assured me of, in the hope that some of our leading surgeons will try it, and ascertain for themselves its utility.—*London Practitioner*, October, 1882.

Suppositories for Hæmorrhoids.—The following formula is given in the *Louisv. Med. News:* Iodoform, ʒ j.; balsam of Peru, ʒ ij.; cacao butter, white wax, ää ʒ jss.; calcined magnesia, ʒ j. Incorporate the mass thoroughly and divide into twelve suppositories. Insert one after each evacuation of the bowels, and oftener if needed.

American Trichinosis.—According to a recent report to the Sanitary Committee of Massachusetts, it appears that of 2,701 pigs examined during five months, no less than 154, or nearly six per cent., contained trichinæ. The animals came from different and distant regions, but the majority were from the Western States. The same report affirms that rats are affected with trichinosis at Boston to a much larger extent than in Germany. Of 51 rats caught in a Boston slaughter house, 30 presented trichinæ. On the other hand, 28 fowls fed in the establishment were found to be healthy. Forty rats taken in another large slaughter house all contained trichinæ, but of 60 found in different stables, only 6 were thus affected. In France little consideration has, until lately, been given to the danger of trichinæ in imported pork. At Lyons, however, inspection has been commenced, and has quickly borne fruit. An enormous consignment of lard, amounting, it is said, to 120 tons, was lately received at Lyons from New York. Of 50 specimens examined immediately after arrival 3 were found to be infested with trichinæ. At Barcelona six cases of death from trichinosis have occurred in three months.

Will Quinine Produce Abortion?—Dr. Otis Manson (*Maryland Medical Journal*) says that from an experience of forty years in the treatment of malarial fevers, he is confident that quinine not only will not produce abortion, but that when properly administered it is a preventive of this unfortunate occurrence. He says that at the commencement of his career, when he was timid in the administration

of quinine, abortion was no uncommon occurrence in pregnant women attacked with the various types of periodical fever, and to whom no quinine had been given. Abortion is, according to this author, a frequent occurrence in fevers of all descriptions, and the female may consider herself fortunate in passing through the commotion of any fever without a premature expulsion of the fœtus. Since he commenced to employ quinine in liberal, yet reasonable doses, in paroxysmal fevers, he has never observed abortion in patients affected with them. The author argues that it is reasonable to suppose that an agent which, when properly administered, will prevent the convulsive rigors of the cold stage, and the high febrile excitement of the exacerbation which follows, would be the best means of preventing abortion in those subject to such violent disturbing influences.

Sudden Death and Coma in Diabetes.—Frerichs distinguishes three forms of sudden death, or coma in diabetes: 1. Sudden death from syncope, collapse, paralysis of the heart after exertion, etc. 2. Coma, ushered in by gastric or other local affections, and accompanied by headache, delirium, anxiety, and dyspnœa. 3. Coma without dyspnœa, commencing with headache, vertigo, a feeling of intoxication, and drowsiness. As regards the alleged causes of coma and sudden death in diabetes, Frerichs states: (1) Œdema, or anæmia of the brain, must be rejected on the evidence furnished by numberless autopsies. So also must (2) the existence of hyperglycæmia, an inspissation of the blood, whereby the corpuscles are changed and rendered unfit for the respiratory function. (3) Uræmia can be proved to exist neither through examination of the urine nor by any changes found post-mortem in the kidneys. (4) Fatty emboli have been discovered in the capillaries of the brain or lungs in only a very insignificant number of autopsies. (5) Acetonæmia. Large quantities of acetone have been found in the urine of diabetic and other patients in whom no nervous disturbances were present. Further, large doses of acetone, administered to men and animals, have failed to produce any dyspnœa or brain symptoms. The theory of necrotic processes in the kidneys, advanced by Ebstein, the author also rejects, as other observers have failed to substantiate his discoveries. The so-called hyaline changes in the urinary tubules, however, are constant. This hyaline substance, Frerichs asserts, is produced by glycogenic degeneration—is, in fact, glycogen. Analogous changes have been found in the liver, the heart, inflamed lung tissue, and other organs.—*Wiener Med. Wochenschr.*, No. 35, 1882.

Scurvy in an Infant.—Dr. Verger related to the Association Française pour l'Avancement des Sciences a rare case of scurvy occurring in a nursing child. The patient, seven months of age, presented a perfect clinical picture of scorbutus in the second stage. The infant was living under the most wretched hygienic conditions. It died after renal and intestinal hemorrhages.—*Le Progrès Médical*, No. 37, 1882.

Linear Incision in Cancer of the Rectum.—At a recent meeting of the Société de Chirurgie de Paris, Dr. Trélat reported a case of extensive rectal cancer in a man fifty-six years of age, in which marked relief followed linear incision of the rectum. The patient was too weak to permit of an operation for artificial anus, so a longitudinal incision was made with the thermo-cautery through the posterior wall of the rectum. The man's condition improved at once, and his life was prolonged for eight months after the operation. In the discussion which followed this communication, Dr. Verneuil stated that he had practised this operation many times with benefit. Le Dentu related five cases in which he had performed linear incision of the rectum in cancer with immediate relief of the pain and tenesmus. Després was opposed to the practice and preferred gradual dilatation.—*Bull. et Mém. de la Soc. de Chirurgie de Paris*, vol. viii., 1882.

Permanent Tracheal Tampon.—Dr. J. Michael relates a procedure adopted by him for a permanent tamponade of the trachea. A piece of wet sponge is cut into a cylinder of proper size with a hole in the centre through which the canula is passed. The sponge is then tightly wound around with string and dried. A sheath of gold-beater's skin is now drawn over the sponge and tied securely to the canula below. After the insertion of the tube water is poured on to the sponge and the sheath is tied firmly above it. The sponge swells and effectually closes the trachea. When the tracheal wound is large enough, Dr. Michael simply wraps a quantity of rubber tissue around the canula and inserts it into the trachea. If local applications are to be made to the larynx, and it is desirable to allow the secretions to escape below, a double canula is used. In the outer tube a fenestrum is cut, which opens and closes with a slide, and the inner tube is provided with a flange that fits closely to the inner surface of the outer canula just below the fenestrum.—*Wiener Med. Wochenschr.*, No. 37, 1882.

Interstitial Injections in the Treatment of Epithelioma.—Dr. Duplony says that the uncertain results obtained in the treatment of cancer by interstitial injections are due to a lack of thoroughness on the part of the operator in not extending the area of injections far enough into the sound tissues. It is essential to the success of the treatment by this method to act not only upon the diseased tissue but also upon what the author calls the generative zone. Dr. Duplony employs concentrated acetic acid which he injects not only into the tumor itself, but into the area beneath and surrounding it in such a way as to encircle the neoplasm by a series of injections. After a variable number of injections, according to the size of the tumor, the new growth is exfoliated, leaving a granulating surface, which is tolerably certain to be free from all cancer elements. The injections are extremely painful, but the pain is of short duration Dr. Duplony has tried this method in two cases with most encouraging results.—*Le Progrès Médical*, No. 37, 1882.

Pilocarpine in the Treatment of Polyuria.—Dr. Ducroux states that in certain varieties of polyuria the nitrate of pilocarpine, in doses of one-fifth of a grain hypodermically, has been found useful. In two cases of polyuria, one idiopathic and the other depending upon interstitial nephritis, a complete cure was effected. In the latter case a marked amblyopia also disappeared during treatment. In two other cases some amelioration of the symptoms was obtained. In three cases, one depending upon lead poisoning, the treatment was unsuccessful. The number of observations has not been large enough as yet to determine the particular cases that are amenable to this method of treatment.—*Le Progrès Médical*, No. 37, 1882.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, December 23, 1882.

HOSPITAL SATURDAY AND SUNDAY.

THE time will soon arrive when the collections for hospitals will be made in this and other cities. It is fair to say that the receipts will probably be greater than on any previous year. One reason for this is that the public is becoming more and more impressed with the good work which the institutions are doing. The old prejudices against treatment in hospital are fast dying out. The poor man is beginning to look to the hospital as his best refuge in times of greatest need. He has been impressed with the fact that he can obtain in the ward better care than in his own home. He leaves the institution, not only with a thankful heart for health restored, but is led to wonder how could he have done without it. Every one accustomed to treat hospital patients has these experiences repeated to him almost daily. They rarely come to light, however, except on the occasion of anniversaries, when the pockets of the rich are directly appealed to. And even then to what little purpose! With few exceptions the really rich men contribute comparatively little toward supporting our hospitals. Their charity is more apt to take the direction of church building, of evangelizing the heathen, or of increasing the salary of the minister. All these objects are excellent in their way, but the sick poor at our very gates have also a pressing claim upon their bounty and protection. The medical profession can clear its skirts of responsibilities toward this needy class by tendering its services gratuitously. If other philanthropists would give an equivalent, there would be no need for extra appeals.

It is a strange fact, however, that where the most is expected the least is realized. It may be learned with much surprise that, as a rule, the churches contribute a very small proportion toward the maintenance of the hospitals. Even is this the case with many of the institutions which are supposed to be under special denominational influences. The consequence is that many of our most useful hospitals, institutions which are ready to receive any and every needy patient simply because they are sick and poor, are running in debt. Such charity should not be trammelled by increasing pecuniary liabilities. The public inside and outside of the church owes a debt to these hospitals which cannot even be paid by the most bountiful donations. But it is to be hoped that the establishment of the Hospital Saturday and Sunday will be the beginning of the end.

This year a new plan is to be tried by which the different trade societies shall be allowed to contribute to the fund. Each dollar given will represent one day's treatment in hospital, for one patient. It will be, in fact, a provident system applied to our larger hospitals, and cannot fail to be satisfactory and useful to all concerned. We hear with much satisfaction that many of the trade societies have organized auxiliary hospital societies for this purpose, and that there is a prospect that large sums may be realized from them. The hospitals have a great claim upon members of these clubs for charitable work already rendered, and it is to be hoped that due advantage will be taken by them of the opportunity for reciprocating.

The system of distributing the funds among the hospitals, in accordance with the actual proportion of charitable work done, is as it should be. The hospital having the most claims in this direction, certainly has the best record of good work done.

The medical profession can hardly be called upon as a class for pecuniary aid; but there are many ways in which it may use its influence with the public in furthering the ends of the hospital committee. But there is really no necessity for urging this upon a profession always foremost in its deeds of practical charity.

HOSPITAL HOMES FOR THE FAMILY PHYSICIAN.

A NEW hospital in Brooklyn, N. Y., with a somewhat novel plan of organization, was thrown open to the public on Saturday last. The institution is in charge of the Catholic Sisters of Charity, and is under the medical directorship of John Byrne, M.D., F.R.C.S., the well-known gynecologist, who is also the father of the institution. It is of Philadelphia brick, is four stories high, and when completed will cover the entire block between Rochester and Buffalo Avenues. Only one wing, however, has been erected, and it is that which has been opened.

The charity is designed for the treatment of female diseases more particularly, and is in reality to be a collection of specialty hospitals under one roof. The new departure in the organization consists of a division into eleven separate departments, each of which is to be in charge of a physician or surgeon "in chief," who is assisted by two associate or visiting physicians, so that each depart-

ment is under the care of three competent specialists besides a consulting staff.

A number of rooms have also been fitted up in the hospital for the convenience of any reputable physician who may desire to have a patient in the hospital and within reach of special treatment, yet under his own care.

The latter feature is one concerning which much may be said. While it is quite true that all good physicians cannot hold hospital appointments, there is no reason why some well-equipped and well-governed institution should not offer their facilities for the treatment of such special cases, as cannot be cared for in private houses or hotels. In fact, this is a necessity that is becoming more and more apparent in our larger cities, and any experiment in a proper direction deserves encouragement. In the larger hospitals such an arrangement could hardly be made without seriously conflicting with their plans of organization, and methods of government. But while impracticable in such institutions it is not difficult to see how hospital homes having the object indicated in view, should not be met with great favor. The result of the experiment in Brooklyn will doubtless be watched with much interest by a large class of physicians who desire extra accommodations and skilled nursing for special and private cases. It is, in fact, adapting the College Hospital plan to the wants of the family physician.

SIR THOMAS WATSON.

THE announcement of the death of Sir Thomas Watson, of London, although not unexpected, brings with it more than ordinary regret. Now that the end has come, that the last chapter in his long and useful life has been finished, we almost irresistibly turn back to study anew the well-rounded record of his influences for good in his day and generation. Few men had greater opportunities in this direction, and few used them to better advantage. With rare intellectual ability and a disposition for patient and honest work, no one during the last century exercised greater influence upon the progress of our art or did more to formulate the fundamental principles of our science than did he. His grasp was large and his view extensive. Upon a higher elevation than that occupied by his fellow workers he surveyed the entire field, and was enabled by a calm and consistent philosophy to bring in accurate perspective their various opinions and prejudices. The results of this work are shown in his master-piece. There is no progressive physician in this country or Great Britain who has been practising for the last quarter of a century who has not studied "Watson's Practice of Physic" with interest and satisfaction; not one who has not been impressed with the soundness of views therein expressed, or who has not been influenced by the opinions therein offered. Sir Thomas was the highest type of a general practitioner, who studied the body as a whole, who appreciated the dependencies of its parts, and who treated it as a whole. This is so apparent throughout his work that every thorough physician especially values it on that account. Advances have been made since the last edition, but the principles on which the general treatment of disease is founded will always be the same. Sir Thomas on these points must always be heard. His studies were from nature —acute, accurate, and achromatic. His descriptions of disease will never be excelled. His grace of style, his genius for description, made him not only a truthful but an enchanting writer. He infused into the atmosphere of medicine a delightful romance, and with his enthusiasm seemed to warm into new life old and almost forgotten principles. Notwithstanding the number of years that his work has been in the hands of the profession, the medical student of to-day still reads it with unabated interest. Its intrinsic value will never be less. It will retain its place among the standard works of medicine as a classic, and will be a most fitting monument for its great and gifted author.

SHALL THE NATIONAL BOARD OF HEALTH BE ENDORSED BY MEDICAL SOCIETIES?

A LARGE part of the powers of the National Board of Health will, under the law creating them, end next Spring unless Congress specially legislates to the contrary. At its last session the National Legislature showed little friendliness to the Board, and during the past summer the placing of the epidemic funds in other hands has been regarded as indicating further lack of confidence in its methods. The Board went to the American Public Health Association at its last annual meeting and obtained the comfort of a strong endorsement by that body. We infer from certain resolutions brought before the New York County Medical Society that the Board is now seeking support and approbation from the medical profession at large.

The claims made for the further continuation of the National Board of Health are the following: It has established a small-pox inspection service in the West, which has rendered material service; it has organized a steamboat inspection service on the Mississippi, and a quarantine at its mouth, whose efficacy and usefulness, we are told, are beyond question; it has done some very good scientific work in investigating the nature of diphtheria, malaria, soil pollution, etc., and it has furnished the country weekly tables of vital statistics. All this is very good and doubtless has had local appreciation at least. To say, as does *The Sanitary Engineer*, that the "Northwest demands," the "Mississippi Valley insists upon," and the "South Atlantic coast

is unanimous in favor of" the special services in those sections is, however, putting it somewhat too strongly.

At its inception we strongly favored a national health organization, and we venture to take some credit for help given to secure it. For some reason, however, the organization has failed to gain the general confidence or support of the public. This is not due alone to the much-talked of lack of political influence, or to the prejudices of the Assistant Secretary of the Treasury and the ill-temper of Washington correspondents. The causes have been partly also in the organization itself; there has been a suspicion that the Board was managed too much in the interests of a clique who wished to advance themselves quite as much as to protect the public health. There has been a feeling also that the Board has not done all that might be expected with the liberal sums of money given it. At any rate the public at large speaks lightly of it and refuses to acknowledge the imperative necessity of its existence. This appears to us to be the actual fact in the case without reference to the justice of the public's position. With regard to the medical profession, it is a mistake to say in a large way that the Board receives its unanimous endorsement. The medical profession as a whole know little and, unfortunately, care not much about a national health organization. This is perhaps natural, for the physician is not a sanitarian, and, absorbed in daily practice, he cannot become deeply interested in problems of inland quarantine or of single and double sewage.

The medical profession should not be said, therefore, to be unanimously approving that in which they are taking comparatively little interest.

A national health board is an organization for protecting the health of the people; and to the people its work is directed. It is fair to ask, therefore, why this organization should go to the doctors for endorsement of its labors in behalf of the general public. Are the doctors the only persons who see it? We confess to feeling, with our esteemed contemporary, the *Boston Medical and Surgical Journal*, that this action of the Board is undignified and hurtful to it.

We believe in the need of a national health board, but there is no use in trying to force it upon an unwilling public. The present Board has done fairly well, but for certain reasons it has failed to make a favorable impression.

We believe that for future success the Board must be thoroughly and radically reorganized, so that there will be no petty Washington quarrels over its work. Medical societies ought to be careful in endorsing it as matters now stand in our great capital, for the situation is a complicated one. The National Board wishes to use the Marine Hospital Service; that service wishes to swallow up the Board; the Naval Medical Department wishes to absorb the Marine Hospital Service, and perhaps the Board also in course of time. In such a state of affairs, with a short session and a busy Congress, is it wise for county medical societies to weaken their influence by resolving that an organization subject to such "abhorrent" forces is perfectly satisfactory and needs only another appropriation?

CLEMENS' ALLEGED DIABETES CURES.

Some six years ago, a German physician, named Clemens, announced his discovery of a new chemical compound, possessing great curative powers in several chronic diseases. This alleged new compound was designated Brom.-Arsen. Solution. It was claimed to be especially serviceable in various skin affections, in chronic malaria, and in long-standing syphilis. So positive was Clemens in his assertions, and so astonishing were the therapeutic results said to be obtainable by the liquid, that for a time his writings attracted considerable attention.

It was soon demonstrated, however, that this alleged chemical compound of arsenious acid and bromine, was merely a mixture representing a solution of arsenate of potash. Consequently, any curative results obtained by its use were alone attributable to the arsenic, and belonged in no way to the bromine. The latter, indeed, always evaporated from the mixture after a few days' standing. Clemens' claims were accordingly speedily perceived to have been based on an entirely erroneous assumption, and his method was soon forgotten.

With the pertinacity belonging to all false reasoners, he has, however, still clung to his former belief in the potency of brom.-arsen. And more than this, somewhat of the stir originally created by his assertions has been now revived by more recent publications contained in the *Allgemeine Med. Zeitung*.

This time, Clemens has directed the power of his brom.-arsen. mixture against true diabetes. And again he boldly claims unparalleled curative action for his liquid. Many cases, he says, were permanently cured, others were greatly benefited, and even in the last stages of apparently hopeless cases life was often prolonged.

As adjuvants to treatment, Clemens uses daily inhalations of oxygen (ozone?) of electrical origin. Electro-static shocks and currents are also passed directly through the liver. Now, although Clemens is by no means a full-fledged charlatan, nevertheless his sweeping assertions savor greatly of quackery. For, as already stated, any benefit to be derived from the use of his medicine, must be equally ob-

tainable by employing Fowler's solution, or similar preparations of arsenic.

In view of such well-known facts, it is painfully surprising to find an elaborate special article on this subject in a recent issue of the *Philadelphia Medical Times*. The writer therein congratulates the readers of the journal, because they are first in America to be informed of this important innovation. And he adds that the new method deserves to be seriously considered and carefully imitated in our country. Had the writer only taken the pains to consult a leading German treatise on materia medica, we doubt whether he would have re-echoed with such confidence the assurances of a well-known pretender.

We have no doubt that certain cases of diabetes can be improved by the exhibition of arsenic. And that electricity, judiciously employed, may greatly improve a constitution vitiated by chronic disease is readily apparent. But between these well-known details and the absurdly pretentious claims of Clemens' alleged discovery there is a wide and irreconcilable difference. And therefore, in this instance, as in all similar ones of attempted fraud, the light of day means but the consignment to a well-merited oblivion of false claims.

EXPERIMENTAL PATHOLOGY IN NEW YORK.

NEW YORK occasionally makes pretensions to medical eminence, and these pretensions we have been accused of unduly praising. It has been our purpose, however, to censure New York's deficiencies as well as to call attention to its merits. We are at times strikingly reminded of the presence of the former, and we would especially refer now to the lack here of opportunities for study and research in experimental pathology and physiology. There are plenty of eminent pathologists in the city—men of fine accomplishments, who have studied long and faithfully. There are plenty of persons who take a special interest in pathological and physiological science, but their work is, for the most part, narrow and petty. We would ask if it is enough to show remarkable specimens at the societies, to diagnose tumors for large pecuniary considerations, and to teach young medical students the rudiments of microscopical science. These are useful and necessary things, but they represent pathology at a standstill.

Our colleges do even less. They have laboratories, but supply no opportunities, worthy the name, for original research, and offer no stimulus to experimental investigation. The instruction of students at a dollar and a half a lesson, is the chief aim of most of our "laboratories;" and it has to be so because of lack of corporate support.

When we compare things in their present state with what they were, it must be admitted that our societies have done some work. But they seem to be quite contented with their present methods and without ambition to rise above discursive gossip over inconsequential specimens.

Now the most important problems of medical science relate to the real nature of disease, and they are problems which we look to our pathologists to solve. Can we not get something better from our prosperous colleges, our numerous societies, and our distinguished specialists?

Our neighbor city, Philadelphia, sets us an example that should be followed here. In the past few years a large amount of original work has been done in the pathological laboratories of that city. It is work of a kind which New York has done, but is now very much neglecting. There should be some institution or body in our city which is willing to establish a laboratory for pathological study and experimentation, as well as for routine examinations and instruction.

PROFESSOR JOSEPH D. BRYANT, SURGEON-GENERAL OF THE STATE OF NEW YORK.

THE appointment by Governor-elect Cleveland of Professor Joseph D. Bryant, of this city, as Surgeon-General of the State of New York, is, from a medical point of view, one of the best that could have been made. Dr. Bryant will represent the profession of the city and State in a thoroughly satisfactory manner. He brings to his office a well-earned reputation for good work in college and hospital as well as a varied and extensive experience in military affairs. We, in common with his many friends, wish him every success.

Reviews and Notices of Books.

MENTAL PATHOLOGY AND THERAPEUTICS. By W. GRIESINGER, M.D. Translated from the German (Second Edition), by C. LOCKHART ROBERTSON, M.D., and JAMES RUTHERFORD, M.D. New York: William Wood & Co. 1882. Library of Standard Medical Authors.

GRIESINGER'S work has been before the English-speaking public for fifteen years, and its good qualities hardly need amplification now. Griesinger is one of the representatives and leaders of modern scientific psychiatry, and his work needs to be studied by every one who intends to make himself acquainted with the subject of insanity. The present volume is somewhat behind in the matter of anatomy and pathology. But, on the whole, it is surprising how little there is in the book which needs to be altered. We believe that the general practitioner should read this book, even if he does not treat insanity. It will be an education to him whose good effects he will soon appreciate.

A Treatise on the Physiological and Therapeutic Action of Sulphate of Quinia. By Otis Frederick Manson, M.D. Philadelphia: J. B. Lippincott & Co. 1882.

Dr. Manson's work is a valuable and laborious compilation of the investigations so far made into the action of quinine. After giving a historical review the author describes the action of quinine: 1, upon animals; 2, upon man in health; 3, upon man in disease.

The therapeutic uses of the drug are then discussed. We cannot agree entirely with Dr. Manson's conclusions as to the physiological action of quinine. He states quite positively that there is nervous stimulation immediately after the ingestion of quinine when given in small and repeated doses; and this he ascribes to its local action on the stomach—a monstrous supposition. Dr. Manson believes that quinine is essentially calming and sedative in its action. In our opinion he lays too much stress upon this and not enough upon its stimulant effects, which, clinically, are very often observed.

On Slight Ailments: Their Nature and Treatment. By Lionel S. Beale, M.B., F.R.S., etc. Second Edition, Enlarged and Illustrated. Philadelphia: P. Blakiston, Son & Co. 1882.

The importance of justly appreciating slight ailments and being able to treat them intelligently can hardly be overestimated. In many cases the key to success in practice may be found in a proper attention to apparently insignificant matters. For the young practitioner, just starting on his career, we know of no work that will better pay perusal than the little volume before us. The present second edition has been improved by a careful revision, by the addition of new matter, and by the introduction of several illustrations. In its present shape Beale's work may be safely commended to the careful study of all young practitioners. And we will add that even many an older man may derive profit from an examination of its suggestive pages.

Die Pflege und Ernährung des Kindes. Von Dr. A. Jacobi, Professor der Kinderheilkunde am College of Physicians and Surgeons zu New York. Separat-Abdruck aus Gerhardt's Handbuch der Kinderkrankheiten. 2te Auflage. Tübingen: H. Laupp. 1882. (The Care and Nourishment of the Child. By Dr. A. Jacobi.)

In this excellent monograph, which forms a portion of Gerhardt's comprehensive "Manual of Children's Diseases," Dr. Jacobi treats exhaustively of the care of the infant during its earliest period of life, adding a few details concerning the management of the child in later years. Explicit directions are given to be followed in the selection of a wet-nurse, and the influence of diet upon the mother's milk is treated of at length. A large portion of the work is devoted to the consideration of the difficult question of artificial feeding, and contains many very practical suggestions, most of which have appeared in the various publications in English by the same author. Six pages at the end of the book are taken up with a condensed abstract of the entire subject, and as references are made by pages to the body of the work it answers the purpose of an index as well. Three short chapters are added upon the care of the teeth, the eyes, and the mind. The book is worthy of careful perusal, and we hope that it may soon be presented in an English dress for the benefit of the author's confrères in this country.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 22, 1882.

Dr. G. L. Peabody, Vice-President, in the Chair.

DESTRUCTIVE INTERSTITIAL METRITIS.

Dr. Geo. F. Shrady presented a specimen of destructive interstitial metritis in behalf of a candidate. It was referred to the Committee on Microscopy for report.

Dr. J. Lewis Smith presented in behalf of candidates: (1) An acephalous monster; (2) Specimens illustrating the lesions of cerebro-spinal meningitis.

REPORT OF THE COMMITTEE ON MICROSCOPY.

Dr. W. H. Porter, from the Committee on Microscopy, reported progress on the sections of intra-uterine pedunculated tumor presented by Dr. Ferguson. He further reported that the tumor presented by Dr. Briddon at the stated meeting, November 14th, was a *lipoma*.

Dr. Sell presented two specimens of

TÆNIA SOLIUM.

One was obtained from a female patient, thirty years of age, single, who had been aware of the presence of the worm for three years. The other was obtained from a female patient, thirty years of age, married, who had been aware of the presence of the worm for three months.

The plan of treatment was somewhat different from that which he had reported at a former meeting, and was as follows: Ten grains of calomel were given on a Friday evening. On Saturday the patients took nothing into the stomach except stewed pumpkin and slippery-elm tea. On Sunday they took the following mixture, divided into four equal portions, and administered at intervals of fifteen minutes:

℞. Pumpkin seeds ..... ℥ j.
Ethereal extract of male fern.... ℥ j.
Kameelæ ..... ℥ ij. M.

If the patient does not have a free evacuation from the bowels within two hours after taking the last dose, or as soon as gurgling, with or without colicky pain, appears, administer an ounce of Rochelle salts, or Epsom salts, or, in cold weather, castor oil. When purgation begins, have the patient sit over a pail partly filled with warm water.

To prepare the medicine, remove the outer envelope of one ounce of fresh pumpkin seeds, and then beat them into a paste with one hundred grains of sugar finely powdered. To this paste add half a fluid-ounce or more of water, and when a homogeneous mixture has been obtained add the other ingredients gradually, and to the whole add water sufficient to make four ounces.

VAGINAL CYST.

Dr. Tauszky presented a small tumor removed from the peri-vaginal and peri-rectal tissue of a patient, thirty-five years of age, who had been married ten years, but had been sterile. During the last six months, coitus, sitting, or walking had been attended by severe pain, and during the last three months the pain had increased so that her sleep had been seriously disturbed. Examination revealed the mass, the size of a large walnut, in the left

side of the vagina, and encroaching upon the left labium minus. It was removed with the handle of the scalpel and curved scissors through an incision made in the mucous membrane and submucous tissue. The wound healed kindly. Dr. Tauszky thought that the tumor might possibly be of the atheromatous variety, although he had not been able to find any reference to such growths in this region. The specimen was referred to the Committee on Microscopy.

FRACTURE OF THE THIRTEENTH DORSAL VERTEBRA IN A HORSE.

Dr. Liautard presented a section of the spinal column of a horse, which illustrated what sometimes occurred when an animal was thrown for the purpose of performing some operation. The legs were brought together with a strap and held, and during the operation the animal struggled, arched the spinal column, and at the same time crowded backward the large mass of intestines. Overbending the spinal column in that manner sometimes resulted in fracture of the body of one of the vertebræ, usually the last dorsal or first lumbar, and when the injury did occur the animal became suddenly quiet, the body was covered with a cold perspiration, and when the strap was removed was unable to get up. In the specimen presented the fracture had taken place much farther forward than usual—namely, in the body of the thirteenth dorsal vertebra, and on looking through the spinal canal it could be seen that the fractured portion must have pressed upon the spinal cord.

Dr. Liautard also presented a specimen illustrating

MALFORMATION OF THE JAWS OF A HORSE.

Normally the male horse had forty and the female thirty-six teeth. In each jaw there were six molar teeth upon each side. The specimen was interesting for the fact that there were *seven* teeth in each molar arch. On the left side of the head, the molars had, instead of meeting squarely, shut over each other, so that the lower ones had been bevelled off upon the outside, and the upper ones upon the inside. On the right side of the head the molars presented the normal appearance, except with reference to number. Some eight or ten years ago, the animal was under his observation, and at that time had difficulty in masticating. Subsequently symptoms of apparent glanders developed, and finally the food passed out through the nostrils. At the post-mortem there was found, besides the deformity of the jaws, disease of the palate-bone, that accounted for the fetid discharge and apparent glanders. There was also a marked change in the curve of the incisor arch, so much so, that the lower front teeth were nearly horizontal.

CYPHOTIC PELVIS—CÆSAREAN SECTION.

Dr. Garrigues presented specimens taken from the body of a woman thirty-one years of age, upon whom he had performed Cæsarean section. To close the incision in the uterus twenty-four carbolized silk sutures were introduced; one half embracing the entire uterine wall and, the other half including only the peritoneum. Union by first intention had taken place throughout two-thirds of the extent of the wound. The abdominal wound was closed with deep silver sutures and superficial silk sutures, and union by first intention occurred throughout.

The pelvis was cyphotic, the long axis of the superior strait being antero-posteriorly.

The bodies of the three lower lumbar vertebræ had almost entirely disappeared. There was marked defect in the first and second sacral vertebræ. The iliac bones sloped inward and the pubis was thrown upward and forward. The ischii approached each other to within one-third the normal distance, and the arch of the pubis was very small, The outlet of the pelvis was nearly of the shape of a leaf of clover, and when covered with the soft parts admitted two fingers only when they partially overlapped each other.

The child had been dead for many hours before labor began. The mother had cardiac and pulmonary disease, and finally was reduced *in extremo* by hemorrhage. Three operations were considered: Cæsarean section, Porro's operation, and laparo-elytrotomy. After due consultation with Dr. Mundé and others, it was decided that the Cæsarean section was the only available one under the circumstances, for prolonging the life of the mother.

EPITHELIOMA OF THE LARYNX.

Dr. Elsberg presented a tumor removed from the interior of the larynx of a man forty-four years of age, who, six years ago, came to him with catarrhal inflammation of the nares, pharynx, larynx, and trachea. At that time there was seen a small tumor, and he advised the patient to either leave it entirely alone or else have it thoroughly removed. Soon afterward the patient passed from under observation. About two months ago he returned, when it was learned that several unsuccessful efforts had been made to remove the growth, and considerable irritation had been produced. On examination it was found that the tumor had grown so as to extend from the anterior nearly to the posterior extremity of the ventricle of Morgagni, and there was slight ulceration. There was no general evidence that it was malignant. It produced no special uneasiness, and it was only because his voice was so much affected that the patient sought medical advice.

The specimen had been examined by Dr. Heitzman, who pronounced it to be epithelioma. The practical lesson to be learned from the case was that tumors in such cavities as the larynx should be left severely alone or else removed thoroughly. Dr. Elsberg, felt sure that in other cases, if not in this one, tumors which were non-malignant had become malignant through irritations to which they had been subjected by picking and incomplete removal.

Dr. Elsberg also presented a specimen of

MYXO-ANGIOMA OF THE TONGUE,

with the following history: It was removed from the base of the tongue of a woman seventy years of age, who had suffered from post-nasal catarrh for many years. When in position it was about two inches and a half in diameter, and nearly occluded the entrance to the pharynx and œsophagus. It was compressible, so that, when removed, it was only about one-third the size it was when in position. It was removed with a wire écraseur, passing one over another from the top of the growth downward until the base of the tumor was reached. Microscopical examination revealed that it was a myxo-angioma, a rare variety of tumor to be found in that region.

Dr. P. E. Donlin presented a specimen of

EXTRAUTERINE PREGNANCY,

removed from the body of a woman twenty years of age. There was no suspicion, so far as he was able to ascertain, that pregnancy existed. Suddenly she was taken with extreme pain in the back, her lips became blanched, her skin whitened generally, and the attending physician believed that there was uterine hemorrhage, although unable to obtain the facts in the case.

Dr. Janeway examined the specimen at the request of Dr. Donlin, and found that it was a case of tubal pregnancy. The most interesting feature of the specimen was the fact that the corpus luteum was in the ovary upon the side opposite to the tube where the pregnancy existed. The centre of the corpus luteum had undergone cystic degeneration. He had presented a similar specimen from a case in which the pregnancy had not advanced beyond three weeks. The fœtus was in the Fallopian tube opposite to the ovary in which the corpus luteum existed. [See Medical Record, vol. xvi., p. 162.] An explanation which had been offered in such cases was that the ovum passed across the abdominal cavity and entered the opposite Fallopian tube.

Dr. Garrigues remarked that it had been proved experimentally that the ovum might pass across in that way. An Italian physician had ligated the Fallopian tube upon one side and removed the ovary upon the other, and the animal subsequently became pregnant.

PERITONITIS IN A CHILD NINE DAYS OLD.

Dr. J. Lewis Smith presented a specimen which illustrated the fact that violent and fatal inflammations were liable to be latent in feeble, badly nourished babies. The child was nine days old, and was nursed by a wet-nurse after its arrival at the New York Foundling Asylum. Vomiting was not a prominent symptom, and the intestinal evacuations were regular. The curator did not expect to find any special lesion at the autopsy, but, to his astonishment, he found general peritonitis. The intestines were agglutinated to each other. The under surface of the liver was covered with recent lymph. The spleen was adherent to the stomach.

In the same institution a child twenty days old died with the same disease.

CHRONIC DIFFUSE NEPHRITIS—THROMBUS IN THE MIDDLE CEREBRAL ARTERY—CEREBRAL HEMORRHAGE.

Dr. Beverley Robinson presented the cerebral arteries and the kidneys removed from the body of a man, who gave the following history: He was forty-nine years of age, and entered St. Luke's Hospital October 25, 1882. He presented the ordinary symptoms of the atrophic kidney of chronic Bright's disease. On October 10th the patient was noticeably failing, especially with reference to his mental powers, and was slightly delirious at night. On October 25th, while sitting upon the edge of the bed, he suddenly fell upon the floor, and it was soon determined that he was aphasic and was paralyzed upon the right side. He died on October 24th at 10.10 P.M.

At the autopsy, made by Dr. Satterthwaite, there were found hypertrophy of the left ventricle of the heart with normal valves, hypostatic œdema of the right and embolic pneumonia of the left lung, atheroma and thickening (no ulceration) of the aorta and other arteries, chronic diffuse nephritis, thickened cerebral pia mater, marked atheroma of the arteries of the circle of Willis, thrombosis of the posterior branch of the left middle cerebral artery, and a small cortical hemorrhage on the convexity of the brain just anterior to the fissure of Rolando.

The query was whether the aphasia and hemiplegia were due to the hemorrhage or to the obstruction in the artery. Dr. Robinson thought it probable that the thrombus was the principal cause of the aphasia.

Dr. Robinson also presented a

CHOCOLATE-COLORED FLUID REMOVED FROM AN ABDOMINAL TUMOR,

with the following history: The patient was forty-three years of age, had been in good health until fourteen days ago, except that her menses had been somewhat irregular. At that time she began to suffer from pain in the right iliac region, which was attended by slight fever. Ten days afterward she went to bed on account of the pain and general discomfort. No pain in micturition or defecation. On admission to St. Luke's, her urine was found to be normal, the cervix elongated but not patulous, uterus normal in size and position, but immovable, and bound down by a large firm mass in the right side of the cul-de-sac. Diagnosis, pelvic cellulitis and peritonitis. The hot-water vaginal douche, iodide of potassium with bichloride of mercury, $\frac{1}{100}$ of a grain dose, were prescribed. About two weeks afterward a fluctuating tumor could be felt in the posterior cul-de-sac of the vagina, which was aspirated, and six ounces of chocolate-colored fluid removed, which under the microscope showed degenerating pus-cells, fatty matter, degenerated and pigmented epithelial cells, but no blood-corpuscles. The fluid had a slightly fishy odor. Two days after the aspiration there had been no rise of temperature or other unfavorable symptoms. Four days subsequently there was no pain and no discharge.

Dr. Wylie referred to a case occurring in his service at Bellevue Hospital, in which there was evidence of pelvic cellulitis with suppuration. The mass was aspirated, and instead of pus, perfectly clear transparent fluid was obtained, and the patient went on at once to complete recovery.

Dr. Janeway said that such a fluid as that presented by Dr. Robinson could come from a cavity where hemorrhage had occurred with the inflammatory process.

Dr. Janeway presented a series of specimens, removed from one body, which illustrated

CHRONIC HEPATITIS, CHRONIC SPLENITIS, CHRONIC PERICARDITIS WITH CALCAREOUS DEGENERATION, CHRONIC PLEURITIS, CHRONIC PERITONITIS.

The chief interest in the specimens consisted in the intercurrence of so many fibrous thickenings, with calcareous degeneration in one, in the same body. The liver weighed eighty-six ounces. The increase in connective tissue was mostly about the ramifications of the portal veins. This explained the ascites from which the patient died and for which he was tapped fourteen times.

Dr. Janeway also presented a specimen of

CHRONIC PERITONITIS.

It was removed from the body of a woman who had been tapped twenty times during the last seven

years. In the right iliac region a tumor was recognized during life, and at the autopsy it was found that it had been formed by the agglutination of the coils of the small intestine to each other. An interesting clinical feature was paralysis of the right leg, which was explained at the autopsy by the existence of a large amount of peri-rectal and post-rectal tissue, that at the upper part of the pelvis pressed upon the internal iliac artery. There was a thrombus in that vessel near the bifurcation of the common iliac.

The Society then went into executive session.

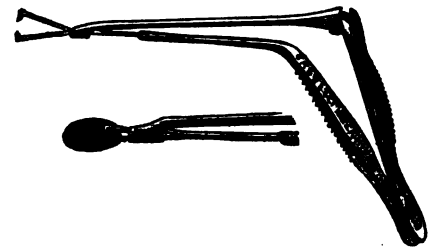
Correspondence.

PARTIAL SEVERANCE OF THE AURICLE FROM THE HEAD FOR THE REMOVAL OF FOREIGN BODIES FROM THE EAR.

To the Editor of The Medical Record.

Sir: Will you kindly grant me space to make a few remarks suggested by reading the report of a case by Dr. Buck in The Record of December 16, where the auricle was partially severed from the head in order to remove a locust-bean from the ear? Nearly all otologists will agree with me, I believe, in the statement that the hearing organ is most liable to be injured in the removal of foreign bodies when the patient is a child. In such patients ineffectual attempts are more frequent, because the sufferer cannot keep quiet under the manipulations necessary, and, unless he is put under the influence of an anæsthetic agent, the operator, whoever he may be, is very frequently more likely to push the object farther into the ear than remove it. In Dr. Buck's case, he found, indeed, that the efforts of the village physician, to whom the child was first taken, had at one or more points torn the external auditory canal, which was bathed in a bloody secretion; but, fortunately, the bean had been impacted in the canal before being pushed down against the drum-head. Under these conditions, Dr. Buck himself made determined but ineffectual efforts with steel hooks to dislodge the bean, with the effect, possibly, of only wedging it more tightly in the canal.

I can sympathize with the operator in encountering a case of this kind, for the removal of locust-beans from the ear was brought to my notice through a difficult case which I was requested to see in consultation with Dr. Henry D. Joy, some two years ago, and which was reported in the *American Journal of Otology*, vol. iii., p. 144. The case was very similar to Dr. Buck's, with this exception: the boy was two years younger, and the drum-head had been ruptured by the ineffectual efforts made to remove the bean before he came to Dr. Joy. Fruitless attempts in this case to find any forceps that would retain a hold on the smooth hard surface, or any curette or hook that could be successfully used, suggested the construction of forceps that could be relied upon in such cases in the future. This object was accomplished, and the instrument, as made by Mr. Ford, was described, with an illustrative cut, in the *American Journal of Otology*, vol. ii., p. 298. Many others, as well as myself, have since then had it in constant use, and I believe with satisfactory results. With this instrument the cortex or shell of the locust-bean can be readily penetrated, and securely held in the pivot-like grasp of the two opposing teeth, which allows the bean, or other object, to rotate on the axis of the "bite," and thus adapt itself to the walls of the canal as it is withdrawn. In skilful hands (and by none other should it be employed), the oval or even flat surface of an object in the canal of the ear may be seized without danger of pushing it farther into the ear. I have thus removed objects as large as, or even larger than the locust-bean from the ears of children, such as glass beads, brass buttons, gold shirt studs, sea-shells, pebbles, pieces of glass, sequestra from the temporal bone, etc.



With respect to the somewhat severe, and to the friends alarming, operation of detaching the auricle for the removal of foreign bodies that children themselves have slipped into the ear, I should myself hesitate to adopt so grave a procedure for the accomplishment of the object in view, trusting rather to careful manipulation, which has, with the efficient instrument already alluded to, in a large experience of my own always been found to be successful.

Dr. Buck, in concluding his paper, draws attention to the great amount of damage to the osseous canal that may be done with impunity. This fact should be borne in mind when contemplating the removal of an impacted foreign body from the ear, for in certain cases it may be better to risk some laceration of the canal than allow an irritating foreign substance to remain impacted in close proximity to the drum-head for many days—in Dr. Buck's own case it remained for nearly a week—before removal, lest, as happened in his case, a chronic purulent inflammation of the middle ear be established.

It occurs to me in this connection, that where secretions from the canal only are present in these cases, the swelling of the parts would be increased by frequent douchings of any kind which macerated the tissues, and I should myself prefer to employ drying agents. If the foreign body should be by chance a locust-bean, the moisture and heat of the canal would be likely to favor its germination and consequent enlargement. My own experiments with these beans, which Dr. Joy published with the case above alluded to, showed that when placed in water, even at a temperature of 65°F., there was rapid swelling of the seed, and the shell was easily picked open at one end.

Very truly yours,

Samuel Sexton, M.D.

12 West Thirty-fifth Street, New York,
December 16, 1882.

Propylamine in Chorea.—Dr J. H. Carstens reports (*Detroit Clinic*) several cases of chorea cured apparently by the use of propylamine. The drug was given in four-grain doses three times a day.

HOW PUERPERAL FEVER MAY BE PREVENTED.

To the Editor of The Medical Record.

Sir: In a recent number of The Record I noticed some statements made by the visiting surgeons of the Maternity Hospital, New York, with reference to the frequency of the occurrence of puerperal fever in time past in that institution. One of the gentlemen alleges that it was due, to a great extent, to the unhealthy hygienic and atmospheric conditions to which the women were exposed while in the waiting wards of Charity Hospital prior to their removal to the Maternity Hospital proper, and that since the waiting wards were transferred to the pavilions the records have been much better. Now, from personal experience while house physician at Charity Hospital, I doubt the correctness of the inference drawn from the improved mortality rate. In my experience, the women actually confined in the waiting wards did better, as a rule, than those delivered at Maternity, and this fact was even recognized by the women themselves, who had a wholesome dread of the Maternity Hospital, and would often conceal their pains until labor was too far advanced to admit of their transference to that institution. It was the custom, too, to deliver all the women in the waiting wards upon the development of puerperal fever at Maternity. The women so delivered, in my experience, did uniformly well. Certain of the women who were affected with syphilis, malaria, renal disease, or other affections, were always retained at Charity to render the Maternity records as favorable as possible, but notwithstanding this fact the record of the waiting wards was excellent.

During my term of service there happened to be an outbreak of puerperal fever at the Maternity Hospital on two occasions, as a consequence of which the Maternity service was transferred to the waiting wards, which soon became overcrowded. The women were then delivered in several pavilions which had been used for cases of erysipelas the year previous, and in which a number of the worst forms of the disease were treated. What means of disinfection were taken I do not know, as the pavilions were said to be in readiness and required nothing but scrubbing and ordinary cleaning to prepare them for obstetrical wards. Even under these circumstances the record of Dr. Wood, the gentleman who had the service as house physician after my term had expired, and who had no advantages supposed to be derived from a selection of cases, inasmuch as all the women were confined in the pavilions indiscriminately, was the best that had been obtained for some time. I should mention the fact that during the time of my service in the waiting wards I also had a large venereal service in which quite a number of operative surgical cases arose.

Now it seems to me that the difference of results was not due to the different surroundings of the patients, which were as unfavorable as possible according to our present views, as compared with those to be obtained at Maternity Hospital, which was completely isolated from the hospital proper, but to the fact that the let-alone policy was generally followed at the hospital. Dr. Wood was especially favorable to the let-alone plan, not allowing any syringing whatever unless there was some special indication for it. and there was no disputing the fact that his patients did well, especially as compared with those of some of the gentlemen who regarded labor as a pathological rather than a physiological process, and one requiring the most energetic measures in order to preserve the life of the woman. I was in the habit of interfering rather less than had been customary, but am convinced that my own patients would have done better had I let them more severely alone. In my capacity of resident surgeon of the State Emigrant Hospital, I had an opportunity of observing the obstetrical records of that institution, and I found that puerperal fever was there almost unknown. Now I think that this was due to the fact that the women were let alone, being delivered by a midwife, and the doctor never touching them unless some complication or unfavorable symptom developed, merely making a daily inspection of the ward which was in the hospital building proper. The results of my observations have been such as to lead me to believe that as a rule we are many of us inclined to interfere too much with our obstetrical cases, and that we had better give Nature the same chance that she had before syringes and "germs" were invented. Not but that I fully recognize the potency of those same minute organisms, and appreciate the value of antiseptics and kindred measures, for I freely acknowledge their usefulness, but I am firmly convinced that less interference with our obstetrical cases, even in public hospitals, is in order.

G. Frank Lydston, M.D.,
Late Resident Surgeon, Charity and State Emigration Hospitals, New York.

Chicago, Ill.

THE CARE OF THE CHRONIC INSANE.

To the Editor of The Medical Record.

Sir: The enclosed slip from a Dutchess County newspaper has medical value.[1] It relates to action by the Supervisors of that county, and involves questions in which the interests of the insane in the counties of New York and Kings are especially interested.

More than two-thirds of the cost of the care of the insane of the State are borne by the counties of New York and Kings, and yet the care of their own insane is a constant subject of dissatisfaction on the part of the medical men who bear the grievous burden of the work in the county institutions, and who are exposed to criticism for not doing what, in the very nature of the case, it is impossible to do. The State Hospital at Poughkeepsie has three hundred acres of land. More land could be got near by, if desired. It suffers in its internal economy, and therefore damage is done its beneficiaries by the process, which is now constantly going on, of drafting the chronic insane from its halls and sending them to Willard's and Binghamton. The true policy is to have the chronic insane at Poughkeepsie, and to provide with State funds for the erection of cheap, substantial lodging-houses for them there, adding workshops and amusement-sheds and school-rooms, so as to make it possible to provide the desirable occupations at all seasons for the patients, and thus obtain through their industry a portion, at least, of the cost of their maintenance. The idea, at present in full operation in the State, of gathering the acute insane in one institution and the chronic in another, is both unscientific and inhumane, and as bad as it can be in an economic point of view. An asylum for chronic cases comes to be considered by

[1] [This refers to a series of resolutions passed by the Board of Supervisors of Dutchess County, pointing out the necessity of caring for the chronic insane nearer their homes, and urging the establishment of a department for the same in connection with the Hudson River State Hospital at Poughkeepsie, N. Y.—Ed.]

the popular mind as a place for incurables, a place on which may be inscribed, "No hope enters here," and the influence of that consideration, sooner or later, pervades the asylum itself, and scientific interest in the scrutiny of the inmates, case by case, dies out, and you have a mere poor-house with scarcely a vestige of a hospital or sanitarium about it. Fortunately, we have at our asylums for the chronic insane medical men who are alive to this danger and are preparing to meet it.

The only relief for the overcrowded asylums of our County of New York is colonization, and the first colony should be a thousand or fifteen hundred from Blackwell's and Ward's Islands sent to Poughkeepsie, and there so treated as to be not only provided with every possible aid to their recovery, but taught to yield a portion of the cost of their maintenance, and provision also made, by giving small wages to many of them for work done, to sustain themselves in their occasional visits to the communities from which they may have come, or to start in life again.

Yours respectfully,
C. R. AGNEW, M.D.

THE QUESTION OF VICE AND DISEASE IN INEBRIETY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have long ago ceased to notice any criticisms or doubts concerning the disease of inebriety or its relations to vice, simply because the subject was not one of opinion or theory, but of facts, within the range of every physician to examine and test for himself.

Frequently I have requested some of the more emphatic defenders of the half vice and half disease theory of inebriety to send me the clinical histories of cases which seemed to support their views. So far no one has ever responded.

The doubts suggested by Dr. Stair in a late number of THE RECORD cannot be answered by argument, but only by appeal to accurately observed facts, seen in the history of cases found in every neighborhood. The observer must put aside all theory and enter upon his work with a true scientific spirit, having no other object except to ascertain the facts, never being satisfied with half truths or meaningless terms to describe unknown states of the body.

Dr. Stair will find satisfactory answers at this bar of inquiry, above the levels of moral discussions and the speculations of untrained, incompetent men.

It may be of interest to group some general facts, which the present study of the subject amply confirms.

First.—All clinical study of cases reveals a physical chain of causation more or less distinct, following a line of march that is traceable. The so-called vice element is always less distinct than in insanity or general paralysis. The term vice is found in all cases to express ignorance of the present condition, as it has always been used in every scientific inquiry.

Second.—The responsibility of inebriates is governed by the facts of each case. No general rule can be made to apply to all. In some cases pronounced irresponsibility exists from the onset. In others a degree of increasing failure to comprehend the nature and character of their acts may be apparent.

Third.—Inebriety is always influenced by surroundings and conditions more or less unknown.

In many instances all the physical characteristics of inebriety are present, and yet the patient is temperate. Like the vast army of neurotics, he is on the border land, likely any moment to become an inebriate. Such persons may explode into inebriety or go down a long lifetime free. This is only one of many phases at present unknown, and yet obviously the result of physical laws and forces. No theory of moral education, will-power, or vice will explain it.

Lastly, inebriety cannot be reasoned out from theory and logic, no more than the interior of Africa can be known by these means. It is a medical subject, and must be studied from a medical and scientific standpoint before we can know anything of its nature and character.

T. O. CROTHERS, M.D.

HARTFORD, CONN., December 15, 1882.

Obituary.

SIR THOMAS WATSON, M.D., F.R.S.,

LONDON, ENGLAND.

THE death of Sir Thomas Watson, which has for some time been anticipated, was announced by cable last week. Up to within the past fifteen or twenty years, no name was more familiar to medical practitioners than that of Watson. His lectures formed by far the most popular text-book on the practice of medicine, and were for a long time almost exclusively used.

Sir Thomas Watson was at the time of his death one of the physicians-in-ordinary to the Queen. He was born at Kentisbeare, Devonshire, in 1792. His education was received at St. John's College, Cambridge, he being graduated as tenth wrangler, with the degree of B.A., in 1815. He was given the degree of M.A. in 1818 and M.D. in 1825. He was elected a Fellow to the College of Physicians in 1826, and since 1862 has been its President. From 1827 to 1840 he was one of the physicians to the Middlesex Hospital, and for some time was Professor of the Practice of Physic in King's College, London. He was physician-extraordinary to the Queen several years, and was appointed a physician-in-ordinary June 12, 1870. He was created a Baronet in 1866. His literary work is mainly comprised in the "Lectures on the Principles and Practice of Physic, Delivered at King's College, London."

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from December 9, 1882, to December 16, 1882.

BANISTER, J. M., Assistant Surgeon. To proceed to Camp on White River, Colorado, and report to the Commanding Officer. Par. 7, S. O. 250, Department of the Missouri, December 11, 1882.

HALL, W. R., Assistant Surgeon. Granted leave of absence for one month. Par. 8, S. O. 250, Department of the Missouri, December 11, 1882.

PORTER, J. Y., Captain and Assistant Surgeon. To proceed to St. Francis' Barracks, St. Augustine,

Fla., and to report to the Commanding Officer of that Post for temporary duty. Par. 2, S. O. 119, Department of the South, December 11, 1882.

WYETH, M. C., First Lieutenant and Assistant Surgeon. Granted one month's leave of absence. Par. 4, S. O. 206, Department of Dakota, December 8, 1882.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending December 16, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

GRAVE-PLUNDERERS IN RICHMOND, VA., AND PHILADELPHIA, PA.—It is stated that Oakwood Cemetery, near Richmond, Va., has been systematically robbed for a long time, the bodies being used by the Virginia Medical College. Recently two medical students and two colored persons were arrested at the cemetery while about to engage in exhumations for the benefit of anatomical science. They have been sentenced to six months' imprisonment.

The arrests made in Philadelphia have excited wide attention, and it is found that some of the authorities of Jefferson Medical College are implicated. Eight indictments against Professor Forbes, of that College, for complicity with resurrectionists were presented by the Grand Jury on Wednesday last.

While the practice of grave-robbing is to be greatly deplored, it is only fair to say that it does not often occur in States or cities where there are proper provisions for supplying material to the colleges.

DEATH OF DR. MICHAEL HOGAN.—Dr. Hogan died at his residence in New York, December 17th, in the sixty-fourth year of his age. He was born in Ireland, and received his medical education in Dublin. He was a member of the County Medical Society and New York Academy of Medicine.

CHANGE IN HOSPITAL SERVICES.—A six months' service by the attending physicians and surgeons of St. Luke's Hospital has been inaugurated. A doubling of the house-staff has been asked for. A similar lengthening of service is proposed for New York Hospital.

PATENT MEDICINES AND EPIDEMICS.—When diphtheria becomes epidemic in a city the advertisements of patent medicines suddenly experience a change. What were advertised as a sure cure for chilblains, scald head, vermin exterminator, polish for brass knobs, etc., are now warranted an infallible remedy for diphtheria.—*Norristown Herald.*

FOLLOWING UP A WINTER COLD.—At the very inception try to abort it with hot drinks, quinine, and a sweat.

In the early dry and congestive stage give cubebs or ammonia muriat.

After the dry stage, when the cough is loosened, give an anodyne (*e.g.*, chlorodyne) with mildly stimulant vapor inhalations (oleum pici, tr. benzoin co., etc.)

When the secretions become freer, use the steam atomizer night and morning with mild, slightly astringent alkalies (benzoate of soda dissolved in bicarbonate of soda, etc.).

If the stage of the profuse muco-purulent discharge sets in, the strength of the astringents should be increased. Finally, the air-tube atomizer should be used with solutions of argenti nitrat., gr. ij. to ʒ vj., or zinci chlorid., gr. ij. to ʒ vj.—*F. H. Bosworth in The Independent Practitioner.*

THE MEDICAL COLLEGE OF VIRGINIA, says the *Southern Clinic*, offers to educate forty young men free of charge, and to do the charity practice of Richmond city free of charge, and to attend to the midwifery practice of the city also free of charge. The editor of the *Clinic* offers in the way of competition, to pay fifty cents to each patient who will call upon him.

Our Virginian brethren do not seem to live in that peaceful harmony which should characterize the members of the noblest of professions. Why not readjust.

PASTEUR VS. KOCH.—Prof. Dr. Robert Koch published in the report of the Imperial Sanitary Bureau, of Germany, experiments which disproved, as he alleged, the statements of Pasteur regarding the rôle of earthworms in the propagation of charbon and regarding the attenuation of charbon virus. M. de Feltz has just presented to the Academie des Sciences the results of another series of experiments. These confirm in all points, he says, the conclusions of Pasteur.

MASSACHUSETTS LAW TOLERATING BOGUS MEDICAL COLLEGES.—Charles J. Eastman, Rufus K. Noyes, and W. D. Corken, corporators and officers of the Bellevue Medical College, of Massachusetts, recently arrested on the charge of issuing bogus diplomas, were examined before Commissioner Hallett, December 15th, on charges of using the mails for fraudulent purposes. Evidence was offered by the Government, and not contradicted, to the effect that the "college" had issued degrees and diplomas to individuals grossly ignorant of the theory and practice of medicine and after a farcical course of instruction covering a few weeks or less. Defendants claimed simply that they were empowered to do all that was alleged by the laws of Massachusetts. It appeared that the institution was legally incorporated and that according to the corporation laws and its charter it enjoys all the privileges of other medical colleges, which was admitted by the Government attorney.

Commissioner Hallett, in giving his decision, said if the Faculty choose to issue degrees to incompetent persons the laws of Massachusetts authorized it. The defendants are therefore discharged.

Thus ends the case for the present. "Dr." Noyes has received a good advertisement, and his college is pronounced legal. The preposterous nature of the law which shields his college, however, is shown most clearly, and it seems impossible that the medical profession and Legislature of Massachusetts will tolerate it much longer.

GRAVE-ROBBING IN MONTREAL AND IN NORTH CAROLINA.—A species of kleptophobia, as regards the buried dead, seems to be affecting the people in consequence of the detection of the Philadelphia robberies. A telegram from Montreal states that the recent robbery of graves in cemeteries adjacent

to that city has created a general feeling of alarm, especially in the rural districts, and the people are organizing for the better security of their dead. Three bodies were stolen from a vault in the burying-ground of St. Anne, several days ago, two were exhumed at Chambly and carried away, and several corpses were recently stolen from the burial-ground at the Oka Indian reservation.

Rumors of grave-robbing near Greensboro, N. C., are also circulated.

THE DEATH OF WILLIAM PIRRIE, M.D., C.M., LL.D., F.R.S.E., is announced. Dr. Pirrie was the leading surgeon in the north of Scotland. His chief literary works were his "Surgery," which has run through three editions in England, and five editions in America; and his treatise on "Acupressure," published in 1867.

DEATH OF DR. JOHN FORSYTH MEIGS.—On December 16th Dr. J. Forsyth Meigs died of pneumonia, at his residence in Philadelphia, at the age of sixty-four years. Dr. Meigs was widely known in this country as joint author with Dr. Pepper of one of the best and most popular text-books on children's diseases ever published in the English language. Dr. Meigs was born in Philadelphia in October, 1818, and was the son of Professor C. D. Meigs. He was graduated from the medical department of the University of Pennsylvania in 1838, and has always practised in Philadelphia, where he had occupied many prominent positions.

THE TRAINING-SCHOOL FOR NURSES AT BELLEVUE HOSPITAL is in need of money and has had to take some of the nurses from the hospital wards in order to send them out as private nurses. The Medical Board has made an appeal to the public for funds. The school depends solely upon the earnings of the pupils and public contributions.

THE PROPOSED HOSPITAL FOR CHILDREN.—Arguments were made last week before the Commissioners of the Sinking Fund in favor of establishing a hospital for children suffering from contagious diseases. The following facts stated by Professor Chandler are of interest: In 1881, out of 7,338 cases of scarlet fever among children in this city, 1,964 cases were fatal. In that year there were 5,272 cases of diphtheria among children, of which 2,249 resulted in death. There were 444 deaths from typhoid fever, 461 from cerebro-spinal meningitis, and 160 from typhus. Measles had also proved fatal to many children. The total number of cases of contagious diseases among children reported to the Health Board last year was 19,157, and 6,160 of these resulted in death. The great majority of these cases were in tenement and apartment houses, and the mortality would have been largely reduced if the children could have had proper medical treatment and good nursing. The death-rate was at least one-third higher than it should be.

It is proposed to establish the hospital at the foot of East Sixteenth Street.

A NEW YORK HOSPITAL DISTURBANCE.—A charity patient in New York Hospital made complaint last week before the justice, of assault and brutal treatment by an orderly. He asserted that the orderlies paid little attention to charity patients unless they were feed. The complaint was dismissed by the justice.

AMERICAN GYNÆCOLOGY SEEN THROUGH ENGLISH SPECTACLES.—In the preface to the fourth edition of Dr. Tilt's work on "The Change of Life," this author gives vent to the following strictures on American gynæcology: "Simpson devised the slitting of the womb for sterility, but when transplanted into America, his operation, in the hands of Dr. Marion Sims, became one for the cure of most diseases of women. It is difficult for us, simple-minded Englishmen, to withstand American advocacy of surgical operations. They speak with the prestige of ovariotomy, successful after having been pooh-poohed for a quarter of a century by all the great surgeons of Europe. They dazzle us by prodigious statistics, of which cases given in detail are few, while failures find no place; so, when Dr. Marion Sims told us that in a short time, in one hospital, he had cured 500 women of all sorts of uterine diseases, by slitting the cervix up to the body of the womb, the more experienced among us were very much astonished, while the younger men rushed off to the instrument-maker's, and followed the new light at a slower pace, suitable to our placid nature. They soon found, however, that the operation did not fulfil Dr. Marion Sims' promises; that it was sometimes attended by very serious accidents; and then they heard that Dr. Sims' most promising pupil was busy sewing up the wounds he had helped his teacher to divide. Some time ago we heard again from America that Dr. Emmet had discovered a new operation for the speedy cure of the ordinary run of uterine cases. This new operation was again supported by hundreds of cases, not only of his own, but also of his pupils'; cases without definite particulars, and without mention of failures, dangers, or of deaths. As some of our American friends express surprise that we have not adopted this new operation with the same enthusiasm as we did Dr. Marion Sims', it is worth while considering what we are now asked to do.

"I gave it to be understood, that until Simpson made his mark, somewhat too large a part was given to inflammation for the explanation of uterine pathology. Since then the tendency has been to undervalue the importance of this most important element of general pathology and of daily practice.

"Dr. Emmet, for instance, does not take the trouble to discuss what relates to inflammation in his voluminous work; he simply asserts that the womb cannot be acutely inflamed, except after parturition; in his large practice he seems never to have met with cases of acute internal metritis, than which I have never seen a disease so sharply accentuated or less amenable to treatment. As for chronic inflammation of either the substance or of the lining membrane of the womb, he says it is a sheer impossibility. Thanks are due to any man who will frankly say what he thinks on any important matter; but when writing 855 pages on diseases of women, to dismiss in two pages the relations of inflammation to diseases of the womb, is neither scientific nor scarcely respectful to what has so long stood as the keystone of uterine pathology; but let us see what Dr. Emmet puts in its place.

"Subacute or chronic inflammation of the cervix, which so often shows itself by uterine ulceration, is for him a myth, a delusion, and nothing but the everted rim of a more or less lacerated cervix. He considers the womb to be so little up to its work, as to be always lacerated by parturition, and that what has hitherto been known as ulceration, is nothing but uterine ectropion. This theory, however, cannot possibly explain the same kind of uterine ulceration often met with in married women who are sterile, and sometimes in single women;

so I may ask to be credited when I affirm that endocervicitis and ulceration are often met with in women who have borne children, without being caused by laceration.

"Dr. Emmet asks us to treat these comparatively mild cases by extensive division of the neck of the womb, sufficient paring away of tissue, and by resewing of the divided cervix.

"But this is not all, while admitting that nature often heals whatever laceration may have occurred, he maintains that it does so after a bungling fashion, by means of a very untrustworthy kind of a cicatricial tissue, which is to be cut away, says the master, 'if the cervix be large, or causes neuralgia;' to be cut away, wherever found, and under all circumstances, say the pupils, for fear of future mischief.

"So now, in America, the womb is to have no peace; if its mouth be surrounded by a rim of ulceration, a delicate and serious operation is to be performed; and however sound the tissues may be, the same operation is recommended, should it be possible to detect any trace of a long-healed laceration. Of the many patients attended by me during the last thirty years, I cannot remember a bad case of cacoplastic cervix with endocervicitis that I have not been able to cure by preliminary intercervical incisions, deep enough to drain long-congested tissues, followed by potassa fusa cum calce, and the subsequent dressing with tincture of iodine, so I do not see why the risk of a much more dangerous operation should be run, even in bad cases, except in a limited number that I have not time to specify. We are not, however, allowed to reserve tracheloraphy for long-standing cases of cacoplastic cervix with endocervicitis; we are actually asked to adopt this operation as the best means of curing the comparatively mild cases of endocervicitis and ulceration, when the cervix seems otherwise healthy and not much larger than usual. These cases can be cured in two or three months by such applications as the acid nitrate of mercury, or nitrate of silver, coupled with proper medical treatment, and it would be preposterous indeed to treat them by tracheloraphy. At all events, the question is now before the profession, and the ever-increasing number of highly intelligent general practitioners, who become our judges on ceasing to be our pupils, know well how to discount the hobbies of metropolitan authorites, and the decision may be safely left to them.

"I have seized this opportunity of entering another protest against the too frequent use of the knife in the treatment of uterine affections, but it must not be supposed that I consider what precedes to be necessary for the safeguarding of the interesting objects of my solicitude in the present work. No, they have fortunately reached that most enviable time of life when the womb is well nigh safe from the onslaught of American surgery and the more vexatious, permanent irritation of pessaries that do not fulfil their object. The comparatively peaceful tenor of pathology at the change of life has reacted favorably upon the author. He knows that he will no longer be called upon to oppose the crotchets of esteemed fellow-laborers, and that in a perfect spirit of peace, he may set himself to describe the closing scenes in the life of woman."

Occlusion of the External Auditory Meatus.—Three cases are reported from the clinic of Dr. Samuel Sexton by the Resident Surgeon of the New York Eye and Ear Infirmary, Dr. Orr. The first case was a man, aged thirty-nine, who fell six feet from a truck and struck the left side of his face upon the hard pavement. A branch of the temporal artery was severed, and the parts about the temple were much contused. Four days after the accident a sanguino-purulent discharge from the left ear occurred, and when Dr. Sexton saw the patient at his clinic, six weeks after the accident, a tegumentary membrane closed the entrance to the external auditory canal. There was, however, a slight cicatrix, but the parts had generally the appearance of a congenital occlusion. The operation for the relief of this difficulty was performed without an anæsthetic. It consisted in forcing a narrow probe-pointed tenotomy knife through a minute sinus, which was believed to enter the canal at its posterior-superior margin, and by a circular incision removing a portion of the integument one-fourth of an inch in diameter. A silver speculum was then introduced into the newly formed meatus and retained by a bandage. Before the operation the patient had stated that he was not aware of the existence of the occlusion, and as there was a history of otitis media duplicata in childhood, it was at first suspected that the closure might have long existed. Subsequent to the operation, however, a small polyp and a large wad of cotton-wool saturated with the secretions were removed from the canal. The appearance of the wool indicated that it had been immured but a short time.

The hearing, which before the operation had been almost *nil*, was entirely restored. The drum-head was found to be intact, and but little affected by the surrounding inflammation. Dilatation, which had to be kept up for some weeks after the operation, was accomplished by the introduction of cotton-wool tents smeared with ung. calendulæ ex herba recenti. The parts finally assumed a very natural appearance, and the vertigo and tinnitus aurium, both of which had been very distressing before the operation, entirely disappeared.

The second case was a man, aged sixty-two, who, at the age of eight, received a blow from a horse's unshod hoof, severing the left auricle from his head. The auricle had been replaced and bound to the head by bandaging, but healing was not completed, the patient states, for eighteen months. Owing to the misplacement of the auricle the entrance to the external auditory canal was completely closed by integument, so that its exact location was difficult. A minute sinus remained, however, through which the patient could force a thin matter by pressure in front of the meatus. Patient could hear a loud voice on this side. He refused to have an operation performed for his relief.

The third case was a child thirteen years old. During the first weeks of her life the right external auditory canal was the seat of an otitis externa acuta, with much granulation-tissue, which was irritated by scratching. The auricle was deformed by the existence of adhesive bands, which united the margin of the concha to neighboring tissues. The canal was closed at the junction of the osseous with the cartilaginous portions by integument. Hearing in the affected ear was almost *nil*.

Dr. Sexton was of the opinion that in cases like the two latter above alluded to, an operation should be performed without delay, should symptoms arise pointing to middle-ear trouble, for the case would be much complicated by any closure preventing the escape of secretions outwardly through the external auditory canal.—*American Journal of Otology.*

The louder the quack the longer the bill.

A Case of Congenital Complete Hepatic Hernia.—Dr. Wm. J. McMahon sends us an account of the following interesting case: From the rarity of hepatic herniæ it seems desirable to mention the following case, occurring in his service at the St. Vincent de Paul Colored Asylum. The child, at birth, presented a tumor at the umbilicus measuring two and a half inches in diameter, and with an elevation of one and a half inch. On examination, conducted by himself and Dr. H. E. Turner, the hernia apparently protruded through a separation of the abdominal muscles at the umbilicus, covered only by the peritoneum. Although no satisfactory conclusion was arrived at as to the contents of the sac, still nothing giving evidence of the presence of intestine or mesentery could be discovered. Subsequent examinations also failed to throw any light upon the subject. The tumor gave dulness on percussion over its entire surface, the bowels were regular in their action, and the stools perfectly natural. The child was nursed from the bottle, took food well, and although there was a slight malformation of the genital organs, yet the kidneys acted well and freely. An attempt at reduction was at once made, but without success. Constant pressure by means of a compress saturated with carbolized olive oil was then applied, but with no effect on the hernia beyond a thickening of its covering. The child emaciated rapidly, developed a condition of general jaundice, and finally died on the ninth day, the appearance of the hernia assuming a dark green hue, but otherwise remaining unchanged. At the post-mortem the umbilical cord was found attached to the centre of the hernia, with a deviation toward its lower border, where some indications of sloughing were present. The abdomen was opened on the right of the tumor, and the contents examined from within outward. The hernial sac was found completely occupied by the liver, displaced, and so firmly attached that its separation caused rupture of the peritoneal covering, which, in this situation, though more or less degenerated, measured one-tenth of an inch in thickness. The heart, lungs, kidneys, and spleen showed an advanced degree of development, sufficiently for a child of one year.

Stretching the Median Nerve.—In hunting, a man was shot in the left arm. Paralysis of the forearm set in, with excessive pains. The piece of lead could not be found. The median nerve was paralyzed, and the muscles of the forearm and hand atrophied, the pains being intolerable. An incision 3 ctm. long was made, the enlarged and indurated nerve laid bare and stretched. The wound healed, *prima intentione*. The pains were then moderated and more of a neuralgic character, and after a while they disappeared entirely. The paresis of the muscles diminished, and by galvanic treatment the patient was cured.—*Le Praticien.*

A Curious Electrical Phenomenon.—A remarkable instance of the development of electricity by friction has been brought to light in a Berlin brewery. The building is constructed of stone and iron, with the floors laid in asphaltum. In the upper part of the malt-house is a malt-cleaning machine, from which the cleaned malt is conducted, through an iron shoot, to wagons, for distribution through the works. If the malt-cleaning machine remains a long time in operation—which frequently does occur without intermission for three weeks at a time—electricity is developed by friction of the malt in the iron shoot, and in the most insulated portions of it. Such is the tension of the electricity that sparks continuously flash here and there, the malt crackles throughout, and sparks fly from it to the hands of the employés. The men at first thought this was a demoniacal exhibition, until an expert calmed their fears. This gentleman, Herr Nehrlich, brought the subject before the Electrotechnical Union, and the discussion thereupon elicited statements from several members who had noticed similar appearances in other breweries, etc. Dr. Werner Siemens showed how, through the existence of the asphalt floors, the malt-room is so insulated from other portions of the building that it electrically resembles a Leyden-jar.

The Proportion of Persons who can be Hypnotized.—Dr. Liébault (*Revue Médicale de l'Est*) found that among 1,014 persons whom he attempted to hypnotize, 27 were entirely unaffected, 33 were only made tired and sleepy, while the remainder could be put into conditions varying from light sleep (100) to the profoundest somnolence.

A Somewhat Unique Case of Opium Addiction.—It is now nearly ten years since we began giving attention to the study and treatment of opium addiction. Dr. J. B. Mattison, of Brooklyn, N. Y., writes: "In all the cases coming under our care, and they number not a few, there has not been an exception, save a single instance, to the assertion made some years ago in this and other journals, that the vast majority of opium *habitués* become such *not* from *choice*, not from merely vicious indulgence, an idea mistakenly held by many both in and out of the profession, but from a *physical necessity*, having, ordinarily, its genesis in some painful ailment demanding the use of opium, which when its legitimate need was fulfilled had forged around its unsuspecting victim a chain so powerful that self, unaided, was powerless to break. Of this fact, to my mind, there is no question, for among those under observation have been men from various walks of professional life, mainly, much as it may cause surprise, from my own fraternity; men ordinarily of iron will; men who have faced death on battle-field and in prison-pen; men of strong mental parts, notably among them one filling a leading seat in the higher council-hall of the nation, whose brilliant intellectual accomplishments surpassed those of any public man whose acquaintance we have had the honor to enjoy, and the personal testimony supported by the clinical history of them all has proven beyond dispute that their opium taking was an *absolute necessity*, before which the will resistlessly went down. We well know that many maintain an opposite opinion, and are disposed to extend censure rather than charity to these unfortunates, but I have no hesitation in expressing the profound conviction, based upon years of observation, that this is a most mistaken view of the subject, and that opium *habitués*, as a class, instead of being maligned and misrepresented, as so often is done, deserve commiseration and the same measure of sympathy as we would desire had this 'horror of deep darkness' fallen on us. The exceptional case to which allusion has been made, came under our care during the past year, and presents a factor in its etiology somewhat unique, and of special interest to any professional gentleman whose zeal in the pursuit of therapeutical knowledge may tend to outrun his discretion. Dr. A. B——, was attacked by facial neuralgia, so

severe as to compel his taking one quarter of a grain of morphia hypodermically, at bedtime, to secure ease and sleep. This amount was increased to one-half a grain per diem during the following month, when, the neurotic disorder having subsided, the opiate was abandoned with little or no inconvenience. Some time after this, a gentleman addicted to the use of morphia placed himself under his care. Then Dr. B——, as he asserts, without the least desire for opium, but solely from a wish to discover, if possible, some antidote drug to aid him in the cure of this patient, began experimenting on himself with hypodermic morphia, with the result of falling a victim to its seductive influence, and yet, though he failed to make the wished-for-discovery, managed the case of his patient so well that success crowned his effort, while he, despite every endeavor, was unable to extricate himself from the pit into which he had unwittingly fallen and was obliged to seek aid for his relief. The moral of this story is obvious. Experimenting on one's self with morphia, especially hypodermically, is dangerous, and if any of our readers are thus tampering with the drug, the best advice we can offer is, *quit*. It may be of interest to note, in closing, that Dr. B—— made a very gratifying recovery, leaving for home at the expiration of seventeen days; had circumstances demanded he could have done so a week earlier, and later tidings reported him doing well."

The Causes of Malaria.—Signor Torelli, who has recently published a map illustrating the prevalence of malaria in Italy, holds that the two principal causes of malaria are the spread of railways and the destruction of forests. Railway embankments interfere with natural drainage, and the destruction of forests causes long periods of drought, during which the earth becomes dry and porous as a sponge, so that when the rain does fall, instead of running off from the surface it is absorbed by the soil, which thereupon remains moist and gives forth noxious vapors for a long period.

Inversion of the Uterus.—Dr. O. J. Hutchins, of Depeyster, N. Y., reports a case of complete inversion of the uterus, with entire protrusion of the organ from the body. The patient was a lady aged thirty-one, primipara, of delicate and anæmic habits, who, after an easy labor, was delivered of a healthy child. Slight traction was then made upon the cord, after which the forefinger was passed into the vagina, and the placenta, which was within easy reach, carefully removed. Immediately following came a hard mass, the presence of which caused a violent expulsive effort on the part of the patient, when the entire uterus, completely inverted, was protruded from the vagina, accompanied by profuse hemorrhage. By gentle but firm pressure the organ was successfully returned within the vagina, but not entirely to its normal position. The patient, however, became suddenly pulseless, with short and labored respirations, and, in spite of free stimulation, the case proved fatal in about one hour and a half. No force was employed or anything given to expedite the labor beyond the administration of a drachm of fluid ergot one hour before the delivery of the child.

Treatment of Diphtheria.—Dr. J. J. O'Dea, of Stapleton, N. Y., recommends the following and, as he claims, successful local treatment of diphtheria: To the entire inflamed surface surrounding the false membrane, and close up to its border, he applies, by means of a cotton-wad, the following solution:

℞. Argenti nitrat. cryst. ..... ʒ j.
Spt. æther. nit. dulc. ..... iv.
Aquæ destill. ..... ʒ iv. M.

In the same manner he then makes an application of the following mixture to the surface of the false membrane, and out to its extreme edge, but no farther:

℞. Acid. carbol. ..... gr. viij.
Liq. ferri subsulph. ..... ʒ ijss.
Acid. sulphurosi. ..... ʒ iijss.
Glycerinæ. ..... ℥ j.
M.

These are to be repeated twice, or possibly three times, in twenty-four hours, the second mixture to be supplemented by a gargle of lime-water, thus allaying irritation and removing the *débris* of false membrane broken down by the action of the acid. When nothing remains of the deposit save some milky white patches he omits the applications and employs only the lime-water gargle or spray.

The Significance of Peptone in the Blood or Urine.—Jaksch, from a long series of examinations, concludes that if one finds peptone in the blood, it can be inferred that there is a depot where leucocytes are forming in excess somewhere. The peptone is naturally taken up by the white corpuscles which give it up under certain conditions, when it is excreted by the urine. Peptonuria indicates that resolution has begun in pneumonia. Peptone appears in the urine before physical signs of resolution appear in the lungs.

A New Method of Amputation of the Upper Extremity.—M. Desprès has devised (*British Medical Journal*) a new method of amputating the upper extremity. It is practicable in patients under twenty-eight years of age, is indicated in cancer of the scapular, and is less formidable than removal of the scapula. It may also be applied in white swelling of the shoulder involving the scapula. The method of operating was as follows: 1. He tied the subclavian artery, external to the scalenus muscle, by a double ligature, to avoid secondary hemorrhage. 2. He made an incision *en raquette*, commencing at the centre of the space separating the eminence of the spine of the vertebræ, at the internal border of the scapula, and at a level with its spine, and following its dorsum, turning round the salient portion of the shoulder and passing under the axilla as far as its centre, and afterward rejoining the original incision at its starting-point. 3. He dissected a superior flap without interfering with the incision for the ligature of the vessel. 4. He divided the clavicle as near as possible to its middle. 5. He tied the axillary vein. 6. The scapula was detached after division of the pectoralis minor and latissimus dorsi, and then dividing the muscles inserted into the scapula. The suprascapular artery should be tied, if necessary, and the wound brought together by sutures. The dangers of this operation consist in 1, the loss of venous blood; 2, the possibility of the entrance of air into the axillary vein; but they are not necessarily mortal. One complication occurred: the extremity of the clavicle perforated the skin; but M. Desprès thinks that it is better to have such a condition than to remove the entire collar-bone, and that this portion of the clavicle preserved covers in the superior aspect of the thorax.

Original Communications.

CASES OF DIABETES WITH URINE OF LOW SPECIFIC GRAVITY.

By S. WATERMAN, M.D.,
NEW YORK.

The following cases of transitory diabetes with urine of exceedingly low specific gravity (1.002), and in which Trommer's test gave promptly the reaction peculiar to the presence of sugar, ending both in recovery, are worthy of record.

Mrs. C.——, of German birth, married, aged twenty-seven, of nervo-sanguineous temperament, had advanced in her second pregnancy, to the eighth month of gestation. On Friday evening February 4, 1870, she was seized with a sudden chill, which lasted about half an hour, accompanied with a sense of excessive exhaustion and sinking in the præcardia. I saw her within half an hour of the attack, when the following symptoms presented themselves: She was exceedingly restless, throwing herself from one position to another, giving herself up to fear and despair. The surface of her body was cool; her temperature 96⅕° in the rectum, pulse ranging from 72 to 74 per minute, but threadlike and empty, heart's action very weak but not intermittent. Her lips were parched and covered with black sordes as if she had been in the latter stages of typhus gravior. She complained of unquenchable thirst, although she drank water continually. Her appearance was expressive of great suffering, and danger of dissolution seemed to be imminent. Her eyes seemed sunken and had a peculiar wild and glassy appearance. The color of her face was very pale. She had urgent calls to urinate every five or ten minutes, and always passed considerable quantities of a perfectly colorless urine. At every call to urinate she was seized with chills and violent shivering. She refused to lie down quietly, preferring to sit up and to shift unceasingly, in consequence of a sense of suffocation which was distressing in the extreme. She wrung her hands or threw them up wildly into the air, her vision was impaired, and she was continually asking for light. The sense of impending suffocation could be traced to a spasmodic constriction of the glottis. Strongly impressed with the belief that she would die, she desired to take leave of her children and relatives.

I learned that she was perfectly well that day until after a hearty supper. For many weeks previously she had suffered from nausea and loathing of food. I made a careful vaginal examination, but could not discover any abnormal condition. I found a head presentation in the first position. There was no undue distention of the abdomen, nor could I detect any tenderness, nor any other abnormal condition of the abdominal organs.

I came to the conclusion that the whole train of these strange and formidable symptoms, so rapidly developed without any premonitory trouble, was probably hysterical in its character; yet I had never seen an attack so peculiar and so terrible. She appeared like a person under the bewildering influence of some powerful narcotic. I ordered the following nervine:

℞. Tr. valerian. ether. ..... ℥j.
Tr. castor. vera ..... ℥ij.
Acid. phosph. dilut. ..... ℥j.

Misc. D. S.—A teaspoonful every half hour and brandy *pro re nata*.

Under the influence of this simple medication the symptoms gradually subsided and she fell into a quiet and refreshing sleep. I found her next morning up and attending to her household duties, complaining of weakness, but of nothing else, and she made a complete and speedy recovery. I had obtained a fair quantity of her urine, passed during the hysterical storm; another quantity of the morning urine was also secured and at once submitted to analysis, with the following results:

Night Urine.	*Morning Urine.*
Specific gravity, 1.002.	Specific gravity, 1.018.
Reaction, alkaline.	Reaction, acid.
Albumen, none.	Albumen, none.
Sugar (by Trommer's test), large quantity.	Sugar (by Trommer's test), small.
Color, white and clear.	Color, straw color.
Urea, scarcely a trace.	Urea, normal.

The night urine, which gave the instantaneous and intense sugar reaction, was allowed to stand a few days. Fermentation took place rapidly, reaction became decidedly acid, and its clearness and transparency changed into a turbid, milky fluid.

What caused this peculiar and strange transmutation? The microscope revealed the presence of fatty matters in exceedingly fine division, which could be dissolved with sulphuric ether. There were no casts. It is generally considered by good authorities (Golding-Bird, Ultzman, Dickinson, Beale, and others), that the presence of oil in the urine does not necessarily point to a pathological condition of the renal gland. It is not unfrequently met with in the urine of pregnant women. Says Dickinson ("On the Pathology and Treatment of Albuminuria"): "The presence of oil in the renal cells, even to a large amount, does not necessarily interfere with the action of the gland." It is foreign to the scope of this paper to enter into a full investigation of the origin and pathological significance of the presence of oil in the urine. Those interested in this peculiar condition of urine may find a full and minute description in the "Guy's Hospital Reports" for 1840, and also in the *Medico-Chirurgical Review* of 1839, p. 228, and *Journal de Chemie-Médicale*, 1839. Later references are furnished by Dr. Ultzman in the "Real Encyclopœdia der gesammten Heilkunde."

To this urine, or more directly speaking, to this fatty substance the name of kiestein was formerly given, and it was supposed to be a sure sign of pregnancy, and to be found invariably in the human female during uterine gestation. This notion is now pretty well exploded, as the same urine has been found in unimpregnated females, and in males also.

With regard to the appearance of fat-globules in the urine in question, after it had undergone the process of fermentation, a rational explanation, I think, can be given. The urine contained probably these oil-globules at the time it was passed. It will be remembered the urine was then strongly alkaline, and this alkalinity kept the oil in a saponified condition. The rapid fermentation was undoubtedly due to the conversion of its sugar into carbonic acid and alcohol. As soon as the alkalinity of the urine was neutralized by the nascent carbonic acid, the fatty substance, no longer saponified by the alkali, was precipitated, giving the urine its milky appearance.

A second case was in Mrs. H——, living in a shanty, corner of Sixth Avenue and Fifty-sixth

Street. She applied to me in February, 1868. My records show her to be forty-five years of age, of plump and muscular appearance, inclined to obesity. Menses ceased ten months previously. She supposed herself pregnant, and thought I could tell by examining her urine. The urine looked perfectly colorless, like water, had no perceptible odor, gave an alkaline reaction, and had a specific gravity of 1.002 at a temperature of 62° F. On the application of Trommer's test as modified by Pavy, an immediate and brilliant reaction took place, evidencing the presence of sugar. The microscope showed branch-like crystals, partaking of the character of urea, and of chlorate of ammonia, but no casts. On slow evaporation a resinous matter remained, hardening in the air, of yellow wax color, insoluble in ether and chloroform, but soluble in caustic potassa, which, with Fehling's solution gave the characteristic precipitate of suboxide of copper. A part of the urine left to spontaneous evaporation presented beautiful octahedra crystals of oxide of lime, and splendid large crystals of salts of urea, which when placed under the polariscope presented the most beautiful sight imaginable.

Subsequent observation proved that Mrs. H—— had not been pregnant. Under proper treatment the anomalous secretion disappeared and left her a perfectly healthy person.

The presence of sugar in the urine is associated in our minds with a high specific gravity of the secretion, and such, I think, is true, almost invariably in diabetic urine. When the urinometer indicates such high specific gravity we are induced to test for sugar, but in urine below the usual specific weight of 1.012 to 1.015, the presence of sugar is not suspected, and the sugar test is seldom, if ever, applied, except by accident. Whether sugar is a normal ingredient of every urine is yet an open question, and has no direct reference to the points under consideration. I have vainly searched for cases similar to these presented by me, and for an explanation of its phenomena. Only Roberts (urinary and renal disease) speaks of it. He says: "If its density persists at a lower point 1.005, to 1.008, the existence of insipid diabetes is to be apprehended. After hysterical paroxysms in women, after similar attacks in men, and sometimes in the apoplectic state, the urine is discharged in large quantity and of exceedingly low density."

Dr. A. Jacobi of this city has a case now on hand, where at a density of urine at 1.007 sugar is present.

In connection with this point of inquiry it is well to remember that various substances, such as carbonate of ammonia (derived from the decomposition of urea) as well as other salts of ammonia, carbonate of lime, phosphate of lime, phosphate of magnesia, and some other substances interfere with the usual sugar test. This I found to be the case not unfrequently when the quantity of sugar was small. Its presence was demonstrated by Trommer's test after the lapse of many days, the urine with the test solution having been set aside for that purpose; it took sometimes eight days before the suboxide of copper was precipitated.

In the two cases above related Trommer's test gave an immediate reaction. How the small percentage above the specific gravity of water, two per cent., could account for the presence of sugar I am unable to surmise. May not Trommer's test, after all, respond to other substances as well as to sugar, and may we not often be led into errors by its reaction? We know it responds to indican. So says Thudicum ("Pathology of Urine"). Indican is, however, not a sugar, and as found in the urine, is a gum-like substance, from which alcohol separates a resinous mass, of a lower specific gravity than water, and which, when acted upon by the oxide of copper with an excess of caustic soda assumes a greenish color, and finally throws down the suboxide of copper.

Alonzo Rognosi made a communication to the Academy of Sciences, December, 1851, stating that he found sugar in the urine of hysterical persons; and in the "Reports of the G. A. University of the Royal Society of Sciences at Gottingen," dated March 15, 1852, Dr. R. Wagner speaks of the presence of sugar in the urine of hysterical persons as a proven and incontestable fact.

A CASE OF
FRACTURE OF TIBIA AND FIBULA;
With Aneurism of Posterior Tibial Artery.

By L. E. BORCHEIM, M.D.,

CLIFTON, ARIZONA.

LATE HOUSE PHYSICIAN TO THE MOUNT SINAI HOSPITAL, NEW YORK.

On August 6th, I was called to attend a patient giving the following history: M. C——, Mexican, aged forty-five, miner by occupation. While standing upon an empty box, in an intoxicated condition, the box was kicked from under him and he was violently precipitated to the ground, and in falling struck his right leg upon a rock. In endeavoring to arise found himself unable to do so, as his leg gave away under him.

My first visit to the patient was made twenty-four hours after the accident, and I found a transverse fracture of the tibia at the junction of the lower with the middle third, also fracture of the fibula (oblique) at its middle third. There was but slight ecchymosis, but considerable œdema and pain. I placed the limb in an improvised fracture-box and ordered an evaporating lotion of ammon. chloride and alcohol, with the intention of reducing the swelling previous to the application of a plaster bandage.

When on the 16th I went to see the patient to apply the permanent dressing, I found him suffering with severe pain in the limb, and upon examination, detected a small mass having a distinct pulsation, which ceased upon applying pressure upon the popliteal artery.

The diagnosis of an aneurism of the posterior tibial artery was accordingly made, and a pad applied by a bandage over the popliteal artery; this, however, gave rise to considerable inconvenience, and the pad was accordingly applied to the superficial femoral artery.

After having persevered in this treatment, at intervals, for three days, and without any success, I finally ligated the superficial femoral at the apex of Scarpa's triangle in the usual manner, and the result gave complete satisfaction.

The process of repair in the fractured bones was apparently not interfered with, and the patient left here a few days ago, still wearing his "Bavarian splint."

I desire to publish the above, owing to the rare occurrence of this complication, myself being able to find but two recorded cases.

CONCERNING THE EFFECTS OF THE WEED UPON HABITUAL SMOKERS.[1]

By W. H. BENNETT, M.D.,

BROOKLYN, N. Y.

A GREAT deal has been said upon this subject, and very frequently by men who know nothing of the effect of tobacco-smoke from personal experience. Some stimulated only by a desire to check, if possible, the spread of an often pernicious habit, have allowed their enthusiasm in the course of philanthropy to exaggerate and misstate facts; while others have committed the greater error of basing their conclusions upon the *supposed* effects of habitual smoking, without having investigated the subject, and without knowing anything about the matter. Many careful observations have been made, but chiefly with large doses, and we know perfectly well the physiological effects of tobacco, when given for experiment for a short time, and also its therapeutical action when given as a medicine in acute disease; but regarding its effects, when used habitually for an indefinite period as a luxury, in comparatively small doses, in the form of smoke, we have but little trustworthy data; and, undoubtedly, in regard to this method of using the weed, something may be said in its favor as well as against it.

However truthful and careful a person may desire to be, it is very possible for him to commit error, and for this very reason repeated experiment is necessary, to demonstrate beyond peradventure any question pertaining to medical science. It is very frequently said that one can tell nothing of the effects of a drug by experimenting on one's self, for the mind will be biassed to a certain extent by preconceived ideas, rendering the results untrustworthy; and, moreover, the action of the material used will so stimulate or depress the mental functions as to materially interfere with one's reasoning correctly. But this argument certainly does not apply in the case of tobacco, where it is taken as a luxury day after day for a number of years. In this case, it certainly does not interfere with our powers of perception to a sufficient degree to render our observations untrustworthy in the least.

From repeated experiments, I am led to believe that a difference of opinion in regard to the effects of tobacco-smoking, where the observations are carefully conducted, and are confined to persons habitually using the weed, will only occur where the quantities daily consumed vary. Of course, the susceptibility of the person to the influence of a sedative must always be taken into consideration, and the quantity taken must be viewed in connection with this; thus, a single cigar or pipe of tobacco may often produce in the weakly an effect equal to four or five times the quantity in a strong, robust person.

Tobacco, if taken in small doses by those accustomed to its use, stimulates mental activity, and prevents drowsiness; it increases the flow of ideas, increases the clearness of mental perceptions, soothes, but does not exhilarate, and this latter effect is most marked when there is mental depression or anxiety. It always causes slight muscular debility, and diminished excitability of the motor nerves, but sensation is not in any way affected. Its effect on the heart is to cause fewer and less energetic contractions. It does not, therefore, prevent fatigue, but owing to its soothing action, the effect of over-work or great exertion is much less severely felt, when followed immediately by a moderate indulgence in the pipe or cigar. More work, both mental and physical, can be performed if small rations of tobacco are allowed than if it be withheld. But if large doses are taken there is continued depression, and if indulged in to excess for any length of time there results a condition similar in many respects to that caused by the abuse of alcohol, although it is not developed to the extreme extent as when the latter drug is used. The mucous membrane of the mouth, pharynx, and posterior nares is seriously affected, and I am sure I have seen unmanageable and destructive ulceration of the soft parts of the mouth, from the smoking of rank tobacco, in short pipes, by old persons. Where a good quality of tobacco is used, or cigars, a chronic catarrh of the parts mentioned is the result. There is disordered digestion, loss of appetite, restlessness, insomnia, and weakness of body and mind, with also, very frequently, disturbance of vision and impaired memory.

Tobacco, in the form of smoke, in small doses excites a free flow of saliva for some time, which is not followed afterward by a diminished flow below the normal amount. It stimulates digestion, and increases the appetite, and if the good effects only are desired, it should be indulged in always after meals. In all doses short of acute intoxication it increases the secretion of urine,[1] and stimulates the peristaltic action of the bowels; but exactly how it produces the latter result cannot be explained. It is equally true that it increases the sexual desire; its action in this respect may be due partly to its influence on the nervé centres and partly to the irritation produced in the urinary tract through which the resulting products are eliminated from the economy.

Smoking, even in moderation is injurious to the teeth, and its effect upon these organs is worse in a cold almosphere than in a warm one, and is bad according to the existing condition of the teeth, and the condition in which they are allowed to remain. A tooth expands and contracts like most other hard substances under variations of temperature, and if these expansions and contractions take place too rapidly, or to too great an extent, the expansive properties of the whole organ not being equal, the external covering being the harder, and more susceptible to change as well as being most exposed to it, cracks, and thus is produced a vulnerable point for the secretions of the mouth to act upon. That the secretions of the mouth are rendered acid by the action of tobacco smoke may be demonstrated by the use of litmus paper within half an hour after using the weed; and it may here be mentioned that the fluids secreted by the mucous membrane of the buccal cavity of any habitual smoker, who uses tobacco freely, are apt constantly to give an acid reaction.[2] This acid secretion facilitates the deposit of earthy matter upon the teeth, as well as exerts a chemical action at previously weakened points; and it keeps the soft part covering the

[1] I have recently read some remarks in the London Lancet upon this subject, but find there no reasons given for the conclusions stated.

[1] This, I know, is contrary to the expressed opinion of several eminent experimenters, but is nevertheless, I am certain, correct.

[2] The saliva is undoubtedly secreted alkaline, but the other secretions, from the mucous gland and follicles, are sufficiently acid to more than neutralize this, and it undergoes change in the mouth. If the inside of the lip or cheek of an inveterate smoker be wiped dry, the first watery exhalation, or more properly, fluid exudation, even though the quantity be so small as to be imperceptible, will redden litmus paper when pressed upon the part.

roots in an irritable condition—the result of the existing catarrh.

The injurious effect of the abuse of tobacco-smoke on the mucous membranes with which it comes in contact is one of its worst features. It produces a chronic catarrh which, under no other source of irritation, gets gradually worse and worse, and in time renders the smoker very uncomfortable. In warm climates where the extremes of temperature are slight, chronic catarrh of the mouth and pharynx is very common among smokers, and as it is customary to exhale the smoke through the nares, a diseased condition of the nasal mucous membrane is also very frequently met with. But in our own climate, where the extremes of heat and cold are great and aggravated, forms of chronic catarrh, so common from other causes, the irritation of tobacco-smoke when allowed to exceed certain limits is of still more serious import, and often is the greatest obstacle to successful treatment. It is hard work to get smokers to believe this; they will tell you that a cigar in the morning relieves their catarrh and makes them more comfortable, and no doubt it does for the time being. What is more natural than that a swollen and infiltrated membrane in a state of passive congestion and covered with a thick or sticky secretion, should be relieved by gentle stimulation, which quickens the circulation and thus diminishes the swelling, and clears off the adherent mucus. If when this is accomplished the irritation should cease there would be more good than harm done, were it not that tobacco-smoke renders the retained secretion of all parts with which it comes in contact more acrid. But if the act of smoking be repeated many times during the day, gentle stimulation is merged into continuous irritation, which no one can fail to see is injurious. Smoking probably is injurious to the buccal and pharyngeal membranes, aside from its irritant effect, for the suction required to draw the smoke into the mouth rarefies the air in this and the adjacent cavities, which, if repeated and continued indefinitely, tends to cause dilatation of the capillaries and give rise to continued passive congestion.

The mucous membrane of the stomach does not escape the baneful influence of excessive and frequent indulgence in tobacco. Probably some of the smoke is swallowed as such, and besides a portion of the oil which is deposited in the mouth is carried down by the saliva. The result is similar to that produced upon other mucous membranes.

The sight unquestionably suffers in cases of excessive indulgence, irrespective of its deleterious effect on the general economy. Although the action of tobacco is by no means so marked on the pupil as that of belladonna, hyoscyamus, or stramonium, in inveterate smokers the pupils are at all times apt to be somewhat dilated, and they do not contract to what would under such circumstances be considered their normal size when exposed to a bright light. In consequence of this the retinæ are exposed to undue irritation. But probably a more important factor in generating disease of the organ of vision is the frequent contact of smoke with the exposed conjunctivæ, which not only produces changes in their circulation and nutrition, but in the circulation and nutrition also of the delicate parts lying in close proximity underneath. To studious men—those who sit bent over their book or desk with a cigar in their mouth, does this latter remark particularly apply. The injurious effects of immoderate smoking on the eyesight are slowly produced, and very frequently, if the habit date from no very distant period, they vanish at once upon its being discontinued; but certain it is that excessive smokers do not possess normal vision. It is not necessary to go into the question of atrophy of the optic nerve, as this ground has been travelled over repeatedly by Mackenzie, Wells, Von Graef, and many others. There can be no doubt that excessive smoking, like excessive drinking, if indulged in to the extent of introducing large quantities of an active poison into the economy, may exert a depressing influence upon, and when long continued cause organic change in such a very sensitive structure.

Excessive smoking relaxes the muscular tissues throughout the entire body, and induces debility. Weakness in the knees is a common complaint of all great smokers, though enjoying the best of health. The spinal cord seems to be feebly impressed; true reflex irritability independent of consciousness is diminished, while there is tremor on exertion and clumsiness in performing simple operations, also indicating impairment of function. On certain functions of the brain excessive indulgence has a depressing influence which is peculiar, while at the same time there is a certain amount of cerebral irritation. Voluntary movements are produced less readily, for the motor nerves are slightly paralyzed; but the nerves of special sensation more readily convey impressions than before, and there may be frequent movement independent and in defiance of volition, instinctive as it were—sensori-motor reflex. Thus a slight noise like the sound of a distant whistle will cause a sudden start or movement of the hand toward the ear that would require an effort to accomplish voluntarily, but which cannot be prevented. Regarding this increased excitation of the nerves of special sense and the sensory nerves, we may look upon it as unnatural and perverted; for take the sense of vision while the retina is unduly sensitive to light, and a sudden glare will cause a start. Normal vision is very commonly not present, and even bright objects cannot be clearly and sharply defined. Although acuteness of perception does not seem to be materially interfered with, and external impressions are readily received, they are not retained, but discarded without due consideration or further mental exertion; the impressions are transitory, and new ideas crowd in to take their place. The function of ideation is active, but the mind is wearied, as it were, and will not use or develop the ideas conceived.

Smoking in moderation gives us all the good effects of tobacco, and not only without being productive of any harm, if we except its action on the teeth, but in many cases with actual benefit to the person using it. Thus it soothes us when in pain and modifies the exhaustion of fatigue. But all are not affected alike, and the dose must be regulated according to the natural susceptibility of the smoker. One's calling in life has much to do with whether he may use tobacco or not, and it also dictates in a great measure in what dose he may take it. The man of sedentary habits, and he who must use his eyes much, or weary his brain with difficult problems or deep and serious thought, or use his hands in careful and exceedingly nice manipulations, and the man who has much to irritate him, if he smoke with benefit must smoke in great moderation. But the active man who takes plenty of bodily exercise, the wit, the person whose avocation simply requires that he use his brain to act or respond on the spur of the moment without having to follow

out the idea to any great length, may indulge more freely.

The effect of tobacco-smoke in causing a deposit on the teeth may be obviated by brushing these organs, both before and after the use of the cigar or pipe, and rinsing out the mouth with a weak solution of soda; and, as a matter of fact, it would be well enough for most persons to do this after eating, whether they are smokers or not.

As a medicine in certain forms of disease, when the dose can be regulated, tobacco is of great value, and in particular cases is superior to belladonna, for those habituated to its use like to take it and do not look upon it as a medicine. Its effects on the mind are experienced at once, and are continued after the depressing action on the muscular system has passed off. The diseases in which it is of value readily suggest themselves when we have made ourselves acquainted with the properties of the drug, but I would call particular attention to the following, *i. e.*, cardiac hypertrophy, when the organ acts too forcibly, habitual constipation, certain cases of asthma, and certain forms of dyspepsia, where the food lies like a load in the stomach after eating. In diseases of the mind, notably melancholia, it is of inestimable value, when its administration is properly understood. Here, by causing a flow of ideas, it dispels for the time the habitual fixed sorrow and relieves the mental strain by turning the thoughts into various channels without any apparent exertion on the part of the patient. And theoretically we might suppose (paradoxical as it may at first seem) that even in acute mania it will tend to prevent the ravings by varying the impressions and giving rise to pleasurable thoughts.

The propriety of withdrawing the accustomed ration of tobacco from persons long habituated to its use is questionable. It is like withholding the seasoning from their food, under which circumstances, no matter how nutritious the diet, it fails to please the palate, and does not receive the attention from the stomach it otherwise would, but lies like a load to disgust the digestive tract, which seems to await the coming of something to direct the commencement of operations.

In all forms of chronic catarrh smoking is bad, even in catarrh of the bladder. In suppurative disease of the middle ear it is especially injurious. In insomnia from mental strain and worry, in cases of debilitated heart, and in certain forms of neuralgia occurring in the weakly, tobacco had best be dispersed with.

The man who expectorates much, and the one who chews the end of his cigar and swallows the spittle will both suffer more or less from dyspepsia.

A New Theory of Acute Yellow Atrophy.—Dr. J. Hlava, of Prague, in a series of articles in the *Prager Medicin. Wochenschrift*, upon acute yellow atrophy of the liver, announces the following conclusions: 1. Acute yellow atrophy begins with an increase in the size of the liver. 2. The process is of a purely degenerative nature. 3. The disease is an infectious one. Hlava found in his two cases small round and rod-shaped organisms, which filled the biliary ducts throughout the organ. They resembled the bacillus gastricus of Klebs.

A Goat Farm has recently been established in England for the purpose of supplying goat's milk to London infants and invalids.

FOREIGN BODY IN THE AIR-PASSAGES.

A Bean Impacted in the Right Bronchus—Tracheotomy—Its Removal—Recovery.

By NATHAN JACOBSON, M.D.,
Syracuse, N. Y.

On the morning of July 6th, at half-past ten, the little child of F—— J——, of East Syracuse, was seen creeping toward a bean lying upon the floor, and immediately thereafter was choking. The mother picked up the child and introduced her finger into its throat. The child vomited, but was not relieved. The father held it up by its heels and slapped it upon the back, but the dyspnœa continued. A neighbor placed the child upon its stomach and passed her finger into its throat, in the meantime pouring water upon the infant's head, and soon the severe and distressing symptoms of breathing were relieved. However, the child continued to breathe with difficulty, "wheezing and rattling."

Dr. E. C. Skinner, of East Syracuse, was called, and resorted to all minor measures for the child's relief, but without material benefit.

At 5 P.M. the child had another severe paroxysm of dyspnœa, and during the night, according to the parents' story, the attacks returned every fifteen minutes. Its condition was not particularly changed during the succeeding day, and about noon of the 8th I was called to see it.

I found a child sixteen months old, fairly well nourished, without fever, face pale, lips slightly purple. Excepting that the respiration was hurried, there was at the moment of examination no apparent interference with breathing. When the child cried it was hoarse.

With the laryngoscope the larynx was seen to be congested, the cords reddened; otherwise nothing abnormal was noticeable. The child struggled so, that, in order to satisfactorily make this examination, it was chloroformed.

Upon physical examination of the chest it was found that the right lung was collapsed, and was receiving no air whatever into any part. The diagnosis of a foreign body impacted in the right bronchus was therefore easily made.

There were no symptoms indicating immediate danger, but the prospects were that with the continued presence of the foreign body in the bronchus, the condition of the lung, at best, would not be improved, and should possibly the foreign body in a fit of coughing be dislodged, suffocation was to be feared. Tracheotomy was recommended, and, with the consent of the parents, performed.

The child was chloroformed. In performing the operation I proceeded very carefully, dissecting the tissues, pushing aside the veins where possible, and not puncturing the trachea until all hemorrhage had ceased. The tracheal incision was made one-half inch in length, and was kept open with a two-bladed dilator by Dr. Skinner.

Forceps of different shapes were in turn cautiously introduced, but all efforts to seize the foreign body failed until I used the tracheal forceps devised by Stoerk and made by Reiner, of Vienna. With these I succeeded in entering the bronchus, and, after a little perseverance, grasped a bit of the skin of the bean. Another effort brought out another piece of the skin, while with the third attempt I grasped one half, and with the fourth the remaining half of the foreign body.

The bean, somewhat swollen from the absorbed secretions, measured in circumference seven-eighths, in its longest diameter three-fourths, and in its transverse five-sixteenths of an inch.

The wound was closed with adhesive straps. A loosely knitted scarf was thrown around the child's neck. In the evening three grains of quinine were given. During the night the child had a convulsion. When seen, at noon of the following day the temperature was 103.5°, respiration 60, and pulse very rapid. The child breathed largely through the tracheal opening, the adhesive straps having given way. A dry hacking cough was present. It was very restless and had slept none since the operation, except at rare intervals, and then only for a few moments. Tr. opii. camphorat. was given to secure rest.

During the succeeding day the fever increased rather than diminished, despite the use of quinine and sponging with cold water, and in the evening had reached 104.2°. The remaining symptoms were also unchanged. The percussion note was clear over both lungs; auscultation was of little avail, because of the loud tracheal breathing.

With the third day after operation the fever began to decrease, the other unfavorable symptoms to abate. July 13th, five days after operation, there was complete defervescence. In five days more the external wound had completely closed.

The child remained somewhat hoarse for about three weeks after operation, but aside from this there was nothing unfavorable in its case. On November 21st, the mother assured me that the child had had no further annoyance from this source and had made a perfect recovery.

REMARKS ON INTESTINAL OBSTRUCTION.

By H. ILLOWAY, M.D.,

CINCINNATI, O.

Case I.—In December, 1878, I was requested by my friend Dr. Keck, to see with him a case of intestinal obstruction. A boy, aged fourteen, of German parentage, was the patient. He was of flabby habit, rather dull, neither working nor studying, living on cakes, coffee and slops, and not much given to substantial food. The doctor had been called two days before and learned a history of what he supposed, at the time, ordinary constipation. He ordered him a laxative. This did not act. He then directed pills containing extr. colocynth co., grs. xii., and calomel, grs. xxiv. He took all and still no action. He was then ordered *six drops* of croton oil in pills. This proved no more effectual than the other remedies.

I examined the abdomen carefully, and found about the region of the umbilicus an elevation which was rather sore on pressure. The boy also complained of pains shooting out from this spot. My diagnosis was intussusception.

I had at one time noticed in the office of the late Dr. Holdt, a syringe constructed like a pump, and throwing a continuous stream with considerable force. I advised against any further medication and suggested to my colleague that I would procure the above-mentioned instrument, when we would proceed with enemata. We returned in the evening, Dr. Holdt, kindly loaning me his instrument. I threw into the bowels a tin basin nearly full of cold water, in fact, so much that the patient cried he could no longer bear it. He got upon the vessel and the water passed from him very much colored with fecal matter. Five minutes thereafter we gave him another injection, again until he cried he could not hold any longer. This time he had a large fecal evacuation—very fluid, of course, from the large quantity of water injected. We now ordered him quinia in one-grain doses, with tinct. nuc. vom., and left him. In the morning we found him much improved, his bowels had moved several times during the night, and once in the morning. In three days more he was up and about.

Case II.—Mr. F——, aged seventy, an old gentleman, hale and hearty, very active, and a good eater. Much subject to flatulent colic. I had treated him at various times for these attacks, and always succeeded in relieving him by a hypodermic injection of morphia ℥x. to xv. Magendie's solution; nothing further being required. He stated that when these attacks came on, it seemed to him as if something had knotted in the right hypochondriac region.

In the winter of 1880, I was called to see the old gentleman, who was again complaining of an attack of colic. I gave him a hypodermic injection of morphia. Next morning early, I was summoned to him again, and found that he was still suffering severely. I ordered him a pill of opium, half a grain, and extr. hyoscyam. half a grain, to be taken every two or three hours, as the severity of the pain might demand. This was continued for two days. He now had difficulty in micturition, passing but little urine and that with much pain. The pain in the bowels still very severe. Vomiting of biliary matter has set in. Dr. Forchheimer was called in consultation. He examined the case, and we agreed upon a purgative in the shape of calomel and jalap. This was 2 A.M. In the morning I visited my patient, and found his condition very bad. Countenance anxious and expressive of great agony. Continued vomiting of biliary matter. Small feeble pulse. He had summoned his children in the expectation of his speedy dissolution. The powders were vomited almost as soon as swallowed. His wife, upon her own responsibility, had administered to him during the night about twelve injections, both from a fountain and Davidson syringe. None of these injections, she assured me had passed from him. I had brought with me (by the kindness of Dr. Holdt) the same syringe that had previously proved so effectual. Fearing to add to the shock, I determined to use hot water in this case. I accordingly had a large china wash-bowl full of hot water brought in, cooled it to the temperature of 106° F. (by the thermometer), and then proceeded to pump him full, until he cried he could hold no more, rubbing himself about the umbilicus, saying he felt the water go all through him. He got up on the vessel, when the injection passed off with a large discharge of gas. Five minutes thereafter I gave him another injection, about the same quantity as before; this time, however, the temperature of the water at 90° F. This was very soon discharged with some fecal matter, and considerable quantity of flatus.

He now felt much better. The pain was very much relieved, and the vomiting arrested. I then waited fifteen minutes and gave him another injection, water at 106° F. This soon passed away with considerable fecal matter and gas. Pain completely relieved. I now left him, directing him to take some beef broth and brandy alternately at intervals. Returned in the evening, and found him doing very well; has had two more evacuations since morning; passed urine freely; taken the beef broth and

brandy with great relish. Completely relieved of pain. There is considerable soreness over the abdomen, more so in the right hypochondrium. He feels very much prostrated. He was now ordered a tonic; kept on light nutritious food, and in a week was on his feet again attending to his duties as usual.

The medical treatment of intestinal obstruction deserves most careful consideration.

The administration of the strong purgatives[1] in this affection is a method of treatment certainly most reprehensible. The use of these remedies directly jeopardizes the life of the patient.

The causes of obstruction are numerous, from a simple impaction of fæces, from a gall-stone lodged in the duodenum, to the more dangerous conditions of volvulus and intussusception.

A correct diagnosis as to cause is, as all authorities agree,[2] in many cases impossible. Hartshorne[3] expresses himself very strongly upon this point. "But at least a probable diagnosis is all that the nature of the case will admit. The differential discernment of special forms of obstruction during life is impossible." It behooves us, therefore, to be very guarded in our treatment, that a condition already bad be not rendered hopeless.

It must be borne in mind that even though we recognize the condition to be due to impaction of fæces, there may also exist a condition of ulceration[4] which violent peristalsis may rapidly convert into a perforation. I have a case in mind where a person who had suffered with constipation for a long time had a purgative prescribed by a physician of this city, and next day at noon was in a condition of collapse from perforation of the bowels.

If the condition be due to a gall-stone impacted in the duodenum, and these cases are by no means rare,[5] we may have a similar condition of ulceration, or rather partial perforation, that upon violent action may become complete.

If the obstruction be due to volvulus the administration of a drastic cathartic is certain not to relieve, and if we have to deal with an intussusception we certainly do not improve our patient's chances for recovery.

There is another point, and a most important one, which we must always bear in mind, when confronted by a case of obstruction, that is, the question of an early operation. At the present day, when the abdomen is opened with impunity, the question has certainly great pertinence. That most remarkable observer and clinical teacher, Trousseau, even in his day advocated an early operation. And here arises the consideration, what chances for success has such an operation where the patient has been dosed with camboge, croton oil, etc., and an existing condition giving rise to intense congestion and inflammation aggravated by such medication and most likely rendered fatal.

In many cases there supervenes a condition of paralysis of the muscular structures of the intestines from the long-continued pressure on the parts by hardened fecal matter, from the sudden distention of certain portions of the intestines by a large accumulation of gas, or from pathological changes inhibiting the action of the nervous centres. This condition cannot be overcome by the administration of a drastic cathartic. It happens not infrequently, therefore, that one or the other of this class of remedies, or several of them, are administered freely to patients and remain totally inert so far as any *evacuant* effects are concerned.[1]

Very often they excite a reversed peristalsis resulting in bilious vomiting, followed by stercoraceous and that whole train of evil symptoms accompanying this alarming condition.

Sir Thomas Watson thus forcibly expresses himself upon the use of those agents: "Withhold purgatives in those cases, because they are not merely useless, but positively hurtful; hurtful not only in the late, but in the early stage of the obstructive process; not merely condemned by an experience which is sometimes equivocal, but contraindicated by whatever rational principles can be deduced from the physiology and pathology of the malady."[2]

The treatment by opium is certainly more rational and more in accordance with our knowledge of the pathological conditions that may exist in this affection. But even to this plan of treatment there are some objections—more particularly to its employment at the onset of the disease.

First.—A case treated with opium becomes necessarily a protracted one.

Second.—In the simpler case we have means that relieve the condition more rapidly and without incurring any greater risk.

Third.—That even opium in large doses cannot always alleviate the intense suffering of the patient. In explanation of this statement I would say that it has been my experience where there was great accumulation of gas, the pains excited thereby could not be relieved by opium; nothing but the expulsion of the flatus would answer.

Fourth.—It may so mask the conditions that the proper moment for resort to operative interference may pass unperceived.

But the chief objection to its employment at the outset refers more particularly to the dangerous conditions of volvulus and intussusception.

There can be no doubt that these forms of trouble occur more frequently than we have any knowledge of, but that nature by a powerful peristaltic effort rights them again. Trousseau[3] has very explicitly called attention to this point: "You can understand how intestinal occlusion may be the consequence of this invagination; it is not, however, an inevitable consequence, for a vigorous contraction of the intestines may suffice to re-establish the normal condition."

Though we certainly, as already stated above, have no right to, possibly cannot, call forth such contraction by the administration of irritating agents, it is certainly a question whether it is wise to prevent such contraction occurring by the administration of large doses of opium.

All authorities recommend enemata; not because any direct curative effects are expected therefrom, but rather upon the principle "to be doing something," and that that something, if it do no good, shall do no harm. "Enemata are often beneficial, partly by relieving the lower bowel, partly, perhaps,

---

[3] Trousseau: Clinical Lect., vol. ii., art., Int. Obstruction. Philadelphia, 1873.

by acting as a kind of local fomentation."[1] It is for this reason, I believe, that, though so unanimously recommended, enemata are so rarely employed in this affection, as can be readily seen by the published histories of this malady; physicians seemingly preferring remedies of more decisive character.

And still enemata are the best means for the treatment of this disease and can be made directly curative in their effects. Certainly, as ordinarily administered nothing more than the effects described in the paragraph just quoted can be expected. An enema to be curative in intestinal obstruction must possess force. It must be sufficiently powerful to break down a mass of hardened fæces. It must have force enough to pass the ileocæcal valve.[2] It must have force enough to excite quickly a normal peristaltic action of the bowels by a powerful stimulation of the paralyzed muscles or inhibited nerves of the intestines.

The syringe in common use for this purpose possesses no force; the water is thrown in in feeble spurts; and even with the monster clyster (which would answer to enemata from the fountain syringe) it is questionable, taking into consideration the capacity, length, and resistance of the rectum, whether much more force is exerted thereby.

The instrument which was used in the treatment is a force-pump supplied with a suction and delivery pipe, has a stroke of one and one-half inches, and is operated by a handle to which is attached the segment of a gear-wheel which mashes in a rack, said rack being part of the piston-rod. If desired it can be firmly attached to a bed or chair by a clamp. It throws a continuous stream.

Without going into further details, it will be evident to all what great force can be exercised with this instrument. This powerful effect will greatly be increased when supplemented by the energetic action of water at a temperature of 75°F. or 106° F. as may at the time seem best.

That with this instrument the stream can be forced beyond the Bauhinian valve is undoubted in my mind. When discussing this point with the late Dr. Holdt (the possessor of this instrument), a gentleman well known here as a thoroughly scientific physician, a man of great attainments and at one time professor in the Russo-German University of Dorpat, he stated to me that he had on various occasions succeeded in throwing the injection beyond the valve.

The powerful action of this instrument is well illustrated by the two cases here recorded.

In Case I., a case undoubtedly of intussusception, the most powerful cathartics in the materia medica had been administered without avail. There was undoubtedly a paralysis of the muscular structure, and this had to be overcome before any relief could be expected. The rapid manner in which relief was afforded and the case cured is already recounted above.

Case II. was in my opinion an invagination of the ileum into the colon. In this case the curative effect of this powerful enema was markedly illustrated. As already related, the patient's condition was very dangerous, and his wife, who is rather expert in such matters, sought to relieve him by the administration of numerous clysters, both with the bulb and fountain syringes, but without avail; perhaps adding to his misery. There was in this case a reversed peristalsis, and it is a question in my mind whether the fluid was not gradually carried upward and ejected by the mouth, a point which is corroborated by the fact that he vomited more that night, and by the statement of the wife that none of the injections had passed away by the rectum. With this powerful syringe, however, and the hot water, the normal peristaltic movement was at once reestablished, the invagination reduced, the flatus expelled; the pain, which seemed uncontrollable, relieved at once, and the patient, who was on the verge of death, redivivus—cured in fifteen minutes.

The immediate relief following in these cases, which can be substantiated by my colleague, Dr. K., in Case I., and in Case II. by the patient himself, who is still hale and hearty, is the best recommendation for the instrument and method here presented.

There is moreover this in its favor, where a cure by ordinary means is possible it will cure at once. Where it does not relieve the condition it will be a certain indication that surgical interference is necessary; and the success of the operation will be in no way prejudiced by the enemata, on the contrary, rather, the hot or cold water may perhaps have improved surrounding conditions.

[1] Reynolds' System of Medicine, loc. cit.

[2] Experimentally this has been done. See Niemayer, Handbuch der Speciel. Pathol. u. Therap., 9th edit. I am informed by my friend, Dr. A. Rothacker, Pathologist Cincinnati Hospital, that it has been done in the post mortem room of the hospital.

Progress of Medical Science.

Etiology of Hemorrhagic Small-Pox.—Dr. L. H. Petit concludes as follows: "The visceral changes found post-mortem in patients dead of hemorrhagic small-pox should be regarded as causes rather than as effects of the disease. It is well always to distinguish among these changes those which are old (various degenerations, sclerosis, etc.) and those which are recent (interstitial hemorrhages). These general lesions, whether the cause or the effect of a general morbid state of the organism, act upon small-pox, as upon traumatic affections, through modifications in the blood or in the tissues—especially in the capillaries. Among those predisposed to hemorrhagic small-pox may be classed former sufferers from diseases of the liver, spleen, heart, kidneys, and perhaps also the lungs, and of affections capable of producing visceral changes—rheumatism, scarlatina, malaria, alcoholism, pregnancy, etc. The therapeutical application of these etiological facts is as yet uncertain, but we may regard the prognosis as very grave when small-pox attacks one suffering from any of the above-mentioned affections; the disease is likely to assume the hemorrhagic or some other grave form."—*Le Progrès Médical*, No. 37, 1882.

The Importance of the Superficial Lymphatics.—In a paper read before the Académie de Médecine of Paris, Dr. Onimus calls attention to the part played by the superficial lymphatic network in the phenomenon of redness of the skin after irritation. The lymphatics lie superficial to the capillaries and contain a pale translucent yellow fluid. If this be abundant the red color of the blood-vessels beneath is hidden, and the skin becomes white. If it be scanty the color of the blood predominates, and the skin is more or less red. After an irritation of the skin the part becomes white, then red, and finally

rose-colored. At first both the lymphatics and the blood-vessels are mechanically emptied of their contents, and a white spot appears. The blood returns immediately to the capillaries, while the re-establishment of the lymphatic circulation is more tardy, and one can see after a while the little white lines running in every direction over the red surface until the whole presents a rose-colored hue. The edges of the reddened spot are often marked by a white elevation, due to the accumulation of lymph. In certain pathological conditions this ring is very prominent, and if pricked with a needle, may be seen to exude lymph. These phenomena explain certain contradictions in the results obtained by electrization. Cutaneous electrization, which incontestably arrests the contraction of the blood-vessels, produces a rubefaction of the skin, and does so evidently by producing a contraction of the lymphatic vessels. The changes in the color of the skin, so important in various diseases, and even the differences between individuals, depend not only upon the blood circulation, but also upon that of the lymph. If agents which produce capillary contraction redden the skin at the point of application, this effect is more often due to the disappearance of the white opalescent veil, thus rendering more apparent the underlying network of capillary blood-vessels.—*Le Progrès Médical*, No. 37, 1882.

A New Means of Detecting Fatty Degeneration of the Liver.—Dr. Lépine and Eymonnet describe a new method, of apparently some value, for determining the existence of fatty liver through examination of the urine. Their procedure is briefly as follows: Every trace of phosphoric acid, as existing in the phosphates, is removed from the urine by means of a mixture containing magnesia or of baryta water. The liquid is then evaporated and the residue calcined with potassium nitrate. If now this be redissolved in a little water acidulated with nitric acid, and treated as before with magnesia, it will be found that a minute quantity of phosphoric acid is still present. This comes from the decomposition, during the process of calcination of the glycerin-phosphoric acid, normally contained in the urine, which is a product of the decomposition of lecithin. In the normal condition glycerin-phosphoric acid is contained in the urine in very small amount—in proportion to the urea of 1 to 200. But in several cases of fatty liver, the authors state that they found it increased in proportion to the urea five- or even ten-fold. The relation of these two conditions—fatty degeneration of the liver and an increase of the glycerin-phosphoric acid in the urine—they explain by the fact that the fat of the liver contains lecithin. They have found this product in fatty livers in the large proportion of three per cent. of the entire hepatic substance.—*Archives Médicales Belges*, vol. xxii., 1882.

Extirpation of the Spleen.—In the *Centralblatt für Chirurgie*, November 18, 1882, are collected the statistics of a large number of cases of extirpation of the spleen. The indications for operation in the several cases were leucæmia, cystic and other tumors of the spleen, hypertrophy, floating spleen, and abscess. The results were far from encouraging. In thirty-seven cases of excision for disease of the spleen, twenty-seven (nearly seventy-five per cent.) resulted fatally. Of eighteen cases operated upon for leucæmia, only one recovered. The latter case was reported by Franzolini. The patient, a girl twenty-two years of age, presented well-marked symptoms of leucæmia. The white blood-corpuscles were about five times more numerous than normal. The patient made a good recovery with no untoward symptoms, except periodical painful attacks of congestion of the abdominal organs. These ceased after a few days. The number of white blood-globules steadily increased, and after four months was reduced to the normal.

Treatment of Malarial Coma.—Dr. Arch Dixon insists upon the hypodermic use of quinine in congestive chills, and says that any attempt to administer remedies by the mouth or rectum is only a waste of time, and results almost invariably in the loss of the patient. He inserts the quinine in warm solution deeply into the cellular tissue, and has never seen abscess or other bad effects follow its use. A bold employment of the wet pack is also urged.—*Southern Practitioner*, November, 1882.

Intra-uterine Vaccination.—Dr. Truzzi, vaccinated a number of pregnant women, during the last three months of gestation, with a view to determine the protection, if any, afforded to the child. The results were negative, as the children were all successfully vaccinated a few days after birth.—*Centralblatt für Gynäkologie*, November 18, 1882.

The Normal Position of the Stomach.—Dr. Lesshaft states that in a moderate-sized stomach the cardiac orifice is on a level with the articulations of the cartilages of the sixth and seventh ribs of the left side with the sternum. Posteriorly it corresponds with the left edge of the intervertebral disc between the ninth and tenth vertebræ. In the median line, the lower edge of the stomach is situated usually midway between the base of the ensiform cartilage and the navel. The lower border of the pylorus lies in a line running exactly in the middle between the linea sternalis and parasternalis. The contents of the stomach are passed along the sides to the pylorus, and then backward through the centre to the fundus. Lesshaft denies that the position of the stomach varies, or that the greater curvature is directed forward when the organ is distended.—*Centralblatt für Klinische Medicine*, November 11, 1882.

Hypodermic Injections of Morphine in Seasickness.—According to Dr. Coelho (*Allgem. Med. Central-Zeitung*, No. 81, 1882), seasickness is promptly controlled by subcutaneous injections of morphine in the epigastric region, in doses of one-eighth to one-sixth grain.

Influence Exerted by Various Agents upon Digestion.—From a series of experiments undertaken to determine the rapidity of the digestive process in the stomach under varying circumstances, Dr. Fleischer deduces the following conclusions: A pint of cold water, taken with the meal, exerts no influence upon digestion. A quart retards it somewhat, and the drinking of three pints causes a considerable retardation of the process. Walking for several hours at a tolerably rapid gait, lengthens the period of digestion. Hot poultices applied after eating materially hasten the process. Cold, in the form of ice-bags over the gastric region, produces no effect. Dilute hydrochloric acid and pepsine produced no effect upon digestion, either in healthy individuals, or in patients suffering from dilatation and catarrh of the stomach. These remedies in combination with hot poultices over the stomach accelerated the process of digestion.—*Allgem. Med. Central-Zeitung*, No. 61, 1882.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, December 30, 1882.

THE MANAGEMENT OF THE TEXAS YELLOW FEVER EPIDEMIC.

We have received from the Surgeon-General of the United States Marine Hospital Service a preliminary report upon the yellow fever epidemic of 1882 in Texas. It contains a description of the measures adopted for checking the spread of the fever and caring for the sufferers. As these measures have been criticised in some quarters this appears to be a good opportunity to present the facts before our readers.

The Marine Hospital Service did not undertake the measures against the epidemic until the fever had caused a panic in Texas, and the southern angle of that State was filled with fugitives.

The following provisions were then made:

Hospital and medical attendance were furnished to the sick poor. A free dispensary was organized in Brownsville, and a *cordon sanitaire* was established. This cordon extended along the south side of the railroad leading from Laredo on the Rio Grande to Corpus Christi on the Gulf, a distance of one hundred and sixty miles. It was one hundred and eighty miles from Brownsville, which town occupies the southern angle of Texas near the mouth of the Rio Grande. As soon as possible a shorter cordon, nearly parallel to the first, was established, extending from the Rio Grande at Santa Maria along the Arroyo Colorado to the Gulf. This line was about thirty miles from Brownsville. Persons wishing to pass it were stopped for ten days, their baggage was fumigated, fomites burnt, and they were then allowed to proceed. The cordon was effective in preventing further spread of the fever in Texas. It was soon found, however, that the disease was spreading among the Mexican towns along the southern bank of the Rio Grande, starting from Matamoras, a town nearly opposite Brownsville. Local quarantines on the Texas side were established to some extent. There was a disposition to break through these, however, and finally the Mexicans, not the United States, established a cordon along the Rio Grande from the western end of the United States cordon to Laredo, a distance of nearly three hundred miles.

This, we are told, had the desired effect of stopping the spread of the disease.

The result of the operations of the Service were that the fever was confined, in Texas, chiefly to Brownsville, where there were over two thousand cases with one hundred and fourteen deaths.

It is averred that the inhabitants of Brownsville were confined to their city and obliged to suffer from the fever; also, that the sanitary cordon is an obsolete measure not recognized as necessary or proper by the sanitary science of the day.

One must make some allowances on both sides in discussing this matter, since the friends of the National Board of Health seem anxious to strengthen it by attacking the Marine Hospital Service.

It is hardly true that the inhabitants of Brownsville were imprisoned and forced to take the fever, for the cordon allowed passage after ten days' delay. No doubt it was difficult for the poor to get away, but it must be shewn that it would have been less so under any quarantine restrictions in order to prove that the cordon itself was oppressive.

The statement that the sanitary cordon is a measure "not in accordance with the sanitary science of the day" is presumptuous twaddle. The "sanitary science of the day," as regarding inland quarantine, is only a mass of crude opinions, based on insufficient experience. Four years ago Dr. Herrick, writing on this subject in Buck's Hygiene, could only advance a few suggestions as to what measures sanitary science taught. The methods adopted by the National Board of Health in case of epidemics, have been reasonably successful. Yet none but enthusiasts would dare to base positive conclusions upon them. As to the cordon, sanitary experience, which is the only legitimate term at present, recommends it under certain conditions. In limiting the plague in Russia, in 1879, this cordon was highly successful. It was at that time recommended by the high authority of Hirsch and the International Sanitary Council. In fact, in sparsely settled countries, at least, sanitary experience still recommends it.

In conclusion we would say that it is quite too early to judge positively upon the merits of the measures for suppressing the Texas epidemic. Those who have already condemned it have, we believe, shown unfairness toward a zealous and intelligent officer, and have also exposed themselves to the charge of being injudicious and hasty in their criticisms.

FORCED FEEDING IN PHTHISIS.

THE practice known as forced feeding, or "super-alimentation," introduced by M. Debové and M. Dujardin Beaumetz, of Paris, has begun to attract some attention. This super-alimentation consists in forcing into the patient's stomach, by means of a sound, large quantities of highly concentrated food. It was first employed in phthisical patients who could not retain food on the stomach when taken in the ordinary way. Strange to say, these patients endured the unpleasantness of stomach-tubes, kept down the injected food, and improved in health. The method has now been extended to cases of hysteria with vomiting, also to dyspepsia and to various wasting diseases when the stomach is rebellious.

The food used is chiefly meat-powder, which is administered in milk, or bouillon, to which eggs may be added. This meat-powder appears to be a really useful preparation, and, as it need not be expensive, it will doubtless become more widely employed. It is made by taking lean meat, mincing it, spreading the paste on porcelain tables, and letting it dry at a temperature of 90° C. This is then taken and pounded into a powder, when it is ready for use. The dose given at first is small, being about twenty-five grammes at a meal. This amount is gradually increased until between four hundred and six hundred grammes are given daily. Such a dose is the equivalent of about four pounds of fresh meat. The amount of meat in an average diet is only about one pound, and when it is remembered that the meat-powder is administered dissolved in two litres of milk, to which several eggs are added, the significance of the term "super-alimentation" will be understood.

Under such a diet the urine is diminished in amount, but the urea is greatly increased, sometimes reaching eighty grammes per day—the normal amount being 32.5 grammes with an average diet. Sometimes albumen appears in the urine. Diarrhœa may occur, in which case pepsin and bismuth are added.

Phthisical patients rapidly gain weight, we are told, when thus forcibly fed, there being often an average daily increase of from eighty to one hundred grammes. Cough and expectoration diminish, and reparatory processes take place in the lungs. We do not hear it stated, however, to what extent permanent cures are produced.

It is hardly probable that American œsophagi will tamely submit to the introduction of a tube *ter in die*, and it is difficult to understand how such a process proves sedative to irritable stomachs, except in hysterical cases. The meat-powders, and the overfeeding, however, are sufficiently rational measures in many cases.

A NEW VIEW ON THE PATHOLOGY OF GOUT.

THE presence of uric acid in the blood of gouty subjects, and the deposition of urates in their various tissues, have been long recognized as factors in the production of the local manifestations of this disease; and certainly theories have not been wanting to account for the occurrence of the well-known nodosities of gout. Nevertheless, a truly satisfactory and convincing explanation concerning their ultimate development has not hitherto been found. Ebstein, of Gottingen, now attempts to supply the missing information. He has recently conducted a long series of experimental investigations and anatomical researches in this direction. The practical outcome of his labors was announced at the German Medical Congress, held at Wiesbaden in the present year.

According to him the characteristic lesion of gout is a localized tissue necrosis occurring prior to any deposit of urates. Indeed, the latter he holds to be directly attributable to the former.

A careful examination of the fibrous and cartilaginous structures revealed the presence of a number of points of more or less necrosed tissue. They became, though never until the necrotic process was completed, the seat of the characteristic urate deposits. Such centres he found in the kidneys, the articular and fibrous cartilages, the tendons, and the intermuscular and subcutaneous connective tissues. He further observes that about these foci is developed a secondary inflammation, differing in character according to the tissues in which it arises. In the cartilages it takes the form of cellular proliferation, while in the other tissues it occurs as a small-celled infiltration.

By causing artificially a suppression of urine in birds, the author succeeded in producing in them typical necrotic foci and the subsequent deposit of crystallized urates. That the uric acid was the responsible agent in the development of this tissue necrosis Dr. Ebstein proved to his satisfaction by another series of experiments. With strict antiseptic precautions, he injected uric acid dissolved in a solution of phosphate of soda, or simply held in suspension, into the cornea of rabbits. The invariable result was inflammation followed by corneal opacity.

On the other hand, the injection of urea and other chemically allied substances led only to negative results. The author also found that uric acid was neither a septic poison nor a mechanical irritant to the tissues. Its action in causing local necrosis, with subsequent urate deposits, was therefore a purely chemical one.

The well-known selective affinity of these deposits for periarticular fibrous tissue and cartilaginous structures is left unexplained by Ebstein. But we are informed that he will be more explicit in all

particulars in his forthcoming comprehensive treatise on the pathology and treatment of gout. Meanwhile we may be content to have received a more rational interpretation of certain familiar phenomena observed in gout than most of those that have so far been offered to the profession. And it is to be hoped that this advance may lead to a corresponding improvement in the treatment of a frequently intractable complaint.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 21, 1882.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE Northwestern Medical and Surgical Society, through its Treasurer, Dr. Fruitnight, donated to the Journal fund of the Academy the sum of $100. The thanks of the Academy were returned through its President to the Society for its generous donation.

PRESENTATION OF THE BUST OF THE LATE PROFESSOR WHITE, OF BUFFALO.

DR. AUSTIN FLINT, in behalf of James Platt White, of Buffalo, presented a marble bust of the late Professor White, of Buffalo. It was the work of J. G. Mitchell, of Rochester, sculptor. The presentation was made in a few well-chosen words, and was accompanied by the resolution that "The New York Academy of Medicine accepts with much gratification the marble bust, and accords to it gladly a permanent place in the hall of the Academy."

The resolutions were seconded by Dr. T. G. Thomas. The President thanked Dr. Flint and Dr. Thomas for the eloquent tribute which they had paid to the deceased honorary fellow, and in behalf of the Academy accepted the generous gift.

DR. T. GAILLARD THOMAS then read a paper entitled

A CONTRIBUTION TO THE SUBJECT OF THE REMOVAL OF THE UTERINE APPENDAGES (TAIT'S OPERATION) FOR RECURRENT PELVIC INFLAMMATIONS; WITH PATHOLOGICAL SPECIMENS.

In the *British Medical Journal* for July 29, 1882, Mr. Tait enunciated views which were entirely at variance with those heretofore held and accepted with reference to certain pelvic diseases, and made extended remarks on the diagnosis and treatment of chronic inflammation of the ovaries. Since the time of Bennett, of England, Simpson, of Scotland, and Sims, of America, a vast deal of attention had been given to affections of the uterus and of the vagina, etc., while disease of the ovaries and of the Fallopian tubes had been left in a cloud of ignorance and uncertainty. Tilt, a firm and constant advocate of the claims of ovarian pathology, had stood almost alone, and had enunciated views with which only few sympathized and still fewer endorsed and sustained. The views which had been advanced by Tait seemed to be those of an original surgeon and were distinct, and if accepted would open a new field and exert upon this department of medical science an entirely new influence. The most original and valuable views enunciated by Tait were embraced under the following heads:

First.—He assumed that the view formerly held, that laparotomy and allied operations should be postponed until absolute risk to the life of the patient rendered them necessary, should be abandoned; and that in the hands of the expert they were so far from danger as to be justifiable even when life was not jeopardized.

Second.—That the usually accepted doctrine that menstruation depended upon ovulation was entirely erroneous.

Third.—That the ovaries had nothing whatever to do with menstruation, but that this phenomenon depended upon the Fallopian tubes.

Fourth.—That many of the bad cases of abnormal menstruation were relievable only by extirpation of the ovaries and tubes.

Fifth.—That in chronic ovarian disease the Fallopian tubes were chiefly at fault.

Sixth.—That the mortality had been only one in his last thirty-five operations, and that this slight loss of life was susceptible of diminution in the future.

Seventh.—That in all those cases heretofore regarded as instances of menstrual recurrent pelvic cellulitis or peritonitis were really tubal dropsy and ovarian disease. The last statement was not made in the paper alluded to, but had been received from Dr. T. A. Emmet, who obtained it from Mr. Tait in a private conversation.

Dr. Thomas further stated that removal of the uterine appendages had nothing whatever to do with the subject of ovariotomy; that the latter operation was resorted to for the removal of large or increasing tumors which, if not removed, almost invariably destroyed life within a few years. The removal of the uterine appendages, or Tait's operation, was performed for severe menstrual disorders and nervous disturbances, which did not so much jeopardize the life of the patient as make it miserable and almost intolerable. The history of ovariotomy was well known. The history of oöphorectomy and its modifications could be summed up in a few sentences. In July, 1872, Hegar, for the relief of certain constitutional disturbances, extirpated ovaries not affected by tumors. Five days afterward the operation was performed by Tait in England. Neither of these operations was published. In August of the same year, Dr. Robert Battey, of Georgia, not only performed the operation but had it published to the world and obtained for it the consideration of the profession. Credit had been chiefly accorded, and deservedly so, to Battey, although he was immediately preceded by two other operators. The operation to which Tait lays claim consists in the removal of the Fallopian tubes as well as the ovaries, because he believes that in that way alone can menstruation be controlled, and also because he regards tubal disease, the most important of the two pathological factors, as invariably present in chronic ovaritis. Dr. Thomas did not propose to consider Tait's views in an analytical manner, but simply to report four cases in which tubal dropsy existed, associated with chronic ovaritis as described by Tait. The cases reported were too recent to permit conclusions to be drawn with regard to ultimate results.

CASE I.—A colored woman, thirty years of age; the mother of one child eight years old. Had suffered from menstrual, or recurrent pelvic inflammations, due, as had heretofore been supposed, to

some unknown influence. Her uterus was large, anteverted, and gave forth too free menstrual flow. Thinking that, perhaps, profuse menstruation was due to fungoid degeneration of the lining membrane, Dr. Thomas carefully curetted the entire inner surface of the uterus, but to his surprise removed only a very few fungoid growths. An anteversion pessary was introduced and resulted in absolute harm. Upon more careful examination he detected enlarged ovaries, and strongly suspected that it was one of the cases in which ovaritis and tubal dropsy were coincident. Further examination convinced him more and more of the truth of this suspicion, and he decided to make an explorative incision, and, if the condition existed, to perform Tait's operation. The incision was made; one ovary was found cystic, and its Fallopian tube was large and felt very much like a coil of intestine. The tube, the ovary, and the ovarian ligament were ligated and removed. The same condition existed upon the opposite side and the same procedure was adopted. This, together with all the subsequent operations, was performed under the strictest antiseptic precautions except with regard to the use of the spray. The patient made a prompt recovery; one menstrual period had passed and no sanguineous flow had occurred. The specimen was presented.

Case II.—The patient was twenty-five years of age; had been married three years; was the mother of one child eighteen months old. She entered his service in the Woman's Hospital. Her menstrual history began at the age of seventeen, and before marriage gave her no trouble whatever. Nine months after confinement she had an attack of pelvic inflammation which occurred just at the time of the cessation of the first menstrual period after confinement. Lactation had ceased. It was probably an attack of cellulitis or peritonitis. Similar attacks had been repeated. There was a constant leucorrhœa and difficulty in locomotion. There was partial laceration of the cervix and perineum. There was a mass the size of a hen's egg in the position of the left ovary, and there was exquisite tenderness in the ovarian region and all about the uterus. Dr. Thomas decided to make an explorative incision, to be followed by Tait's operation if the condition proved to be such as to warrant it. Some cysts occupied the ovary, and the tubes were distended with a large accumulation of pus. Both ovaries and tubes were removed, and could be seen in the specimen presented.

At this point, Dr. Thomas remarked that, while Battey's operation could be performed without coincident removal of the tubes, the latter procedure could not be performed without removal of the ovaries.

The patient recovered without any remarkable rise of either the temperature or the pulse.

Case III.—Miss ——, twenty-two years of age, entered his private hospital. Her menstrual life began at the age of fourteen, and at the first epoch she suffered from severe dysmenorrhœa. During the last year the pain had been almost constant, lasting throughout the entire interval, and greatly increased at each menstrual period. Physical examination revealed enlarged and somewhat prolapsed ovaries, although the prolapsus was not marked. He was unable to discover any enlargement of the Fallopian tubes. Dr. Emmet had previously examined the patient and believed that he found evidences of pelvic inflammation. Dr. Thomas removed both ovaries and tubes, and found the former filled with small cysts, and the latter distended with pus and the lining membrane inflamed. The pus, however, was not confined to the cavity of the tubes. The condition present was that which had been described by the older writers as "profluent dropsy of the tubes." The specimen was accidentally lost. The patient recovered without an unfavorable symptom. No menstrual discharge occurred at the next period, and the patient was perfectly comfortable.

Case IV.—Miss ——, aged twenty-seven, entered his private hospital. Her menstrual life began at the age of fourteen, and she suffered from severe dysmenorrhœa up to two years ago. From that date she had been a constant invalid on account of repeated attacks of pelvic peritonitis, occurring just before menstruation. In September last one of these attacks occurred, and the patient nearly lost her life, the temperature rising to 104° F., the pulse to 140, and there was excessive pain. At the time of the operation she was emaciated, exceedingly pale, and there was a depreciation of vital forces which resembled that seen in the third stage of pulmonary consumption. Her temperature was 100° F., the pulse 115 to 120, the stomach was irritable, and she suffered from never-ceasing pelvic pain. The ovaries were not very much diseased, although they contained a number of small cysts, but the Fallopian tubes were in a condition of tubal dropsy, and throughout their entire extent were firmly bound down by adhesions. The operation was tedious and difficult, and at its conclusion no one who witnessed it could avoid making an unfavorable prognosis. The patient died on the sixth day. The specimen was presented.

These cases made up Dr. Thomas' entire experience with reference to this subject. All that he aimed to do in the paper was to hold up the views of a brilliant and an original investigator. Tait's immediate results from oöphorectomy had been, like Keith's and Wells' from ovariotomy, exceedingly gratifying. Out of seventy-five cases there had been only six deaths, and out of the last sixty-one cases there had only been three deaths, and out of thirty-five operations for pure chronic ovaritis with tubal dropsy there had been only one death. No such records had been made in this country. The question why statistics were better in Europe than in this country was interesting and important, and it behooved American operators to look at the matter in a most careful manner, and endeavor, if possible, to determine why the success had been greater there than here.

Dr. H. J. Garrigues then read a paper entitled,

GASTRO ELYTROTOMY (THOMAS' OPERATION) COMPARED WITH OÖPHORO-HYSTERECTOMY (PORRO'S OPERATION).

During the last four years gastro-elytrotomy had been performed three times: the operators were, Hime, of Sheffield, Edis, of London, and Gillette, of New York. These, together with the cases which had already been performed, made eight, in which there had been four recoveries and four maternal deaths. The results compared favorably with those from the rival operation, oöphoro-hysterectomy, or Porro's operation. According to Harris, of Philadelphia, Porro's operation had been performed eighty-four times, with thirty-seven recoveries and forty-seven deaths.

The chief objection which had been urged against gastro-elytrotomy had been that it could not be carried out according to the strictest rules of antiseptic

surgery; but Dr. Garrigues believed that the operation could be rendered sufficiently antiseptic to warrant its further trial, and especially until a greater number of Porro's operation had been performed under conditions which were only equally favorable.

Dr. Garrigues then directed attention to the danger of hemorrhage in Thomas' operation, and concluded that it was not liable to be so much as in Porro's operation, where it was likely to be very severe. The difficulty in arresting hemorrhage from the stump in Porro's operation was very great. He then proceeded to review the different methods which had been employed for controlling this hemorrhage, such as the ecraseur, the elastic ligature, the application of the soft rubber tube of Esmarch, etc.

With reference to shock and exhaustion, they had so far proved to be the only causes of death in gastro-elytrotomy, but by operating earlier and only on proper subjects, he believed the dangers from these sources could be very greatly overcome. He believed that in favorable subjects the danger from shock was much smaller in gastro-elytrotomy than in Porro's operation. The danger from exhaustion was greater in gastro-elytrotomy than in Porro's operation, on account of the profuse suppuration, which almost inevitably occurred. Peritonitis might occur after gastro-elytrotomy, but he believed it was infinitely less likely to do so than in Porro's operation. Several other accidents were mentioned which were liable to occur with either operation, such as tetanus, pulmonary œdema, heart-clot, etc.

It had been believed that the intra-peritoneal method of treating the stump in Porro's operation would yield better results than had been yet obtained. The method, however, had been tried in five cases, and four of the patients died. He believed that in the country the old classical operation, Cæsarean section, could be performed with better results than either Thomas' or Porro's operation. In hospital practice gastro-elytrotomy should be the operation adopted, if the cervix was dilated or dilatable. If the circumstances were such as to render operative interference necessary before dilatation of the cervix had begun, he should prefer Müller's operation.

The following conclusions were reached: 1. Thomas' operation, or gastro-elytrotomy, had been performed eight times; one-half of the mothers recovered, and all the children survived except two, which were dead before the operation. 2. Gastro-elytrotomy might be performed with many antiseptic precautions. 3. Porro's operation had given less favorable results than gastro-elytrotomy. Müller's modification has given no better results than Porro's. 4. The dangers from hemorrhage, peritonitis, septicæmia, etc., were greater in Porro-Müller's operation than in gastro-elytrotomy. 5. The intra-peritoneal method of treating the stump with Porro's operation had been adopted in five cases, and four patients died. 6. One advantage of the Porro-Müller operation was the possibility of performing it before the commencement of labor. 7. Gastro-elytrotomy was less repulsive to the patient than was either of the other operations, and it could be performed with a less number of assistants. 8. It did not sterilize the woman. 9. All who had performed it upon the cadaver preferred it to oöphoro-hysterectomy (Porro's operation). 10. In country practice the Cæsarean section would probably be preferred to all its substitutes.

Both papers being before the Academy, the President asked Dr. W. M. Polk to open the discussion. He spoke first with reference to the position which the occupation of gastro elytrotomy should occupy, and, second, with regard to the supposed difficulties in the performance of either Cæsarean section or Porro-Müller's operation.

First, in placing the operation, it seemed to him that it was, perhaps, a mistake to put it in direct antagonism with Cæsarean section or any of its modifications. There were fixed indications for Cæsarean section, and there were cases in which it was the only operation proper to be performed. On the other hand, there were many cases in which Cæsarean section had been performed which might give way to gastro-elytrotomy. Besides, there were certain cases in which embryotomy had been resorted to, and in which gastro-elytrotomy might well have been performed. In brief, he believed that when the operation was properly placed it would rest between embryotomy, upon the one hand, and Cæsarean section upon the other. So far as Cæsarean section was concerned, gastro-elytrotomy could never take its place as a complete substitute. With regard to the difficulties in performing Cæsarean section, he referred to the remarks made by one of its ablest advocates, Dr. Harris, of Philadelphia, who spoke of it as a scientific operation which required extraordinary anatomical skill. Dr. Polk, however, had reached the conclusion that it was a very easy operation to perform when placed in contrast with either Porro's or Dr. Thomas' operation.

Dr. Polk then passed in review the successive steps necessary to be taken in performing Porro's operation and Thomas' operation, and compared them up to the point at which the child was reached. In the first place, the hemorrhage in either was not liable to be excessive or beyond the control of the surgeon. With reference to Porro's operation, it was necessary to exercise extreme care on entering the peritoneal cavity, for no operator could say that he would not find a coil of intestine in contact with the abdominal wall. In performing gastro-elytrotomy, opening the peritoneum *might be avoided* in such a manner as to reach the subperitoneal space by making the incision below the reflexion of the peritoneum and then pushing this membrane up from its attachments in the iliac fossa at the brim of the pelvis, and in the anterior pelvic fossa as far as the cervical wall. When the transversalis fascia was reached the further steps in the operation should be taken without the use of the knife. This could not be accomplished in the Porro-Müller operation after the peritoneal cavity had been opened. With reference to shock, Dr. Polk believed that it was much greater in the Porro-Müller operation than it could possibly be in gastro-elytrotomy.

After the vagina had been entered, the cervix being dilated, came what he regarded as the greatest difficulty in the performance of gastro-elytrotomy, and that was the tilting the uterus sufficiently far to bring the cervix above the brim to enable the accoucheur to perform extraction either with the forceps or by means of version. He believed, however, that the external incision could be continued up to the last false rib if necessary, and that it was not necessary to injure the peritoneum; making that extension gave considerable space for manipulation. It was absolutely necessary while making traction to support carefully the sides of the incision, thus removing the dangers to which the ovarian vessels

would otherwise be exposed. Dr. Polk believed that there was no necessity for injuring the base of the bladder, but should it accidentally be injured harm would not necessarily follow. He also believed that it was unnecessary to injure the ureter and that there was no danger, necessarily, of injuring the uterine artery. The ovarian vessels were in danger only while making traction upon the uterus.

Dr. Polk then described at some length the method of entering the vagina, speaking of the little danger that would follow a small incision into the bladder, should it accidentally be made, and also referred to the position of the uterine artery in the pregnant and non-pregnant condition. He believed that the danger of suppuration in Thomas' operation could be overcome to a very great extent by sewing up as much as possible the upper part of the external wound, leaving the lower portion open and introducing a drainage-tube. He thought it must be evident to all that the dangers in Cæsarean section and its modifications were very much greater than those in gastro-elytrotomy. The chief point to which he wished to direct especial attention was the position which the operation should occupy, namely, that there were cases in which Cæsarean section was the only operation which could properly be resorted to, and that gastro-elytrotomy occupied a position between Cæsarean section, on the one hand, and embryotomy on the other.

Dr. I. E. Taylor believed that Cæsarean section, when performed early, was superior to all operations which had been proposed as substitutes for it. With reference to Porro's operation, statistics showed for it more favorable results than had been obtained by gastro-elytrotomy. Thomas' operation was doubtless a valuable one in certain cases, but peritonitis, metritis, etc., being nearly barred out by improved methods of treatment, there remained the question of hemorrhage, which was a most important one. Besides, the cervix must be dilated in some way before delivery could be attempted, and after that had been accomplished version, perhaps the forceps, and possibly embryotomy, with all its difficulties and dangers, must be resorted to. He believed that the chances of saving the mother and the child were much better with Porro's operation than with gastro-elytrotomy. Dr. Taylor discussed at some length the objectionable features of all these operations.

Dr. Skene thought it was hardly fair to compare the statistics of the older operations with the statistics afforded by laparo-elytrotomy. When laparo-elytrotomy had had equal opportunities with Cæsarean section, he thought it would then be time to bring forward statistics, and previous to that it was a misuse of statistics to quote them when comparing the two operations. He felt perfectly confident that when laparo-elytrotomy had had the same opportunity, and had been submitted to the same extensive test that had either Cæsarean section or Porro's operation there would be no question in regard to its final success. The difficulty of removing the child from the uterus, which had been spoken of by Dr. Taylor, he believed to have no foundation in fact, and that the obstruction presented was that offered by the bony pelvis rather than by the uterus. With reference to one of his patients dying with shock, as had been mentioned by Dr. Garrigues in his paper, he took exceptions, believing that the patient died from exhaustion incident to severe operations which had preceded the laparo-elytrotomy. With reference to controlling hemorrhage in laparo-elytrotomy, it could be easily done. The simplicity of the operation, and the ability to control hemorrhage, placed it infinitely above either of the other operations with which it had been compared.

Dr. Lusk remarked that he had seen only one Porro operation, and had not witnessed a gastro-elytrotomy, and therefore his remarks would be based upon study rather than experience. With a contracted pelvis and a dilated cervix he believed that there was no operation to be compared with gastro-elytrotomy, but there were cases in which dilatation did not exist and operative interference was demanded early, and we therefore needed some alternative. Gastro-elytrotomy might finally come to meet the requirements of these cases, but when Porro's operation was proposed it seemed to meet all the indications. Porro's operation had been performed in selected cases; but despite all these advantages there had been only forty-seven recoveries and fifty-five deaths, which was rather a large mortality. Patients still died of shock, many of septicæmia, and a few from hemorrhage, and the question arose whether it was not time to relinquish the operation. Was the old classical operation of Cæsarean section deserving of the bad reputation which had been heaped upon it? Dr. Lusk then spoke of the statistics which had been gathered concerning the success of Cæsarean section in various localities, and remarked that when we turned from hospital experience to results which had been obtained in country districts there had been collected a sufficient number of cases of which complete records had been obtained to place its success above any of the proposed substitutes. The operation was performed many times, under conditions which would not be admitted for a moment when considering the propriety of either Porro's operation or gastro-elytrotomy. There was one danger in Cæsarean section, and that was from gaping of the uterine wound. But that could be overcome by closing the wound with sutures. The results had been just as good as those obtained in any of the other operations. According to Harris, in sixteen cases in which the uterine sutures had been applied there had been eight recoveries and eight deaths. Dr. Lusk then spoke of the modification of the incision which had been proposed, namely, to dissect up the peritoneum for a distance of perhaps two-fifths of an inch, and then remove a melon-shaped piece from the wall of the uterus, so as to permit the peritoneal surfaces to be folded in and brought in contact with each other by sutures.

Dr. Gillette thought that laparo-elytrotomy was not to be compared with Porro's operation, either with reference to danger or difficulty in its performance. He thought, however, that the operation had not advanced sufficiently far to be compared with either Cæsarean section or Porro's operation, or any of its modifications. He was unwilling to make the plea for Cæsarean section which had been made by Dr. Lusk. He believed that there would always remain the danger from peritonitis, and also from gaping of the wound, no matter how carefully the stitches were introduced, even after adopting the modification embraced in folding in the peritoneum. The uterus which had been opened by Cæsarean section would not contract and maintain contraction in all cases any more than would the uterus after normal labor.

Dr. T. A. Emmet remarked, with reference to Tait's operation, that he had had no personal ex-

perience in its performance. He had seen a number of cases in which it had been performed, and must say that he saw nothing else when abroad which interested him so much and at the same time puzzled him exceedingly. He saw in Tait's laboratory sixty specimens, all of which had been removed within the last eighteen months, and it was surprising to him where all these cases could come from, and what could be the explanation. Whether the condition of affairs described by Mr. Tait was more common there than in this country he was not prepared to say. Many years ago he had the opportunity to perform a large number of autopsies among immigrants and he had never seen the condition referred to more than a dozen times. He asked more particularly as to what would be his guide with reference to performing the operation, and Mr. Tait was unable to give him any answer except that in all cases of chronic pelvic inflammation which did not get well of themselves within a reasonable time he opened the abdomen and invariably found this dropsical condition of the tubes, distended with either serum or pus. Dr. Emmet was also surprised at the success of the operation abroad, and had had opportunity to see that the women upon whom it had been performed had been very much improved by it. The improvement which had followed the operation had been something beyond conception. There seemed to be no question with reference to Tait's success, but with regard to this operation upon the broad ligament he was not prepared to perform it at present. He wished to wait a little farther for additional light upon the subject.

Dr. Garrigues, in closing the discussion, said that he favored the revival of the old Cæsarean section operation as referred to by Dr. Lusk. As to excising the muscular tissue of the uterus and removing a portion, as mentioned by Dr. Lusk, he thought that modification could only have a limited degree of usefulness. It would be an excellent resource in cases where the muscular tissue bulged so that the edges of the wound could not be brought closely together, but when the edges of the incision in the uterus could be closely coaptated, he thought it was altogether unnecessary to adopt the modification. However desirable it might be to coaptate two peritoneal surfaces with each other, the importance of which had been pointed out many years ago by Mr. Spencer Wells, he thought that it was not desirable in these cases when the edges of the incision could be closely brought in contact and held there by deep and superficial sutures. In a case which he had already reported union by first intention had taken place throughout nearly the entire extent of the wound, although the patient lived only a short time after the operation was performed.

With reference to Thomas' operation, he thought it was unfair to compare it by means of statistics with the old operation. It was well known that it had been performed substantially by Ritgen and Baudelocque, but it had been so entirely changed by Dr. Thomas that we should accept it as it now stands, and as devised and revised by Dr. Thomas, and study the results as obtained from that date.

The Academy then adjourned.

Milk in Nasal Catarrh.—Copious injections of milk are recommended in nasal catarrh.

Mosquito Bite.—A one-tenth per cent. solution of atropine is said to instantly relieve its itching.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from December 16, 1882, to December 23, 1882.

Alden, Charles H., Major and Surgeon, now in St. Paul, Minn., to proceed to Fort Yates, D. T., and report to the Commanding Officer of that post for duty. S. O. 212, par. 3, Department of Dakota, December 14, 1882.

Banister, J. M., Assistant Surgeon, to proceed to camp on White River, Col., and report to the Commanding Officer for duty. S. O. 250, par. 7, Department of the Missouri, December 11, 1882.

Brown, Justus M., Major, Surgeon. Granted leave of absence for fifteen days. S. O. 119, Department of the South, December 11, 1882.

Hall, W. R., Assistant Surgeon. Leave of absence for one month is granted. S. O. 250, par. 8, Department of the Missouri, Dec. 11, 1882.

Maddox, T. F. C., Assistant Surgeon. To report to the Commanding Officer Fort Clark, Texas, for duty. S. O. 138, Department of Texas, December 16, 1882.

Medical Society of the County of Warren (N. Y.) and the New Code.—At a meeting of the Medical Society of the County of Warren, held at Glens Falls, December 19th, the following was adopted: *Resolved*, That the delegate of the Medical Society of the County of Warren to the Medical Society of the State of New York be instructed to vote for the repeal of the New Code at the next meeting of the State Scciety. On motion, the Secretary was instructed to transmit the above resolution to the New York Medical Record for publication.

Diphtheria in Philadelphia and the United States.—The number of cases of diphtheria in Philadelphia the past year has reached very nearly 900, being about the rate of 43.34 deaths to every 1,000 deaths, according to the *Sanitary Engineer*. The ratio of deaths throughout the United States was, in 1880, according to the *Medical News*, 51.33 deaths per 1,000.

INDEX.

A

Abbott, Dr. A. W., how to count a rapid pulse, 194.
Abdomen, contusions of, 687.
Abortion, produced by hyperemesis, 392.
Abscess, central pulmonary, mistaken for empyema, 55; cerebral, 224; hepatic discharge of into the bronchi, 572; hepatic in a child, 412; opening of a spinal into a bronchus, 271; popliteal, 231; post-pharyngeal, 106; retropharyngeal, 273.
Abscesses, in elephants, 531.
Absorption, proper vehicles for, 696.
Acid, arsenious, 389; boracic, in furuncle, 573; carbolic, 362; carbolic, as a germicide, 314; carbolic, in the abortive treatment of the eruption of small-pox, 125; carbolic, in the treatment of buboes and lymphadenitis, 40; carbolic, in piles, 136; carbolic, poisoning with, 46, 672; chrysophanic, internal administration of, 278; hippuric, 414; nitric, for chilblains, 531; phenic, cases treated with, 85, 104; phenic, in snake bite, 375; phenic, in whooping-cough, 168; phenic, in yellow fever, 145; pyrogallic, in phagedenæ, 237; salicylic, action of upon the ear, 489; upon the skin, 711; salicylic, foot-powder of, 388.
Acne, 167.
Aconite, preparations of, 616.
Addison's disease, 81.
Adenoma, mammary, 546; of the neck, 133; uteri, 216; with cirrhosis of the liver, 377.
Agnew, Dr. C. R., the care of the chronic insane, 722; the prevention of irregular practice, 560.
Ague, burned alum in, 625.
Air-passages, foreign bodies in, 125, 599, 733.
Albumen, examination of urine for, 208; in the urine, new tests for, 559, 764; retractility of, 12.
Albuminuria, 124; absence of in amyloid kidney, 295; observations on, 710.
Alcohol, antipyretic action of, 156; aspects of the question of, 305; at meals, 196; in burns and scalds, 252.
Alcoholism and strychnia, 434; chronic, 302.
Alimentary canal, foreign bodies in, 195.
Alimentation, forced, and washing in dyspepsia, 560.
Allen, Dr. Harrison, notice of book by, 605.
Allen, Dr. Wm. H., notice of death of, 643.
Allison, Dr. H. E., tumor of the brain causing epilepsy, 229.
Alum in ague, 625.
Amblyopia, nicotinic, 183.
Amenorrhœa, and pilocarpin, 132.
American Academy of Medicine, 519, 523.
American Dermatological Association, 307.
American Gynecological Society, 381.
American Medical College Association, 16.
American Neurological Association, 18.
American family, the decadence of the, 126.
Americanitis, acute, 518.
Amputation, contraction of the vessels after, 573.
Amputations, Billroth's, 577; diminution in mortality after, 363; of the upper extremity, 728; sub-periosteal, 124.
Amyl nitrite, 177, 476; for ague, 324; hypodermic use of, 111; in singultus, 231.
Anatomical proportions, 319.
Anatomy, a new law in Maryland, 530.
Anæmic, pernicious, arsenic in, 55.
Anæsthesia, alcoholic, 135; laryngeal, 28, 560.
Anæsthetic, Edison's, 374.
Anæsthetics, 244; danger of giving during or immediately after repeated doses of morphia, 274; new, 644; the safest, 111.
Andrews, Dr. J. A., medical impressions of China, 52.
Aneurism, by anastomosis, 636; double cardiac, 104; of the aorta, 191, 634; of abdominal aorta and superior mesenteric, 635; of the posterior tibial, 730; of the right middle cerebral artery, 75; of the right subclavian artery, 413; popliteal, 610; double popliteal, 303; traumatic axillary, 303.
Animal heat, influence of the central nervous system in the regulation of, 139.
Ankle-joint, conservative surgery in chronic disease of, 570.
Antipyretics in typhoid fever, 213.
Antiseptic atmosphere, 303.
Antiseptic occlusion, primary, in military practice, 484.
Antisepticism, 244.
Anuria without uræmia, 12.
Aorta, aneurism of, 191, 634; abdominal, aneurism of, 635; anomalous distribution of arteries from the arch of, 582; rupture of, without aneurism, 130.
Apoplexy, placental, and shortened funis, 74.
Arabs, experimenting upon the, 549.
Armstrong, John A., medical Latin, 566.
Armstrong, Dr. W. P., notice of book by, 411.
Army retirement bill, 71.
Arsenic, in pernicious anæmia, 55; and iodine in intermittents, 336.
Arsenical paralysis, 499.
Arsenite of soda, in phthisis, 265.
"Artefacts," 667.
Artery, external iliac, ligature of, 303; innominate, ligation of, 303; middle cerebral, aneurism of, 75; pulmonary thrombosis of the, 102.
Arteries, broad animal ligatures applied to, 103.
Arthritis deformans, 611; fungous, 74.
Ascarides lumbricoides, treatment of, 433.
Ascites of alcoholists, 480.
Ashhurst, Dr. John, Jr., notice of book by, 578.
Aspergillus in the ear, 711.
Asses' milk, 363.
Asthma and nasal polypi, 122; ipecac in, 56; resorcin in, 55.
Asylum reform movement, 630.
Asylums, Kentucky insane, 549; the city insane, and the grand jury, 557.

Asymetry, cerebral, 362.
Ataxia, locomotor, complicated with acute cardiac disease, 651, 661.
Athetosis relieved by nerve-stretching, 21.
Atropia for ear-ache, 391; for mosquito bite, 744.
Atwood, Dr. Francis, notice of death of, 250.
Auditory canal, external, foreign body in, 676.
Austin, Dr. G. L., notice of book by, 691.
Axilla, lipoma of, 634.
Azoospermism, syphilitic, 182.

B

Bacillus, 415; and man, 252; of syphilis, 392; of tubercle, 195, 390, 392, 503, 519; of tuberculosis, prospective attack on, 576; or fat, 643.
Bacteria and syphilis, 380.
Bacterium, a sphæro, 672.
Balfour, Mr. F. M., notice of death of, 280.
Ballery, Dr. G. H., silk-worm gut sutures in gynecological surgery, 121.
Banks, Dr. E. A., whalebone instrument for treating tight stricture of the urethra, 419.
Barker, Dr. P. C., the vaccination question, 58.
Bartholow, Dr. Roberts, notice of book by, 578, 579, 692.
Bath, the electrical, 409, 461, 526.
Baths in surgical diseases, 108.
Battery, a new medical, 641.
Beach, Dr. Willard P., hospital report, 655.
Beale, D. Lionel S., notice of book by, 718.
Beard, Dr. George M., a case of trance lethargy, 306; nervous diseases connected with the male genital function, 617; notice of book by, 188.
Beaumetz, Dr. Dujardin, on the treatment of croup, 673, 701; diphtheria, 393, 421.
Belladonna, and opium, 28; poisoning by, treated with bromide of potassium, 308.
Bellevue Hospital Report, 570.
Benedict, Dr. A. C., trumped-up lunacy, 330.
Bennett, Dr. Ezra B., notice of death, 528.
Bennett, Dr. W. H., habitual smoking, 731.
Berry, Dr. J. J., internal derangement of the knee-joint, 230.
Bibby, Dr. Edward N., notice of death of, 631.
Biernier, on contracted kidney, 349.
Bigelow, Dr. Henry J., 275.
Bile, medicinal agents in after-absorption from the rectum, 599.
Bill, Dr. J. H., a plea for a more thorough study of chemistry in medicine and the arts, 175.
Black ants as antiscorbutic food, 585.
Bladder, catarrh of, bromide of potassium in, 545; primary cancer of, 612; spontaneous perforation of, 636.
Blenorrhœa, neonatorum, 137.
Blind man, what he sees, 636.
Blindness, decrease of, in Prussia, 531; the prevention of, 219; transitory, following childbirth, 375.
Bliss, Dr. D. W., feeding per rectum, 64.
Blisters, new method of preparing, 558.
Blood, abstraction of from the right heart, 705; feeding with dried, 515; of animals living at a high altitude, 489; significance of peptone in, 728; the new corpuscle of the, 464, 644.
Blood-corpuscles, nucleated, differential staining of, 153; red, decrease of, during the administration of iodoform, 350.
Bloodletting in heart diseases, 462.
Blood-vessels, contraction of, after amputation, 573.
Bodenhamer, Dr. Wm., hemorrhoidal diseases, 225.
Body-snatching in Philadelphia, 691.
Bone, diseases of, in puerperal state, 571.
Bones, fœtal, in the uterus, 657; healing process in fractured, 412.
Burns, local treatment of, 653.
Bone-setters, natural, 279.
Bone-setting, 246.
Borcheim, Dr. L. E., fracture of tibia and fibula, 730; paroxysmal hæmatinuria, 699.
Borgias, the poison of, 531.
Borate of quinoidine, 388.
Boro-glyceride, 267, 356.
Boston City Hospital, 402.
Bosworth, Dr. F. H., a nasal electrode, 331.
Bothriocephalus latus, 123; new variety of, 270.
Boylston prize and medical women, 100.
Brain, abscess of, 224; pigment in, 633; sarcoma of, 191, 220, 442; the face as an index of, 302; tumor, 20; weighing 61 ounces, 334; weight and brain power, 504.
Brandt, Dr. Wm. E., diarrhœa tubularis, 33.
Breast, carcinoma of, 375.
Breath-sounds, interrupted, 247.
Briddon, Dr. Chas. K., intestinal obstruction, 116.
Bright's disease, 439; significance of casts in, 81.
British lying-in hospital, 322.
British Medical Association, 238, 242, 301.
Bromide mania, 20.
Bromides, Charcot's method of giving them in epilepsy, 28, 140.
Bromism, in a nursing child, 336.
Bronchi, discharge of hepatic abscess into, 572.
Bronchitis, fibrinous, 102; inter-pleural plastic exudation, 370, 417, 444.
Brown, Dr. Bedford, case illustrating vaso-motor disturbances, 89.
Bruen, Dr. E. T., notice of book by, 18.
Brush, Dr. E. F., acute milk-poisoning, 424.
Bryant, Dr. J. D., 717.
Bubo, treatment of, 463.
Buboes, abortive treatment of, 40.
Buchanan, Dr. Andrew, notice of death of, 280.
Buck, Dr. Albert H., a case of foreign body in the external auditory canal, 676.
Bucknill on the mental condition of Guiteau, 298.
Bulkley, Dr. L. D., notice of manual by, 327; notice of book by, 691.
Bull, Dr. William T., on the radical cure of hernia by Heaton's operation, 541.
Burdett, Mr. Henry C., relative mortality of city and cottage hospitals, 387.
Burdock, tincture of, in psoriasis, 585.
Burnett, Dr. J., sponge-grafting, 500.
Burns, alcohol in, 252.
Burrall, Dr. F. A., the exemption of plumbers from zymotic disease, 428, 585.
Butler, Dr. John, notice of book by, 188.
Byrd, Dr. Harvey L., chloroform narcosis, 330.
Byrd, Dr. Wm. A., excision of the intestinal canal when covered with peritoneum, 163.
Byrne, Dr. W. J., strychnia poisoning, 643.

C

Cæcum, epithelioma of the, 162.
Cainca, tincture of, as a diuretic, 662.
Calcium, sulphide of, as an antisuppurative, 41; in small-pox, 140.
Calculi, perineal, 626.
Calculus, cystic oxyd, 133; oxalate of lime, 77; renal, in children, 294; vesical, 555; vesical, distoma hæmatobium a cause of, 687; vesical, impacted, 231; vesical, in a child one month old, 686; vesical in an infant, 294; vesical, of great size, 611; xanthic oxyd, 133.
Calhoun, Dr. Charles William, leprosy, 692.
California State Medical Society, 111.
Calomel, action of, on fermentation, 433.
Cammann, Dr. D. M., bronchitis and inter-pleural plastic exudation, 370, 444.
Cancer of the breast, preceded by a disease of the mammary areola, 13; of the rectum, 713; primary of the bladder, 612; radical cure of, 15; vertebral with paraplegia, 23.

Cannabin tannicum, hypnotic value of, 326.
Capsicum and chinoidine, in intermittent fever, 400.
Carbuncle, local treatment of, 44; treatment of, 135.
Carcinoma, acute miliary, 490; of the breast, 375; uteri, 216.
Carduus marianus, in hæmoptysis, 625.
Caries, dry treatment of, 137; of the spine, 124; of the spine, early diagnosis and treatment of, 152.
Carlsbad salt, artificial, 656.
Caroba, in skin affections, 163.
Carotid compression and physiological brain-rest, 82.
Carpus, exsection of, 612.
Cascara as a laxative, 657.
Casts, significance of, in Bright's disease, 81.
Cataract, extraction of, in the lens capsule, 305.
Catarrh, intestinal, 262; nasal, milk in, 744; vesical, bromide of potassium in, 545.
Causalgia, 106.
Cauterization, punctate, in the treatment of pulmonary diseases, 376.
Cerebral irritation in children, 323.
Cerebral seat of suicidal and homicidal impulses, 622.
Cerebro-spinal fluid, new function for the, 336.
Cerebro-spinal meningitis, parasitic nature of, 323.
Chancre, excision of, as a means of aborting syphilis, 606.
Chandler, Dr. W. J., on nerve-stretching, 253, 282.
Charcot, J. M., notice of book by, 102.
Charity Hospital, ophthalmic division of, 558.
Cheesman, Dr. W. S., hydatid cyst of the liver, 644.
Chemistry in medicine and arts, 175.
Cheyne-Stokes respiration, 333.
Chiari, the pathologist, 392.
Chilblains, nitric acid for, 531.
Childbirth, decrease in deaths from, 266; followed by transitory blindness, 375.
Childhood, eruptive diseases of, 109.
Children, cutaneous diseases of, 603; the growth of, 550.
China, medical impressions of, 52.
Chinese, the, a drug-taking people, 325.
Chinoidine of capsicum in intermittent fever, 400.
Chinolinum tartrate, 712.
Chloral, syrup of bromide of, 136.
Chloroform, alarming narcosis from, 664; deaths from, 28, 128, 139, 165, 391; Dr. Kinloch's case of death from, 157; Narcosis, 330.
Choked disk and intra-cranial disease, 97.
Cholecystotomy, 304.
Cholelithectomy, 258.
Chorea, post-paralytic, 21; propylamine in, 721; rest cure, 351.
Cicatrices, mechanical, 361.
Circumanal glands, 332.
Circumcision, for phimosis with soft chancres, 236.
Cirrhosis, multiple, of the kidneys, liver, and lungs, 295; of liver, 656; of the liver with adenoma, 377.
City of London Hospital, 265.
Clements, Dr. J. W. S., resolutions on the death of, 503.
Climate, improvement of at a slight elevation, 529; of Florida, 356.
Clavicle, fracture of, 611.
Claviculo-scapular region, gunshot wound of, 622.
Code, the new, 362; the new, and Herkimer Co., 700; the new penal, 660.
Cod-liver oil, dugong oil a substitute for, 511.
Colic, lead, 361; nephritic, 140; spasmodic, quinine in, 638.
College-bred men in the medical profession, 681.
Cologne, antiseptic, 391.
Colon, invagination of the, 160.
Color-blindness, following destructive brain lesion, 81.
Colors, poisonous, in food articles, 389.
Colotomy, lumbar, 44.
Coma, malarial, 737.
Comedones, 28.
Comfort and dress, 252.
Compatibility of certain medicines, 684.
Condurango, 587.
Confinement, sudden death after, 230.
Congestion, pulmonary, abstraction of blood from the right heart for the relief of, 705.
Congress of German surgeons, 100.
Conjunctiva, amyloid tumors of, 627.
Conjunctivitis caused by the electric light, 363.
Coniin, action of, 546.
Constipation, in infants, 137.
Consultation, medical, 184; what is a? 164.
Contagious diseases, Norwegian methods of dealing with, 626.
Contraction following hip-joint disease, 95.
Contusions of the abdomen, 687.
Convallaria maialis, 281, 556; action on the heart, 662.
Coover, Dr. Fred. W., humanized vaccine virus v. bovine, 654.
Cord, spinal, alterations of, in phosphorous poisoning, 624; segmental nature of, 235.
Cornea, source of nourishment of, 643.
Corneal condenser, 614.
Cornil, Dr. V., notice of book by, 354.
Cornwell, Dr. Henry G., adenoid encysted tumor of the eyelid, 346; purulent cyclitis from septic embolism of the eye, 180.
Corning, Dr. J. Leonard, congestive headache, 708; sleep, 10.
Corns, remedy for, 447.
Corpuscle, the ovarian, 385.
Corrosive sublimate, in gonorrhœa, 687; in surgery, 108.
Corson, Dr. John W., 168.
Cottage Hospitals, mortality after amputation in, 326.
Cotton-seed, in spasmodic croup, 627.
Cow-pox, spontaneous, 351.
Cox, Dr. Christopher C., notice of death of, 631.
Cremation, 100.
Cretinism, 324.
Cronin, Dr. P. H., voice production, 222.
Cross-legged progression, 8.
Crothers, Dr. T. D., obscure cases of inebriety, 507; vice and disease in inebriety, 723.
Croup, diphtheritic, 632; diphtheritic, tracheotomy for, 512; membranous, 191; spasmodic, cotton-seed in, 627; treatment of, 673.
Curtis, Dr. Holbrood, a simple means of checking pulmonary hemorrhage, 401, 701.
Cutaneous diseases of children, 603.
Cyanosis febrilis cum hæmoglobinuria, 488.
Cyclitis, purulent, from septic embolism, 180.
Cystitis, 523; chronic, 92; chronic, treated with the curette, 489; gonorrhœal, 685; treated by urethrotomy, 329.
Cystoma of the ovary, 189; colloid, of the ovaries and omentum, 610.
Cysts of the broad ligament, 442; of the fibula, 322; of the kidney, 470; of the pancreas, 435, 441; hydatid, cure by capillary puncture, 545.

D

Damages, liabilities for, because of injury to patients during operations, 517.
Dana, Dr. Chas. L., autopsy upon the body of Guiteau, 53; microscopic appearance of Guiteau's brain, 135; the mechanical effect of nerve-stretching upon the spinal cord, 113.
Davis, Geo. S., notice of book by, 691.
Deafness following mumps, 573; ratio of, to population, 359.
Death, sign of, 224; sudden, after confinement, 230.
Deformity of the middle ear, 335.
Deformities of infancy and early childhood, 233.
Delafield, Dr. Francis, notice of book by, 495.
Delegates, instruction of, 659.
Delivery with membranes unruptured, 491.
Dentifrice, 616
Derby, Dr. N. R., quinine in spasmodic colic, 638.
Dermatitis, malignant papillary, 13.

Dermoid tumor of the eyelid, 346.
Diabetes, 700; bromide of potassium in, 360; constant early sign of, 389; iodoform in, 56, 308; pathology of, 304; prognosis of, 624; sudden death and coma in, 713; treated by bromide of potassium, 463; urine of low specific gravity, 729.
Diarrhœa tubularis, 33.
Diastasis of the head of the femur, 570; of the upper epiphysis of the humerus, 471.
Digestion, influence of various agents upon, 737.
Dilatation, acute, of the heart, 632; as a cause of cardiac murmurs, 572.
Diphtheria, 128, 393, 421, 449, 512, 728, 744; of scarlet fever, 579; heroic treatment of, 56; of the skin, 350; pilocarpin in, 335; transportation of by the wind, 41.
Discharges, uterine and vaginal, 309.
Diseases, contagious, 626.
Disease, compulsory notice of infectious, 691; constitutional anomalies in relation to, 688; curing, by anointing with oil, 429; of the Scythians, 22; the sleeping, of Africa, 23.
Disinfection by hot air, 391.
Dislocation, complete, of the radius and ulna outward, 672.
Dislocations of the humerus, 575; voluntary, of a contortionist, 69.
Distoma hæmatobium a cause of vesical calculus, 687.
Diverticulum of the small intestine, 635.
Divorce and insanity, 71.
Doctor, a conscientious, 447; social position of, 129; social relation of the, to his patient, 154.
Doctors' clothes, 380; hotel, 156; natural history of, 355.
Dose, influence of, on the action of remedies, 623.
Draper, Dr. John C., notice of book by, 577.
Drops, comparative size of, 167.
Dropsy, 248.
Drug-taking nation, 325.
Drunkards and dipsomaniacs, voluntary, 237.
Dugong oil, 511.
Duhring, Dr. L. A., notice of work by, 411.
Dyes, aniline, poisonous properties of, 391.
Dysentery, and nitrate of silver, 235; and typhoid fever, 976; chronic, koroniko in, 657; injections of hot water in, 627.
Dysmenorrhœa, viburnum opulus in, 613.
Dyspepsia, forced alimentation and washing in, 560.

E

Eagan, Dr. Peter R., erysipelas as a cause of puerperal peritonitis, 558.
Ear, action of salicylic acid and quinia upon, 489; aspergillus in, 711; deformity of the middle, 335; occlusion of the external, 726; removal of foreign body from, 721.
Ear-ache, atropia for, 391.
Echinococcus in America, 475, 514.
Eczema, 251, 388.
Edson, Dr. Benjamin, gelsemium in rhus-poisoning, 121.
Education, pre-natal, 267; the high-pressure, 436.
Egyptian war, 300.
Elbow-joint, acute suppuration of, 346.
Electric bath, 461, 526; uses and abuses of, 640.
Electrical phenomena, 727.
Electricity, in the treatment of extra-uterine pregnancy, 384; static, 47.
Electro-cautery in eye diseases, 506.
Electrode, a nasal, 331.
Electrolysis in the treatment of urethral stricture, 169, 197.
Electro-physiology, of the human nerves, 302.
Elephant, birth of, 223.
Elephantiasis, 359.
Emigrants, the care of, 185.
Empyema, 514; central pulmonary abscess mistaken for, 55; in a child, 698.
Emphysema, pulmonary, 589.
Encephalon, effects of irritating the, 462.
Endarteritis obliterans, in etiology of myocarditis, 129.
Endocarditis, diabetic, 182; primary, 247; ulcerative, 439.
Engel, Dr. Hugo, localization of intestinal catarrh, 262; the prodromic stages of diffuse kidney affections, 396.
Engelmann, Dr. G. J., notice of book by, 438.
Enteritis, acute, following burns, 582.
Enterotomy, inguinal, 45.
Epilepsy, caused by tumor of the brain, 229; sensory, 122.
Epiphysis, upper, of the fibula, separation of, 77.
Episcopal Hospital, 404.
Epithelia of the kidney, 13.
Epithelioma, interstitial injections in the treatment of, 713; of the cæcum, 162; of the larynx, 719; of the penis, 77, 160.
Epithelium, alveolar, of the lung, diagnostic value of sputum in, 265.
Erdmann, Dr. B. A., notice of book by, 17.
Ergot in obstetrics, 382; in pertussis, 324.
Ergotine in typhoid fever, 686.
Erysipelas, 236, 656; as a cure for insanity, 546; as a cause of puerperal peritonitis, 556; curative action of, 600; faucial, 265; propagated through the digestive tube, 434.
Erysipelas-coccus, 631.
Ether, death under, 168; injections of, producing paralysis, 434; spray of, in neuralgia, 515.
Ethics, medical, the county societies and the New York code, 194.
Eucalyptus globulus in gynecological practice, 513; oil, 381.
Euthanasia, 167.
Evetzky, Dr. E., notice of death of, 700.
Examining board, a national, 390.
Excision, early operative treatment of joint disease as a preventive, 245; of the intestinal canal when covered with peritoneum, 163; periosteal of the wrist, 125.
Excursions, the value of summer, 299.
Exostosis of the femur, 633; of the hand, 130.
Expert testimony, 358, 602.
Exsection, of carpus and metacarpus, 612.
Eye, and the liver, 700; diseases contagious, in schools, 14; diseases of, dependent upon suppression of the menses, 514; diseases of, electro-cautery in, 506; the embryology of the, 432.
Eyelashes, false, 252.
Eye-speculum, 445.

F

Fable, a modern, 251.
Face, as an index of the brain, 302.
Faith, as an essential element of success in practice, 334.
Farquaharson, Dr. Robert, notice of book, 632.
Fat, the assimilation of, 237.
Femur, diastasis of the head of, 570; exostosis of, 633; osteo-sarcoma of, 270.
Fermentation, action of calomel on, 433.
Fever, a theory of, 437; intermittent, arsenic and iodine in, 336; intermittent, flores siliginis in, 56; puerperal, and impure vaccination, 196; prevention of, 722; remittent, pernicious after parturition, 608; scarlet and diphtheria, 579; typhoid, 38; typhoid, and dysentery, 679; typhoid and malarial waves, 671; typhoid and tubercular meningitis, 28; typhoid, antipyretics in, 213; typhoid antiseptic treatment of, 437; typhoid, at seventy-two years of age, 504; typhoid, ergotine in, 686; typhoid, in Paris, 604; typhoid, management of the accidents in, 215; typhoid, new form of, 444; typhoid, sudorific treatment of, 9; typhus, 269; yellow, 240, 276; yellow, and phenic acid, 145; yellow, in 1882, 28, 301, 333, 364, 392, 420, 448, 476, 504, 528, 738.
Fibroma of the renal capsule, 687.

Fibro-myoma, uterine, 655.
Fibula, cyst of, 322; separation of the upper epiphysis of, 77.
Field, Dr. E., foreign bodies in the alimentary canal, 195.
Filix Mas, how to use it, 308.
Finger elongator, 82.
First aid to the injured, 111.
Fistula, biliary, operation for, 112; urethral, 664; vesico-vaginal, caused by position, 587.
Flores siliginis, in intermittent fever, 56.
Florida, the climate of, 356.
Flügge, Dr. C., notice of book by, 17.
Food, antiscorbutic, black ants as, 585.
Foods and flours, prepared composition of, 388; commercial, 360; farinaceous infant, 40.
Fowlwort, a new styptic, 621.
French Association for the Advancement of Science, 416, 443.
Fresh air fund, 588.
Friction-sounds from dilatation of the heart, 530.
Fuller, Dr. William, removal of a portion of intestine, 430.
Funis, shortened, and placental apoplexy, 74.
Furuncle, boracic acid in the treatment of, 573.

G

Galactogogues, 389; cotton-leaf tea as a, 224.
Galactorrhœa, treated by strapping, 435.
Galattofore, as a galactogogue, 389.
Galen, works of, 308.
Gall-stones, 55.
Galvanoplasty, 111.
Gangrene of the intestine, 546; or a boil, 615.
Gastro-elytrotomy, 741.
Gastro-enteritis, alcoholic, 417,
Gastroscopy, 108,
Gastrostomy, 168, 665.
Gelsemium, in rhus-poisoning, 121.
Genital function, nervous disease connected with, 617.
Genu-valgum, 108.
German Surgical Society, 107, 130.
Germicide, carbolic acid as a, 314.
Gill, Dr. H. Z., artificial feeding of infants, 206.
Glands, the circumanal, 332.
Glass-wool, 109.
Glaucoma, acute, cases of, 146.
Glisan, Dr. Rodney, notice of book by, 101.
"Glou-glou pleural," 43.
Glucose, as a diuretic, 215.
Godding, Dr. W. W., notice of book by, 438.
Goitre, 324; etiology of, 443.
Gonococcus, 359.
Gonorrhœa, corrosive sublimate in, 687; frequency of, 503; micro-organisms of, 466; of the rectum, 84; use of condom in, 504.
Gossypium bortadense, as a galactogogue, 224.
Gout, 739.
Grave-robbing, 724.
Gregg, Dr. Rollin G., the recognition of micrococci, 202.
Green, Dr. Traill, the eruptive diseases of childhood, 109.
Griesenger, Dr. W., notice of book by, 717.
Gross, Dr. Samuel D., notice of book by, 579; reception to, 557.
Guachamaca, extract of, for spasms, 532.
Guaiac, in acute tonsillitis, 531.
Guiteau, 15; autopsy upon the body of, 43, 53, 71; brain, microscopical appearance of, 134.
Gynecologist, an ancient, 591.
Gynecologists and virgins, 555.
Gynecology, American, seen through English spectacles, 725.

H

Hæmatinuria, paroxysmal, 699.
Hæmaturia, 337.
Hallux valgus, 120.
Hamilton, Dr. A. McLane, myxodema, 645.
Hammond, Dr. Græme M., on the proper method of executing, by hanging, 426.
Hanging proper method of executing, 426.
Hanks, Dr. H. T., operations for restoring complete lacerations of the female perineum, 1.
Hardaway, Dr. W. A., notice of book by, 605.
Harnden, Dr R. S., multiple sarcoma of the skin, 697.
Hartshorne, Dr. Henry, notice of book by, 101.
Hauser, of Prague, 359.
Hayes, Dr. Justin, uses and abuses of the eletric bath, 640.
Haywood, Dr. R. B., climatic treatment of phthisis, 196.
Hæmoptysis, tincture of carduus marianus in, 625.
Headache, congestive, 708.
Health of criminal women, 577.
Health-resorts, winter, 98.
Heart, action of convallaria upon the, 662; acute dilatation of, 632; effect on, produced by smoking, 183; fatty, 686; hydatid of, 491; malformation of, 76; perforation of the left ventricle of, 407; placental origin of congenital disease of, 655; rapid, 97; rhythm of, 710; spurious murmurs of, 655; stenosis of the left ventricle, 407; valvular lesions of, 161, variations and duration of ventricular systole, 301; blood-letting in diseases of, 462.
Heart-failure, hot applications for, 332.
Heart-murmur, diastolic, without valvular lesion, 351.
Hebbard, Dr. W. W., patent medicines and quack nostrums, 360.
Helenine, action of, on bacilli of tubercle, 503.
Hematemesis, periodical, 37.
Hemato-pericardium, traumatic, 351.
Hemenway, Dr. H. B., influence of dose on the action of remedies, 623.
Hemeralopia, in jaundice, 463.
Hemiplegia, spinal, following gangrene of the great toe, 303.
Hemorrhage, after tonsillotomy, 358; etiology of cerebral, 439; from partially detached placenta in twin labor, 595; from the bowels in typhoid fever, 215; into the pons, 22; pulmonary, the checking of, 502; simple means of checking, 401; vaginal, in a newborn child, 348.
Hemorrhoidal diseases, 225.
Hemorrhoids, prophylaxis of, 178; suppositories for, 712; treated by hot water and dilatation, 329.
Henle, Dr. J., notice of book by, 411.
Henry, Dr. M. H., amputation of redundant scrotum for the cure of varicocele, 509; incarceration of insane, 694.
Hepatic duct, rupture of, 295.
Hepatotomy, 260.
Hermann, Dr. E. N., imperfect nutrition of infants, 320.
Hernia, 106; hepatic, 727; radical cure of, 107; radical cure of, by Heaton's operation, 541, 551, 548; strangulated, 412; strangulated of the vermiform appendix, 600; strangulated, reduction followed by expulsion of a portion of small intestine, 322; strangulated, treated by belladonna, 168; strangulated ventral, 655; traumatic phrenic, 554.
Herniotomy, 107.
Hiccough, persistent, 231, 530.
Hilles, Dr. M. W., notice of book by, 101.
Hinsdale, Dr. Guy, a medical curiosity, 150; Hospital Report, 92, 321.
Hip-joint, disease of, followed by contraction, with treatment by weight and pulley, 95; muscular action in pathology of, 284.
History, natural, and education, 251.
Hogan, Dr. Michael, death of, 724.
Holbrook, M. L., notice of book by, 18.
Holmes, Dr. Oliver Wendell, 671; on physical diagnosis of specialism, 503.
Homœopathic critic criticised, 307.
Homœopathy, progress of, 358.

Horse, fracture of vertebra and malformation of jaw in, 719.
Horse-sense in diagnosis, 280.
Hospital for Diseases of the Throat and Chest, 94.
Hospital of the City of Boston, report, notice of, 187; of the University of Pennsylvania, 92, 321; proposed, for children, 714; Saturday and Sunday Association, 555, 574, 714.
Hospitals, 99; cottage, 217, 358, 379; cottage and city, 387; cottage, mortality after amputations in, 326; temporary, 408.
Hotels, sanitary inspection of, 238.
Hour-glass contraction, ante-partum, 595.
Houston, Dr. Thomas, an obstinate malingerer, 277.
Howard, Dr. H., notice of book, by, 354.
Howell, Dr. S. Y., Langenbeck's last clinic, 272.
Hudson River valley, 410.
Humerus, diastasis of the upper epiphysis, 471; green-stick fracture of, 130; reduction of dislocation of, 515; sarcoma of, 441.
Humphrey, Dr. Lawrence, hospital report, 265.
Hunter, Dr. Alexander S., self-sustaining speculum, 695.
Hunter, Dr. Jas. B., uterine and vaginal discharges, 309.
Hurd, Dr. E. P., cases in practice, 36; on the convallaria maialis, 281, 556.
Hutchins, Dr. O. J., inversion of the uterus, 728.
Hutchinson, Dr. Wm. F., the electric bath, 461.
Hadatid cyst, cure by puncture, 545; of the heart, 491; of the pleura, 687.
Hydroa, of the mouth, 377.
Hydrocele, excessive reaction after injection with glycerine and carbolic acid, 554; on some new methods of treating, 57, 76.
Hydronephrosis, double, 470.
Hydrocephalus following forceps delivery, 391.
Hydrophobia, cure of, 462; injections of the virus of, into the circulation, 227.
Hygiene, imperfect sexual, 55; the National Museum of, 551.
Hyperemesis, a cause of abortion, 392.
Hypnotism, phenomena of, explained, 494; the proportion of persons affected, 727.
Hypodermic use of laxatives, 604; use of silver salts, 28.
Hysterectomy, 383.
Hysteria in the male subject, 457.

I

Idiocy, 324.
Illoway, Dr. H., intestinal obstruction, 734.
Iodoform, 193; in chronic broncho-pulmonary affections, 546; in diabetes, 56, 308; and enlarged tonsils, 152; and Listerism, 138; and phthisis, 70; in treatment of wounds, 132; in tubercular meningitis, 41; in ulcer of the stomach, 27.
Immigrant inspection service, 631.
Incubation, 447.
Index catalogue, 518.
Inebriety, a vice or disease, 668, 723; obscure cases of, 507.
Infant, a bearded, 335.
Infants, artificial feeding of, 206; imperfect nutrition in, 320.
Infectious diseases, acute blood-changes in, 107; notification of, 301.
Injections, hypodermic, of silver salts, 28; rectal, of hot water in dysentery, 627; vaginal, in etiology of peritonitis, 573.
Inoculation in the treatment of pannus, 560, 588; of bovine tuberculous matter in man, 307.
Insane, care of the chronic, 722; incarceration of, 694; medico-legal decision concerning, 699.
Insanity and divorce, 71; and responsibility, 136; caused by brandy and absinthe, 443; cured by erysipelas, 546; domesticity as a cause of, 531; nutrient treatment of, 624; statistics of, 153.
Instinct, seat of, in man, 668.
International Congress of Hygiene, 458.
International hygienic building, 16.
Intestinal canal, foreign bodies in, 91; catarrh, 252; obstruction, 116, 132; perforation, 215.
Intestine, gangrene of, 546; length of, 153; perforation of the, 472; removal of a portion of, 430; resection of, 131; small, diverticulum of, 635.
Intussusception, 407.
Ipecac an oxytocic, 277; in asthma, 56.
Iridin, 55.
Iron in capsules, 140.
Island of Reil, lesion of, 294.

J

Jaborandi, and urticaria, 56; in pleurisy, 625.
Jacobi, Dr. A., county delegates and the New York York code, 417; notice of book by, 718.
Jacobson, Dr. N., foreign body in the air-passages, 733.
Jaundice, hemeralopia in, 463; in pregnancy, 462.
Jenkins, Dr. J. Foster, notice of death of, 504, 615.
Johnson, Dr. Lawrence, notice of book by, 240.
Joints, diseases of, in the puerperal state, 571; resection of, for disease, 444; stiff, treatment of, 246.
Jones, Dr. Herbert C., curious effect of lightning-stroke, 558.
Judson, Dr. A. B., Mr. Shaw's view of the cause of rotation in lateral curvature of the spine, 372.

K

Kelsey, Dr. Charles B., notice of book by, 410; on the treatment of stricture of the rectum, 141.
Kidney, affections of, prodromic stages of diffused, 396; atrophy of, 612; amyloid, 461; amyloid, without albuminuria, 295; cirrhosis of, 295; congenital absence of right, 613; contracted, 349; cysts of the, 470; epithelia of, 13; early recognition of disease of, 628; excision of, 168; frequency of floating, 532; operative fixation of, 131.
Kinloch, Dr. R. A., supposed death from chloroform, 165.
Kinnicutt, Dr. F. P., oil of wintergreen as an efficient salicylate in acute rheumatism, 505, 522.
Knee-joint, a hitherto undescribed lesion of, 50; internal derangement of, 230; rupture of, 245.
Kohn, Dr. Samuel, case of foreign body in the intestinal canal, 91.
Koroniko, in chronic dysentery, 657.
Krog, Dr. Carl, notice of death of, 504.

L

Labor, complicated by pulmonary congestion and œdema, 596; management of, with reference to subsequent uterine disease, 583; sudden death after, 36.
Laceration, of the perineum, 1.
Ladies' doctors, 698.
Langenbeck's last clinic, 272.
Langtry, improbable interview with, 531.
Larynx, anæsthesia of, 560; easy and painless introduction of a tube into, 573; electrization of, 469; epithelioma of, 719; papillomatous tumors of, 611; paralysis of, 452.
Laryngitis, ulcerative syphilitic, 76.
Laudanum, to infants, 258.
Laxatives, subcutaneous use of, 604.
Lead colic, 361; paralysis, 20.
Leal, Dr. John B., notice of death of, 363.
Lefferts, Dr. Geo. M., foreign body in the air-passages, 599.
Leg, gun-shot wound of, 46.
Leidy Memorial, 140.
Leloir, Dr. Henri, notice of book by, 241.

Leonard, Dr. C. Henri, notice of book by, 438.
Leprosy, 78, 336; at Mount Lebanon, Syria, 692; the contagion of, 514.
Leucocythæmia in infants, 84
Leucorrhœa, 382; in children, 328; uterine, 310; vaginal, 309.
Leuf, Dr. A. H. P., notice of book by, 692.
Lewis, Dr. W. Bevan, notice of book by, 438.
Lichen planus affecting mucous membrane, 13.
Life, the chemical cause of, 363.
Ligature, the elastic, for extirpation of tumors of the abdomen, 235.
Ligatures, broad animal for arteries, 103.
Lightning-stroke, curious effect of, 558.
Liniment purgative, 560.
Liniments, facial, 319.
Linsley, Dr. J. H., examination of the urine for albumen and sugar, 208.
Lipoma of the axilla, 634.
Listerism and iodoform, 138.
Litholapaxy, 246, 709.
Lithotomy, long-beaked staff for, 246.
Lithotrity, rapid, 47, 133, 555, 667.
Liver, acute yellow atrophy of, 733; and the eye, 700; amyloid, 473; cirrhosis of, 295, 656, 686; cirrhosis of with adenoma, 377; cirrhosis of, rapidly progressive, 432; cystic tumor of, 344; fatty degeneration of, 737; hydatid cyst of, 644; surgery of, 258, 688.
Liver-pad, 700.
Lloyd, Dr. T. M., cardiac pulmonary and aortic thrombosis, 459.
Localization, cerebral, 439.
Locomotor ataxia, 390; dry cupping and rest in, 373; skin eruptions in, 489; the so-called family form, 19; with well-marked tendon reflex, 448.
London Hospital, 38.
Loring, Dr. E. G., improved means of oblique illumination, 614.
"Love parasite," 532.
Lowell, Dr. A. L., resolutions, 672.
Lunacy, 330; in England, 446; trumped-up, 268.
Lunatics, the commitment of, 604.
Lungs, cauterization in the treatment of diseases of, 376; cirrhosis of, 295.
Lutidine, as an antidote for strychnia, 153.
Lycoperdon as a hemostatic, 712.
Lydston, Dr. G. Frank, opium-poisoning in an infant, 364; prevention of puerperal fever, 722.
Lyman, Dr. H. M., dry cupping and rest in locomotor ataxia, 373.
Lymphadenitis, abortive treatment of, 40.
Lymphatics, superficial, 736.
Lymphoma injections of iodine in, 334.
Lyon, Dr. A. A., broken thermometers, 699.

M

McBride, Dr. T. A., improved Camman's stethoscope, 586.
McCoy, Dr. J. Cresap, on sunstroke, 278.
McIntyre, Dr. Charles, the percentage of college-bred men in the medical profession, 681.
McMahon, Dr. Wm. J., hepatic hernia, 727.
Macalline, 153.
Mackenzie, Dr. Morell, diphtheria, 449; paralysis of the muscles of the larynx, 452.
Macnamara, Mr. C., notice of book by, 606.
Magnetism, the therapeutical employment of, 545
Malaria, causes of, 728; and skin diseases, 697; and sulphur, 531; effects of on man, 236; hereditary and congenital, 687; in children, 662; in Italy, 668.
Malarial parasite, Laveran's 140.
Male fern, supposed death from, 675.
Malingerer, 277.
Malley trial, the, 16.
Mania, malarial, 25.
Manson, Dr. O. F., notice of book by, 718.
Marine Hospital Service, 502.
Martin, Dr. E., notice of book by, 354.
Massage, 447.
Mastitis treated by strapping, 435.
Materia Medica Society, 192.
Mattison, Dr. J. B., opium addiction, 727.
Mauthner Dr. Ludwig, notice of book by, 18.
Meat, juice of, 234.
Meatus, external auditory, 726.
Medical College, a bogus, 138.
Medical Colleges, New York, 616; bogus, in Massachusetts, 724.
Medical curiosity, 150.
Medical education and the American Academy of Medicine, 639; and the medical profession in Europe, 524; progress in, 493.
Medical ethics, New York code of, 447.
Medical examinations, national, 277.
Medical jubilees, 70.

Medical societies, relations of county and State, 166.
Medical specialties, 158.
Medical students, percentage of college-bred men among, 387.
Medical women, progress of, 616.
Medicine, general, 658; the sunflower in, 126.
Medicines, antipyretic, 234; compatibility of certain, 684; patent, some facts about, 42; proprietary, 644.
Medico-legal Society, N. Y., officers, 700.
Meigs, Dr. John Forsyth, notice of death of, 725.
Meningitis, cerebro-spinal, 220, 612; cerebro-spinal in the new-born, 56, 547; in children, 444; tubercular and typhoid fever, 28; tubercular, iodoform in, 41.
Menses, suppression in etiology of eye diseases, 514.
Menstruation, condition of uterine mucous membrane during, 582; sore throat with, 572.
Mesentery, sarcoma of, 72.
Mesmerizer, shall the travelling, be abolished? 266.
Metritis, exfoliative, 413.
Micrococci, recognition of, 202, 429; test for, 454.
Microscopists, discoveries of, 388.
Midwifery in the Sandwich Islands, 389.
Milk, blue, 279; chemical composition of, from cows fed on distillery refuse, 529.
Milk-poisoning, acute, 424.
Miracles, therapeutic use of, 112.
Missouri State Medical Association, 112.
Möbius, Dr. Paul Julius, notice of book by, 241.
Morbus feminarum, 22.
Morgan, Dr. John G., notice of book by, 241.
Morgue, Paris, 559.
Morphine, danger of large doses in nephritic colic, 140; solubility of officinal salts, 536.
Morris, Dr. Robert T., the local treatment of burns, 653.
Mortality of negroes, 689.
Morton, Dr. A. Stanford, notice of book by, 18.
Morton, Dr. Wm. J., autopsy upon the body of Guiteau, 53; microscopical appearance of Guiteau's brain, 134.
Mosquito, bite of, 744.
Mouth, hydroa of, 377.
Mucous membrane affected by lichen planus, 13; dry treatment of, 136; physiology and pathology of, 352.
Mud-baths, 566.

Mumps, deafness following, 573.
Murmurs, cardiac hemic, 572; chlorotic, 247; spurious cardiac, 655.
Murrell, Dr. W., notice of book by, 606.
Muscarin, 547.
Muscle-reading, 671.
Muscle-sense, 125.
Muscle transplantation, 131, 488.
Myelitis, arsenical, 20; central, 19; produced by Paris green, 499.
Myocarditis, interstitial, 129.
Myograph of nerve-degenerations, 18.
Myopia, and the necessity for its connection with glasses, 415.
Myositis of the floor of the mouth, 490.
Myxo-angioma of the tongue, 719.
Myxœdema, 219, 443, 645.
Myxofibroma of the nares, 270.

N

Naphthalin, treatment of wounds with, 132.
Narcosis, chloroform, 330.
Nares, myxofibroma of, 270.
Naso-pharyngeal tumor, 311, 328.
National Board of Health, 84, 715.
Nausea, hot water in, 625.
Neal, Dr. James C., the climate of Florida, 356.
Neal, Dr. Richard, notice of book by, 355.
Necrosis of the lower jaw, 412; of the spurious processes of the vertebræ, 162.
Needle forceps, 527.
Neilson, Dr. T. B., hospital report, 404.
Nephrectomy, 304.
Nephritis, infectious nature of that accompanying cerebro-spinal meningitis, 323.
Nerve-degeneration, myograph of, 18.
Nerve-fibres, new method of staining, 585.
Nerve-force, rate of transmission, 252, 547.
Nerve-stretching, 26, 253, 282; athetosis relieved by, 21; mechanical effect produced upon the spinal cord by, 113; the median, 727; the optics, 28.
Nervous control, equilibrating value of, 317.
Nervous diseases, functional charges of electrical resistance in, 575.
Neurasthenia, sexual, 617.
Neuralgia, crural, 554; ether spray for, 515.
New-born, a new disease of the, 488.
New Hampshire Medical Society, 50.
Newman, Dr. Robert, treatment of urethral stricture by electrolysis, 169, 197.
New York Academy of Medicine, 24, 47, 439, 495, 583, 606, 740; section in obstetrics, 608; section in practice, 498, 661.
